| *Grain Futures Administration* | J. W. T. Duvel, *Chief.* |

## The 1926 Yearbook

The Yearbook has been prepared under the supervision of Nelson Antrim Crawford, Director of Information, with A. P. Chew as associate editor. E. C. Powell gave editorial assistance.

# FOREWORD

The Yearbooks, which have been published regularly from 1894 on by the United States Department of Agriculture, reach more persons than any other books on agriculture issued anywhere in the world. The bulk of their circulation is among everyday farmers. It is highly important that they be accurate, broad, interesting, and useful to the farmer. Incidentally they should have reference value to the technically trained agriculturist.

These essentials have been kept constantly in mind in the preparation of the 1926 Yearbook. The farmer knows the basic principles of his business; the typical American farmer is an intelligent farmer. He does not need to be told elementary facts.

What the farmer wants to know is the new discoveries which have been made in agriculture—results of research by scientists, experiences of farmers' marketing organizations, authentic data on quantity and quality of agricultural production. Material of this sort is presented in the present Yearbook. Up-to-date information is offered from every phase of agriculture. For the convenience of the reader, the articles are arranged in alphabetical order. Illustrations appear where they will definitely add to the usefulness of the text.

Current statistics of agricultural production are published, as usual. My annual report as Secretary of Agriculture, which appears in the volume, endeavors to interpret contemporary agricultural conditions.

The Yearbook, I believe, presents a broad and illuminating picture of agriculture to-day—a picture which not only will be of practical value to farmers but will also, I hope, add to the understanding of such members of other groups in the population as examine the volume. Subsequent Yearbooks, it is contemplated, will follow a similar plan, keeping the picture of agriculture constantly up to date.

Obviously, it is impossible to deal in comprehensive detail with every subject in one book. Those who desire further data on subjects of particular interest to them are invited to write to the specialists whose names are signed to the respective articles. The principal purpose of the department is to supply reliable information to the farmers; I want no farmer to hesitate to communicate with the department or any member of it.

W. M. JARDINE,
*Secretary of Agriculture.*

# CONTENTS

Page

The Year in Agriculture ..... 1
What's New in Agriculture ..... 125
Miscellaneous Lists ..... 789
Agricultural Statistics ..... 801
  Statistics of Grains ..... 803
  Statistics of Fruits and Vegetables ..... 896
  Statistics of Field Crops Other than Grain ..... 958
  Statistics of Farm Animals and Animal Products ..... 1036
  Foreign Trade of the United States in Agricultural Products ..... 1174
  Miscellaneous Agricultural Statistics ..... 1200
Index ..... 1273

# AUTHORS AND ARTICLES

ALEXANDER, LUCY M., *B. S.*, Assistant Specialist in Foods, Bureau of Home Economics.
Meat Cooking a Fine Art that Science Assists.

ALLARD, H. A., *B. S.*, Physiologist, Effect of Length of Day on Plant Growth, Bureau of Plant Industry.
Daylight a Factor in Flowering.

ALMQUIST, J. A., *Ph. D.*, Chief, Chemistry Division, Fixed Nitrogen Research Laboratory.
Nitrogen Fixation Progress.

ARNER, G. B. L., *B. L.*, *A. M.*, *Ph. D.*, Agricultural Statistician, Bureau of Agricultural Economics.
Corn Consumption in Europe.
Foreign Trade Index Number for Foodstuffs.
Sugar Supply Sources of the United States.

ASHBROOK, FRANK G., *B. S.*, Biologist, in Charge, Fur Resources, Biological Survey.
Fur Farming a Growing Industry.

BABCOCK, C. J., *B. S. A.*, Associate Market Milk Specialist, Bureau of Dairy Industry.
Milk Flavors and Odors Ascribed to Four Main Causes.

BACK, E. A., *B. S.*, *Ph. D.*, Senior Entomologist, in Charge, Stored-Product Insect Investigations, Bureau of Entomology.
Furniture Destruction by Insects.

BAKER, A. C., *B. S. A.*, *Ph. D.*, Senior Entomologist, in Charge of Tropical and Subtropical Plant Insect Investigations, Bureau of Entomology.
Citrus Aphid—A New Pest in Florida.

BAKER, E. W., Assistant Chief Marketing Specialist, Bureau of Agricultural Economics.
Livestock Market News Distribution.

BALDWIN, H. T., *B. S. A.*, Specialist in Exhibits, Extension Service.
Exhibits in Farm Education.

BARR, J. E., Assistant Marketing Specialist, Bean and Pea Standardization, Bureau of Agricultural Economics.
Soy-bean Standards Promulgated for Commercial Crop.

BEAN, L. H., *M. B. A.*, Agricultural Economist, Marketing Statistics, Bureau of Agricultural Economics.
Income from Agricultural Production.
Flour Consumption Falling in the United States.
Measuring Changes in the Prices of Farm Commodities.
Wages of Farm Hands Governed by Three Factors.

BECKER, JOSEPH A., *B. S. A.*, *M. S.*, Agricultural Statistician, Bureau of Agricultural Economics.
Milk Production Indexes.
Wheat Reports on Production and Holdings.

BELL, W. B., *M. S.*, *Ph. D.*, Biologist, Economic Investigations, Biological Survey.
Wolves, Coyotes Take Big Toll from Stockmen.

BENNETT, H. H., *B. S.*, Soil Scientist, Inspection District 4, Soil Survey, Bureau of Soils.
Soil Types and How They May Be Recognized.

**Birdseye**, Miriam, *A. M.*, Extension Nutritionist, Extension Service.

Eating to Keep Body in Health.

**Black**, W. H., *B. S.*, Animal Husbandman, in Charge, Beef Cattle Office, Bureau of Animal Industry.

Calf Crop in Beef Industry.

**Brandes**, E. W.; *M. S.*, *Ph. D.*, Senior Pathologist, in Charge, Sugar Plants, Bureau of Plant Industry.

Sugar-Cane Varieties that Resist Disease.

**Brigham**, Reuben, *B. S. A.*, Agriculturist, in Charge, Visual Instruction and Editorial Work, Extension Service.

Photographs Tell Story of Agriculture.

**Brodell**, A. P., *B. S.*, Assistant Agricultural Economist, Farm Management and Costs, Bureau of Agricultural Economics.

Labor Requirements Measured for Principal Crops.

**Brown**, B. E., *M. S.*, Biochemist, Soils and Fertilizer Investigations, Bureau of Plant Industry.

Nitrogen from the Air Makes Good Fertilizer.

Potash Hunger in War Years Taught Lesson.

**Brown**, Edgar, *Ph. B.*, Senior Botanist, in Charge, Seed Laboratory, Bureau of Plant Industry.

Seed Import Control Law Strengthened.

**Brown**, Hylton R., *B. S.*, Assistant Engineer, Development Work, Bureau of Chemistry.

Grain-Dust Explosions Cause Big Farm Loss.

**Bruce**, Donald, *A. B.*, *M. F.*, Silviculturist, Forest Service.

Timber's Harvest Time Depends on Soil Conditions.

**Buckley**, John S., *D. V. S.*, Senior Pathologist, Chief, Pathological Division, Bureau of Animal Industry.

Rabies Becoming More Prevalent in United States.

**Buckley**, S. S., *D. V. S.*, *M. S.*, Associate Animal Husbandman, Swine Office, Bureau of Animal Industry.

Ton-Litter Aim Improves Hog Raising Methods.

**Bunyea**, Hubert, *D. V. S.*, *A. B.*, Associate Veterinarian, Pathological Division, Bureau of Animal Industry.

Poultry Disease Prevention.

**Burch**, D. S., *B. S. A.*, Editor, Bureau of Animal Industry.

Breeding Improved Livestock.

**Burgess**, A. F., *M. S.*, Senior Entomologist, in Charge, Gipsy Moth Investigations, Bureau of Entomology.

Moths—Preventing Their Depredations.

**Burgess**, J. A., *B. S.*, Marketing Specialist, Market News Service, Bureau of Agricultural Economics.

Livestock Reports Issued Weekly to Country Bankers.

**Burk**, L. B., *B. S.*, Marketing Specialist, Livestock Marketing Investigations, Bureau of Agricultural Economics.

Grading Animals and Meat to Show Quality.

Purebred Livestock Markets.

**Caine**, John T. III, *M. S. A.*, Chief, Packers and Stockyards Administration.

Packers and Stockyards Act; How It Is Administered.

**Caldwell**, J. S., *A. M.*, *Ph. D.*, Physiologist, Fruit and Vegetable Utilization, Bureau of Plant Industry.

Beverage Juices from Apples and Grapes.

**Campbell, Maude**, *M. S.*, Assistant Specialist in Clothing, Bureau of Home Economics.

Garment Fitting for the Home Dressmaker.

**Carlson, T. A.**, *M. S.*, Assistant Engineer in Forest Products, Forest Products Laboratory, Forest Service.

Crates for Livestock Built to Fit the Animals.

**Chambliss, Charles E.**, *M. S.*, Associate Agronomist, Rice, Bureau of Plant Industry.

Soy-Bean Rotation Increases Rice Yields Greatly.

**Chatfield, Charlotte**, *B. S.*, Associate Specialist in Foods and Nutrition, Bureau of Home Economics.

Food Studies Throw Light on Diet Problems.

**Chilcott, E. C.**, *M. S.*, Senior Agriculturist, in Charge, Dry-Land Agriculture, Bureau of Plant Industry.

Great Plains Agricultural Development.

**Christensen, Chris L.**, *B. S.*, Agricultural Economist, Chief, Division of Cooperative Marketing, Bureau of Agricultural Economics.

Cooperative Marketing Mainly Dependent on Business Management.

**Clark, Edna Louise**, *Ph. B.*, Associate Home Economist, Bureau of Home Economics.

Clothing Expenditures of Farm Families.

**Clark, J. Allen**, *M. S.*, Agronomist, Western Wheat Investigations, Bureau of Plant Industry.

Wheat Varieties for the Western United States.

**Clay, Harold J.**, *B. Sc.*, Marketing Specialist, Fruits and Vegetables, Bureau of Agricultural Economics.

Honey Market Reports Now Issued.

Peanuts: How They Reach the Consumer.

**Cobb, N. A.**, *B. S.*, *M. A.*, *Ph. D.*, Senior Nematologist, Bureau of Plant Industry.

Nemas and Recent Progress in Nematology Research.

**Coleman, D. A.**, *M. S.*, *Ph. D.*, Assistant Chief Marketing Specialist, Grain Investigations, Bureau of Agricultural Economics.

Oil Test for Oil-Bearing Seeds Found.

**Colley, Reginald H.**, *A. M.*, *Ph. D.*, Pathologist, Forest Pathology, Bureau of Plant Industry.

Building Decay and Ways of Preventing It.

**Collier, G. A.** Marketing Specialist, Bureau of Agricultural Economics.

News Service on Grain Markets.

**Collier, George W.**, *B. S.*, Assistant Agricultural Economist, Bureau of Agricultural Economics.

Cattle Feeding for Profit.

**Coombs, Whitney**, *Ph. D.*, Agricultural Economist, Agricultural Finance, Bureau of Agricultural Economics.

Taxation of Farm Property Burdensome.

**Coons, G. H.**, *A. M.*, *Ph. D.*, Pathologist, Sugar-Beet Investigations, Bureau of Plant Industry.

Beets of Primitive Type in Disease Control.

**Cooper, M. R.**, Economic Analyst, Farm Management and Costs, Bureau of Agricultural Economics.

Peach Survey of National Scope Shows Pitfalls.

**Cotton, R. T.**, *M. S.*, *Ph. D.*, Entomologist, Stored-Product Insect Investigations, Bureau of Entomology.

Furniture Destruction by Insects.

CRAWFORD, NELSON ANTRIM, *M. A.*, Director of Information.

**Books on Farming Increase.**

**Press Aid to Farmers Increasing.**

CREECH, GILBERT T., *D. V. S.*, Associate Veterinarian, Pathological Division, Bureau of Animal Industry.

**Swine Erysipelas Identified with "Diamond Skin."**

CRITCHFIELD, B. H., *B. S.*, *M. A.*, Economic Analyst, Bureau of Agricultural Economics.

**Production and Consumption Surveys Useful.**

DAGGIT, E. M., *B. S.*, *M. A.*, Associate Agricultural Economist, Bureau of Agricultural Economics.

**Flaxseed Price Largely Influenced by Argentine Crop.**

**Peach Prices Are Mainly Governed by Size of Crop.**

**Potato Supply—Effect on Markets.**

DANA, SAMUEL T., *A. B.*, *M. F.*, Director, Northeast Forest Experiment Station, Forest Service.

**Wood Lots in Northeast Pay Well for Care.**

DAVIS, R. O. E., *Ph. D.*, Chief, Soil Physics Division, Bureau of Soils.

**Nitrogen Fertilizers Listed and Described.**

DAVIS, W. C., Assistant Chief Marketing Specialist, Bureau of Agricultural Economics.

**Meat Retailing Methods.**

DAY, P. C., *Phar. D.*, Meteorologist, in Charge of Climatological Division, Weather Bureau.

**Drought and Its Effects in United States.**

DENMEAD, TALBOTT, *LL. D.*, Deputy Chief U. S. Game Warden, Biological Survey.

**Draining Marshlands Unwisely.**

DETWILER, SAMUEL B., *B. S. F.*, Senior Pathologist, in Charge, Blister Rust Control, Bureau of Plant Industry.

**Black Currant Is Nurse of Blister Rust.**

DEWEY, LYSTER H., *B. S.*, Botanist, in Charge, Fiber Plants, Bureau of Plant Industry.

**Flax—a Drought-Resistant Form Now Developed.**

DICKSON, JAMES G., *M. S.*, *Ph. D.*, Agent, Plant Pathologist, Wheat Scab, Bureau of Plant Industry.

**Corn Varieties Resistant to Rot Disease.**

DIXON, H. M., Extension Economist, Extension Service.

**Farm Accounts an Aid to Efficient Planning of Work.**

DOOLITTLE, S. P., *M. S.*, *Ph. D.*, Pathologist, Mosaic Diseases of Truck Crops, Bureau of Plant Industry.

**Cucumber Mosaic and How to Control It.**

DOYLE, C. B., Agronomist, Cotton, Rubber and Other Tropical Plants, Bureau of Plant Industry.

**Cotton Growing in One-Variety Communities.**

EDLER, G. C., *B. S.*, Assistant Chief Marketing Specialist, Seed Marketing and Reporting Service, Bureau of Agricultural Economics.

**Seed Records Win Support of Seedsmen.**

EDWARDS, H. T., *B. S.*, Technologist, Fiber Plants, Bureau of Plant Industry.

**Abaca in the Tropics of America.**

EWING, PAUL A., *B. A.*, Associate Irrigation Economist, Division of Agricultural Engineering, Bureau of Public Roads.

**Irrigation and Its Cost to the Farmer.**

**Ezekiel, Mordecai**, *M. S.*, Agricultural Economist, Bureau of Agricultural Economics.
Hog Cycles and Possibilities of Regulating Them.
Hog Price Changes Studied.

**Fairbank, H. S.**, *C. E.*, Highway Engineer, in Charge, Editorial Section, Bureau of Public Roads.
Highways and How They Are Paid For.

**Fellows, H. C.**, *B. S.*, Assistant Marketing Economist, Grain Investigations, Bureau of Agricultural Economics.
Oil Test for Oil-Bearing Seeds Found.

**Fisher, O. S.**, *B. S. A.*, Extension Agronomist, Extension Service.
Seed Improvement Associations in United States.

**Fletcher, C. C.**, *M. D.*, Associate Chemist, in Charge, Miscellaneous Soil Amendments, Bureau of Soils.
Fertilizer Purchasing by Farmers.

**Flint, L. H.**, *B. S., M. S., Ph. D.*, Assistant Physiologist, Soil Moisture, Bureau of Plant Industry.
Electroculture Experiments Not Yet Conclusive.

**Fohrman, M. H.**, *B. S., A. M.*, Dairy Husbandman, Bureau of Dairy Industry.
Infertility in Cattle and Vitamin Diet.
Livestock Judging Aided by Use of Camera.

**Folsom, J. C.**, *M. Sc.*, Assistant Agricultural Economist, Land Economics, Bureau of Agricultural Economics.
Perquisites Hold Good Farm Help.

**Foss, H. N.**, *LL. B.*, Assistant to the Solicitor, Office of the Solicitor.
Law and the Farmer's Business.

**Foster, Arthur C.**, *M. S.*, Pathologist, Celery and Lettuce Diseases, Bureau of Plant Industry.
Celery Disease and Its Control.

**Frankenfield, H. C.**, *A. M., M. D.*, Senior Meteorologist in Charge, River and Flood Service, Weather Bureau.
Floods and the Farmer.

**Frey, R. W.**, *B. S.*, Associate Chemist, Leather and Tanning Investigations, Bureau of Chemistry.
Leather Damaged by Impure Air.
Shoe Soles from " Bend " of Hides Most Durable.
Tannin Content of Chestnut Stumps and Roots.

**Frothingham, E. H.**, *A. F., M. S. F.*, Director, Appalachian Forest Experiment Station, Forest Service.
Woodlots in the Piedmont Region a Profit Source.

**Frysinger, Grace E.**, Home Economist, Extension Service.
Home Life on the Farm.

**Gage, Charles E.**, Tobacco Statistician, Bureau of Agricultural Economics.
Tobacco Markets Show Cigarettes in Growing Favor.

**Gaines, E. F.**, *M. S., Sc. D.*, Agent, Cerealist, Cereal Smuts, Bureau of Plant Industry.
Wheat Varieties Resistant to Stinking Smut.

**Galloway, B. T.**, *B. Agr., Sc., LL. D., D. Agr.*, Senior Pathologist, Foreign Plant Introduction, Bureau of Plant Industry.
Bamboo Groves Thrive in the United States.
Quetta Nectarine—A New Fruit of Indian Origin.

**Galpin, C. J.**, *M. A., Litt. D.*, Senior Agricultural Economist, Chief, Farm Population and Rural Life, Bureau of Agricultural Economics.
Population Flow from Farms to Cities Declines.

**Garner**, W. W., *A. B.*, *Ph. D.*, Senior Physiologist, in Charge, Tobacco and Plant Nutrition, Bureau of Plant Industry.

**Tobacco Not Always Helped by Rotation.**

**Garver**, R. D., *B. S.*, Forest Examiner, Forest Products Laboratory, Forest Service.

**Chestnut Blighted Wood Good for All Timber Uses.**

**Gibbons**, C. E., *B. A.*, Marketing Specialist, Livestock Marketing Investigations, Bureau of Agricultural Economics.

**Meat Standards and the Livestock Producer.**

**Gilbert**, J. C., *B. S.*, Marketing Specialist, Bureau of Agricultural Economics.

**Radio Aids in Distribution of Market News.**

**Gile**, P. L., *A. B.*, Chief, Soil Chemical Division, Bureau of Soils.

**Colloids and Soil Behavior Possibilities.**

**Goldman**, **Edward** A., Biologist, in Charge, Bird and Game Reservations, Biological Survey.

**Game Surpluses Perplex Wild-Life Guardians.**

**Gould**, B. R., *A. B.*, *M. B. A.*, Assistant Agricultural Economist, Transportation, Bureau of Agricultural Economics.

**Freight Rates Since War Period.**

**Gravatt**, G. F., *B. S.*, *A. M.*, Associate Pathologist, Forest Pathology, Bureau of Plant Industry.

**Chestnut Blight Is Unchecked.**

**Griffiths**, **David**, *M. S.*, *Ph. D.*, Horticulturist, Bulb Culture Investigations, Bureau of Plant Industry.

**Bulb Culture Makes Progress.**

**Guernsey**, E. W., *Ph. D.*, Associate Chemical Engineer, Fixed Nitrogen Research Laboratory.

**Cyanides and Hydrocyanic Acid in Farm Operations.**

**Hardy**, J. I., *M. S.*, *Ph. D.*, Animal Husbandman, Sheep Office, Bureau of Animal Industry.

**Wool Shrinkage Tests Important to Sheep Raisers.**

**Harlan**, C. L., *Ph. B.*, Livestock Statistician, Bureau of Agricultural Economics.

**Livestock Estimating Work Much Enlarged.**

**Pig Surveys and Market Stabilization.**

**Harlan**, **Harry** V., *M. S.*, *D. Sc.*, Senior Agronomist, Barley Investigations, Bureau of Plant Industry.

**Barley Varieties New to United States.**

**Hastings**, **Alfred** B., *A. M.*, *M. F.*, Forest Inspector, Forest Service.

**Forest Trees for Planting.**

**Hawkins**, **Lon** A., *B. S.*, *Ph. D.*, Physiologist, Fruit and Vegetable Investigations, Bureau of Plant Industry.

**Orange Freezing a Hazard in All U. S. Groves.**

**Hawley**, **Edith**, *Ph. D.*, Food Economist, Bureau of Home Economics.

**Food Habits of Farm Families.**

**Hawthorne**, H. W., Associate Agricultural Economist, Bureau of Agricultural Economics.

**Income Data Show Earnings Vary Widely.**

**Haywood**, J. K., *B. S.*, *M. D.*, Chairman, Insecticide and Fungicide Board.

**Insecticide and Fungicide Board's Work.**

**Hedgcock**, **George** G., *B. S.*, *A. M.*, *Ph. D.*, Pathologist, Forest Pathology, Bureau of Plant Industry.

**Fire-Scar Damage in Woodlands Heavy.**

**Hedges, Florence**, *A. B.*, Assistant Pathologist, Pathological Laboratory, Bureau of Plant Industry.

Bean Wilt Traceable to Infected Seed.

**Henderson, B.**, *S. B.*, *A. M.*, Assistant Agricultural Economist, Land Economics, Bureau of Agricultural Economics.

Land Settlement Policies.

**Henry, Alfred J.**, Senior Meteorologist, Editor Monthly Weather Review, Weather Bureau.

Long-Range or Seasonal Weather Forecast Methods.

**Henry, Arthur W.**, *M. S.*, *Ph. D.*, Agent, Assistant Plant Pathologist, Flax Rust, Bureau of Plant Industry.

Flax Rust Control Through Immune Strains Possible.

**Hill, A. Elizabeth**, *M. S.*, Assistant Textile Chemist, Bureau of Home Economics.

Washing Clothes a Problem in Temperatures.

**Holbert, James R.**, *M. S.*, *Ph. D.*, Agronomist, Corn Root-Rot and Stalk Rot, Bureau of Plant Industry.

Corn Varieties Resistant to Rot Disease.

**Holm, George E.**, *M. S.*, *Ph. D.*, Chemist, Dairy Research Laboratories, Bureau of Dairy Industry.

Skim Milk in Dry Form Has Various Uses.

**Hooker, W. A.**, *B. S.*, *D. V. M.*, Economic Zoologist, Office of Experiment Stations.

Experiment Station Work on Animal Disease Control.

**Houck, U. G.**, *B. S.*, *D. V. M.*, Senior Veterinarian, Chief, Hog Cholera Control Division, Bureau of Animal Industry.

Hog-Cholera Control Calls for More Immunization.

**Hulbert, L. S.**, *LL. B.*, Marketing Economist in Cooperative Marketing, Bureau of Agricultural Economics.

Cooperative Marketing Recognized in Numerous Laws.

**Hunter, Byron**, *M. S.*, Associate Agricultural Economist, Bureau of Agricultural Economics.

Size of Farms Important on Irrigated Land.

**Hutson, J. B.**, *B. S.*, Economic Analyst, Bureau of Agricultural Economics.

Working Day of Farmers a High Average.

Work Time of Horses on Farm Varies Widely.

**Hutton, L. D.**, *M. S.*, Associate Pathologist, Barberry Eradication, Bureau of Plant Industry.

Barberry Eradication in Wheat Areas.

**Irwin, H. S.**, *M. S.*, Assistant Marketing Specialist, Bureau of Agricultural Economics.

News Service on Farm Feedstuffs.

Wheat Reports on Production and Holdings.

**Jacob, K. D.**, *B. S.*, Associate Chemist, in Charge, Phosphate Investigations, Bureau of Soils.

Phosphate Fertilizer Deposits of U. S. Ample.

**Johnson, E. R.**, *M. S.*, Assistant Agricultural Economist, Farm Management and Costs, Bureau of Agricultural Economics.

Egg Supplies in Winter.

**Johnson, O. M.**, *B. S. A.*, Agricultural Economist, Land Economics, Bureau of Agricultural Economics.

Tenancy Changes from 1920 to 1925 Not Excessive.

Jones, D. Breese, *Ph. D.*, Senior Chemist, in Charge, Protein Investigations, Bureau of Chemistry.

Proteins in Feedstuffs Vary Much.

Jones, Fred R., *M. S.*, *Ph. D.*, Pathologist, Forage-Crop Diseases, Bureau of Plant Industry.

Alfalfa Wilt Due to Bacteria.

Jones, S. A., *M. D.*, Agricultural Statistician, Bureau of Agricultural Economics.

Crop Acreage by Actual Measuring.

Poultry and Egg Production Estimates Now Made.

Jordan, E. M., Assistant in Livestock Marketing Investigations.

Livestock Market Statistics.

Jull, M. A., *B. S. A.*, *M. Sc.*, *Ph. D.*, Poultry Husbandman, in Charge, Poultry Office, Bureau of Animal Industry.

Poultry Accreditation a Stabilizing Market Influence.

Kalmbach, E. R., Biologist, Food-Habits Research, Biological Survey.

Blackbird Control in Grain Areas.

Kearney, Thomas H., *LL. D.*, Senior Physiologist, in Charge, Alkali and Drought Resistant Crops, Bureau of Plant Industry.

Cotton of American-Egyptian Variety in U. S.

Kempton, F. E., *M. S.*, *Ph. D.*, Associate Pathologist, Barberry Eradication, Bureau of Plant Industry.

Barberry Eradication in Wheat Areas.

Kephart, L. W., *B. S.*, Associate Agronomist, Clover Investigations, Bureau of Plant Industry.

Sweet Clover of New Varieties Proves Useful.

Sweet Clover for Permanent Pasture Lands.

Kerr, Robert H., *B. S.*, Chemist, Meat Inspection Division, Bureau of Animal Industry.

Sausage—the Real and the Imitation Kinds.

Kiernan, J. A., *V. S.*, Senior Veterinarian, Chief, Tuberculosis Eradication Division, Bureau of Animal Industry.

Bovine Tuberculosis Being Suppressed.

Kincer, J. B., Meteorologist, in Charge, Agricultural Meteorology, Weather Bureau.

Frost Forecasting Indispensable in Orchard Heating.

Kirkpatrick, E. L., *M. S.*, *Ph. D.*, Associate Agricultural Economist, Bureau of Agricultural Economics.

Family Living Level on the Farm.

Krase, H. J., *M. S.*, Associate Chemical Engineer, Fixed Nitrogen Research Laboratory.

Urea—a Nitrogen Fertilizer with Many Advantages.

Leighty, C. E., *B. A.*, *Ph. D.*, Agronomist, Eastern Wheat Investigations, Bureau of Plant Industry.

Wheat Breeding for Resistance to Leaf Rust.

Leonard, Lewis T., *B. S.*, *M. A.*, Associate Physiologist, Legume Bacteria, Bureau of Plant Industry.

Legume Inoculation and Fixation of Air Nitrogen.

Lewis, W. E., *B. S.*, Marketing Specialist, Grades and Standards, Bureau of Agricultural Economics.

Tomatoes for Canning Now Standardized.

Lindstrom, C. A., Specialist in Exhibits, Extension Service.

Exhibits in Farm Education.

**MacKellar**, W. M., *V. S.*, Veterinarian, Tick Eradication Division, Bureau of Animal Industry.
Tick Eradication Succeeding in Southern States.

**Magness**, J. R., *M. S.*, *Ph. D.*, Physiologist, Fruit and Vegetable Handling, Transportation and Storage, Bureau of Plant Industry.
Apple Picking at the Right Time.

**Magoon**, C. A., *A. B.*, *Ph. D.*, Bacteriologist, Fruit and Vegetable Utilization, Bureau of Plant Industry.
Sweet Corn Quality Due to Farm and Factory Influences.
Sweet Potatoes in Canned Form Find New Uses.

**Malcolm**, Ola Powell, Field Agent in Home Demonstration Work, Extension Service.
Home Industries for Farm Women and Girls Numerous.

**Marquis**, J. Clyde, *M. S. A.*, Director Economic Information, Bureau of Agricultural Economics.
Reporting Service on Markets is Country-Wide.

**Marsh**, C. Dwight, *Ph. D.*, Physiologist, in Charge, Stock-Poisoning Plant Investigations, Bureau of Animal Industry.
Poisoning of Livestock by Plants.

**Mattoon**, Wilbur R., Extension Forester, Forest Service.
Timber Measuring on the Farm Not a Difficult Task.
Timber Selling from the Farm to Consumers.

**McDonnell**, C. C., *Sc. D.*, Senior Chemist, Insect Investigations, Bureau of Chemistry.
Pyrethrum Powder as Insecticide.

**McDowell**, J. C., *B. S. A.*, *M. A.*, Dairy Husbandman, Bureau of Dairy Industry.
Cow-Testing Tales Prove Breeding and Feeding Pay.
Proving Dairy Sires Through Daughters' Records Worth While.

**McKay**, A. W., *B. S.*, Marketing Economist in Cooperative Marketing, Bureau of Agricultural Economics.
Cooperative Marketing to be Forwarded by Educational Program.

**McKee**, Roland, *B. S.*, Horticulturist, Foreign Plant Introduction, Bureau of Plant Industry.
Chinese Dwarf Meyer Lemon Introduced.
Olives of the Barouni Variety Do Well.

**McKinney**, H. H., *M. S.*, Pathologist, Virus Diseases, Bureau of Plant Industry.
Wheat Mosaic Control Through Immune Strains.

**McLaughlin**, W. W., *B. S.* in *C. E.*, Associate Chief, Division Agricultural Engineering, Bureau of Public Roads.
Agricultural Engineering and Farm Efficiency.

**McMurtrey**, J. E., jr., *B. S.*, Assistant Physiologist, Physiology and Nutrition of the Tobacco Plant, Bureau of Plant Industry.
Magnesia in Fertilizer for Tobacco Plant.

**Meier**, Fred C., *A. M.*, Extension Plant Pathologist, Extension Service.
Stinking Smut of Wheat—Progress in Its Control.

**Meloy**, G. S., *LL. B.*, Assistant Chief Marketing Economist, Cottonseed Products, Bureau of Agricultural Economics.
Cottonseed Crushing Industry Grows.
Cottonseed Grades Are to Be Issued.

**Mendum**, S. W., *M. S.*, Agricultural Economist, Bureau of Agricultural Economics.
Farm Returns from 1922 to 1925 Studied.

**Merrill**, F. A., *B. S.*, Specialist in Agricultural Education, Extension Service.
Agricultural Education in United States.

**Miller**, A. W., *D. V. S.*, Senior Veterinarian and Chief of Field Inspection Division, Bureau of Animal Industry.
Foot-and-Mouth Disease in the United States.

**Miller**, J. M., *B. S.*, Entomologist, Forest Insects, Bureau of Entomology.
Bark Beetles and Timber Conservation.

**Mohler**, John R., *A. M.*, *V. M. D.*, *D. Sc.*, Chief, Bureau of Animal Industry.
Livestock Problems that Have Been Solved.

**Moore**, A. N., *M. A.*, Assistant Agricultural Economist, Agricultural Finance, Bureau of Agricultural Economics.
Credit for the Farmer.

**Morse**, W. J., *B. S.*, Agronomist, Soy Beans, Cowpeas, and Velvet Beans, Bureau of Plant Industry.
Mung Bean in United States Agriculture.
Soy-Bean Output Increasing in United States.
Soy-Bean Varieties Newly Developed for U. S. Farms.

**Mulford**, Furman Lloyd, *B. S.*, Associate Horticulturist, Bureau of Plant Industry.
Chrysanthemums for the Northern United States.

**Nason**, Wayne C., *B. S.*, Assistant Agricultural Economist, Bureau of Agricultural Economics.
Hospitals for Agricultural Communities.
Recreation for the Farming Population.
Village Planning Contributing to Better Farm Life.

**Nelson**, E. W., *M. A.*, *D. Sc.*, Chief, Bureau of Biological Survey.
Reindeer in Alaska Thrive and Multiply.

**Paine**, H. S., *B. S.*, Senior Chemist, Carbohydrate Investigations, Bureau of Chemistry.
Sirup "Sugaring" Preventable by Use of Invertase.

**Parker**, Edward C., *B. Agr.*, Assistant Chief Marketing Specialist, Hay Standardization, Bureau of Agricultural Economics.
Hay Standards and Inspection System.

**Parker**, J. B., *B. S. A.*, Associate Dairy Husbandman, Bureau of Dairy Industry.
Cow-Testing Associations a Factor in Low-Cost Dairying.

**Pearson**, G. A., *B. S.*, *M. A.*, Silviculturist, Southern Forest Experiment Station, Forest Service.
Forest Grazing Control Aids Tree Growth.

**Perkins**, Fred W., in Charge, Office of Motion Pictures, Extension Service.
Movies for the Farmer.

**Peterson**, Esther C., *M. S.*, Assistant Textile Chemist, Bureau of Home Economics.
Starches and Other Finishes for Fabrics.

# THE YEAR IN AGRICULTURE

## THE SECRETARY'S REPORT TO THE PRESIDENT

Washington, D. C., *November 1, 1926.*

To the President:

Further moderate improvement in the agricultural situation as a whole has taken place during the last year. Certain regions have suffered reverses, notably the cotton States, whose principal crop, produced in exceptional abundance, is selling at very low prices. Parts of the spring wheat States have harvested a poor crop. Generally speaking, however, the position of agriculture is better now than it has been in any year since 1920. Livestock raisers, dairymen, and winter-wheat growers have earned good returns, and underlying conditions in the Corn Belt have improved. The year, in short, has been similar to the last few years in that it has seen marked but not uniform improvement in agricultural conditions.

Since the depression period of 1920–21 every agricultural section of the country and every important branch of agriculture have made progress. Recovery has not been uninterrupted; nor, as I have indicated, have all groups of producers shared in it equally. Nevertheless, the gain has been substantial. For the crop year 1925–26 the net income of the agricultural industry as a unit is estimated at about $2,757,000,000, or 4 per cent more than for the crop year 1924–25. In the same period the net return on the value of the capital invested in agriculture was about 4.6 per cent, compared with 3.1 per cent in the crop year 1922–23 and only 0.6 per cent in the crop year 1920–21.

Unfortunately, the recent slump in cotton prices makes it doubtful whether the crop year 1926–27 will carry forward the story of improvement at the rate established in the last few years. An average price of about 18 cents a pound for the estimated cotton crop would be necessary to yield the cotton States an income equal to that of last year. Recently the farm price of cotton has been around 12 cents a pound. While there are prospects that this extremely low price will be only temporary, it does not seem probable at this writing that returns to the cotton growers will be satisfactory. It is also true that over much of the country farmers are still struggling with a burden of debt and reduced buying power.

### Difficult Problems Persist

Even a good year, therefore, would have to be spoken of in terms of improvement rather than of full prosperity. The situation continues to present problems of heavy production and some lingering disparity between the prices of farm products and the prices of industrial goods and services. These facts must not be forgotten. On the other hand, they should not blind us to the real gain that has been made. If the Cotton Belt is the black spot in the agricultural picture for the time being, it does not darken the whole of the picture by any means.

It is impossible to appraise the condition of agriculture in a given region by considering solely the current price of the principal crop grown there. In the case of the Cotton Belt, for example, we have to set up against the present low price of cotton the fact that cotton, until the last few months, had sold at high prices since 1922. In 1922, 1923, and 1924 the South enjoyed a combination of large production and high prices. Because of that fact it is unquestionably better able to meet the present emergency than it otherwise would have been. It has more ample resources wherewith to finance the marketing of this year's crop, and is in a good position to protect itself in some measure against the worst effects of the temporary price slump.

### Position of Leading Crops

It will be convenient to glance briefly at the present situation in regard to the leading crops against the background of the depression period from which we are emerging. Winter-wheat growers have harvested and marketed early an excellent crop of high quality. Wheat is not selling at as high a price this year as it was at this time last year. In parts of the spring-wheat States, where yields were reduced by drought, there is distress. Spring wheat was practically a failure in much of South Dakota and central North Dakota. Indeed, all crops suffered there. A great deal of the area seeded was not harvested. Business conditions have naturally been affected adversely. In northern and eastern North Dakota, however, the situation is much better. The Mountain States, particularly Montana, have made good progress this year in recovery from the effects of the depression. It may be said, indeed, that over the greater part of the wheat States conditions have been good for three years. In 1924 our wheat farmers produced 863,000,000 bushels, and for what they sold they received an average price of $1.28 a bushel. In 1925, with a crop of only 669,000,000 bushels, the average price received for wheat sold by farmers was $1.46 a bushel. This year high yields in many States will compensate most farmers for the drop in the price.

### Corn Belt in Better Shape

In the Corn Belt conditions are now somewhat more favorable than they have been for several years. There is a tendency toward a better balance between corn production and hog production, and therefore between corn prices and hog prices. Although there is no undue surplus of corn as there was last year, there is enough of it on hand to fatten a probably increased number of pigs. It is well to bear in mind, however, that the supply of corn is still large, and that a hog-cholera scare is reducing the number of hogs. Similar optimism is warranted in regard to the livestock industry generally. There was a lack of balance in that branch of agriculture in 1925. Corn, oats, and hay were heavy crops, while the number of animals to be fed, especially hogs, was relatively small. Livestock producers were therefore unable to take full advantage of the low price of feedstuffs. That trouble has now been fairly well corrected, and the livestock industry in general is in a stable condition. The range country has had a good year. Cattlemen have done fairly well, and there is a growing optimism among them. Those who have the resources to do so are stocking up their ranches. Prices of breeding stock have advanced for the first time in five years. The cattle industry is moving once more toward prosperity.

### Sheepmen in Fifth Good Year

The sheep industry is enjoying its fifth consecutive prosperous year. It is apparently still expanding. Prices for wool and lambs at present are perhaps not high enough to encourage continued expansion of the sheep industry except in areas especially suited to it. They are high enough, however, to justify the statement that the sheep industry as a whole is in a very satisfactory condition. It is a favorable augury that world stocks of old wool were reduced to a low point at the end of last season.

On the whole the dairy industry has been in a relatively favorable position since 1921. Its products did not suffer as great a slump in prices during the depression as those of the grain and meat industries and it did not remain depressed so long. Comparatively low prices caused some apprehension among dairymen in 1924. Last year, however, the markets for dairy products began to reflect a better balance in production, and this year dairymen in the East and North have had fairly good returns.

In the far West the present year has been one of continued improvement on the whole. The Pacific coast had an early and favorable crop season in contrast with the East and has done reasonably well with grain, livestock, truck crops, and citrus fruits, but apples, pears, and peaches have been low in price.

### Crop-Readjustment Results

This brief summary of agricultural conditions shows that farmers are getting results from the steps they took, following the depression of 1921, to curtail overproduction and to bring their leading enterprises into profitable balance. This undertaking bore substantial fruit in the first years after it was started. Last year, however, it became apparent that in most lines (cotton being an outstanding exception) practicable readjustments in production had largely been made. Farmers, therefore, sought other means of improving their lot. They paid particular attention to improving the quality of their output and toward regulating to better advantage its movement to market. It seems reasonable to credit to these activities a considerable part of the improvement that has been effected in the general situation. Agriculture is now unquestionably on the upward grade, as a result in large measure of the intelligence, energy, and determination of the farmers themselves. I look forward with confidence to further progress from the same causes. This is not to say that everything necessary for the reconstruction of agriculture on a sound footing can be done by the farmers themselves. Later I shall have some remarks to make on the assistance agriculture is entitled to ask from other groups in the community and from the Nation. Just here, however, I want to emphasize what the farmer can do for himself by efficient production properly regulated to the demands of the market.

### Variations in Efficiency

Many farmers can improve their methods with profit to themselves. There are great variations in the efficiency of production on different farms. Some dairy farms produce 100 pounds of milk with $1 worth of feed, while on other farms $2 worth of feed is required to produce the same quantity. On some farms a bale of cotton is produced with 200 hours of labor, while on others, where natural advantages are just as great, 300 hours are required. Some hog raisers manage to produce 100 pounds of pork for every 250 pounds of grain fed to hogs. Others use more than 500 pounds of grain in the production of 100 pounds of pork. These examples indicate some of the possibilities that exist for increased efficiency on the farm. Similar variations in efficiency and similar possibilities for improvement exist in farm enterprises in all sections of the country.

There are opportunities for farmers to improve the quality as well as to lessen the costs of their production. It should not be forgotten that high-quality goods cost no more to ship than low-quality goods. They consequently leave a bigger margin for the producer after all expenses of marketing have been paid. Efficiency in production does not mean maximum production per acre nor does it necessarily mean production at the lowest cost per unit of production. The farmer is most efficient who uses the methods that will give him the greatest returns from his farm as a whole. This aim clearly calls for attention not only to the unit cost of production but to the quality and the volume of the things produced. However, it should be remembered that increasing efficiency in production will not by itself result in permanently improved income for agriculture as a whole. If farmers in general let lower costs and temporarily larger returns encourage them to increase the total volume of their production too much, they will drive down prices as fast as they reduce their production costs.

### Problem Has Many Aspects

In considering what can be done for agriculture by collective action among farmers, by other groups in the community, and by the Nation acting through governmental agencies, it is well to bear in mind that the farm problem must be approached from many angles. Much recent discussion has emphasized the surplus problem as the root of the farmers' difficulties. Surpluses of various crops unquestionably exercise an influence on prices entirely disproportionate to their amount. Moreover, difficulty in the disposal of surpluses is not confined to any one section of the country or to any particular class of farm enterprises. It is a difficulty that dairymen, fruit growers, livestock raisers, cotton growers, grain growers, tobacco growers, and producers of nearly every staple farm product have to grapple with from time to time. Nevertheless, the farm problem is not merely a question of disposing of temporary oversupplies, although that is a very important question. It is necessary to deal also with costs on the farm, with taxation, with transportation charges, with merchandising methods, with adjustment of production to probable market requirements, and with many other matters. With the more important of these I shall deal in some detail later in this report.

## THE SURPLUS PROBLEM

As to the surplus problem, there are two general avenues of approach to its solution. One is through a better adjustment of production to market requirements. I recognize the difficulties of controlling production, but I am convinced nevertheless that through organized and well-directed efforts much more can be done than we have hitherto done to eliminate the recurring surpluses that prove so detrimental to the farming industry. Our accomplishments in this direction since the war indicate possibilities for the future.

The other approach is through marketing. It seems to me that the central problem is one of merchandising. Better control of the movement of agricultural products into consumption channels is needed. This means that adequate marketing, storage, and credit facilities must be available and that producers must be organized to act together in their marketing operations. An orderly flow of products to market, I believe, can best be effected by farmer-controlled agencies. Legislative action should be designed to create and enlarge such agencies and supplement their efforts. No general formula will cover all commodities and all regions. Every region and every commodity has its special marketing problems. What is needed is concentrated and coordinated effort backed up by adequate resources. To do this may require further enabling legislation.

As I have frequently stated, the great need to-day is to give the farmer greater bargaining power through centralized selling brought about by the consolidation of our existing cooperative associations along commodity lines. There are many advantages in cooperative effort, and I shall touch upon them more in detail in my discussion of the cooperative marketing movement. What we are concerned with here is the subject of agricultural legislation as it relates to marketing.

Many of our recent agricultural laws have been directed to the marketing of farm products. The United States warehouse act gives to the farmer a warehouse receipt for his stored products which is universally recognized as sound collateral for loans. Cooperative organizations are making constantly wider use of Federally licensed warehouses. The intermediate-credit banks established under the agricultural credits act of 1923 are extending credit to organized farmers, and this credit fits well into cooperative effort. These and other acts have made a real contribution to the marketing of farm products.

### Funds Needed for Marketing

If we are to give particular attention to centralized cooperative effort, even present credit facilities may not be sufficient. Cooperative associations are not able to obtain sufficient cash advances on their products to enable them to practice orderly marketing in a complete sense. At the best they can only obtain 65 or 75 per cent of the going market price of their products, and there are thousands of farmers who can not operate on this basis, for their current expenses demand more nearly the market price at the time the crops are harvested. For the same reason many of them can not join a cooperative association.

If additional funds were available to make advances to cooperative associations in addition to credit available from existing agencies, they could make liberal payment to members at the time the products were delivered and their power to regulate the movement of products into consumption channels would be greatly enhanced. It would be possible for them to carry surplus production from one season to another. The individual farmer would have the money for his products but would not lose control over them.

Action of this sort would tend to stabilize the prices of farm products. This is a very different thing from price manipulation. Studies made by the department show that over a relatively few years the production and market requirements of most farm products are in fair balance. This indicates that a program of orderly marketing, with resultant stabilized prices, is easily within the realm of possibilities. Such a program would not menace the interests of consumers but would contribute materially toward the general stability of supply and markets.

### Consumers' Interests Safeguarded

It may be well to emphasize the fact that no hardship to the consuming public is caused by a program of stabilized prices. Periodic and seasonal depressions in the prices of farm products are not reflected in corresponding declines in prices to consumers, but they play havoc with the agricultural industry. A sound program of price stabilization would guarantee an even flow of products to the consumer at fair prices. It would thus be a benefit to both the producer and the consumer. Agriculture does not lend itself to monopolies or to improper price manipulation. Attempts have sometimes been made by agricultural organizations to exact prices out of line with basic supply and demand conditions. The result has invariably been unfortunate for the authors of the plan. Efforts at price stabilization in harmony with supply and demand conditions, on the other hand, are quite generally successful. Organization of farmers in cooperative associations formed on a commodity basis seems to me the best way to stabilize prices.

## DEVELOPMENTS IN COOPERATIVE MARKETING

This opens up the general subject of cooperative marketing. Gluts and wastes can not be overcome, nor can the spread between what the farmer receives and what the consumer pays be narrowed sufficiently until effective machinery has been set up to feed farm products into the markets of the country in an orderly manner and at a rate consistent with consumption requirements. This is a formidable undertaking. There is a natural division of interests between different agricultural sections of the country. Farmers of the East are heavy buyers of western grain. The South is a heavy buyer of northern pork products, grains, and feedstuffs. The North is a buyer of cotton products. Even within the same region the grain grower's finished product may be the livestock feeder's raw material. Our marketing policy should have regard for the interests of agriculture as a whole. A plan of organization that will work fairly and effectively as between the cotton producers of the South and the milk producers of the New England States, the corn growers and the hog raisers of the Corn Belt, the citrus growers of California, Florida, and Texas, the cattlemen of the range and beef-cattle States, the potato growers of Maine, Idaho, Wisconsin, and Minnesota, and the producers of all the other crops grown in this country, can not be improvised in a moment. I believe, however, that we are on the right track when we emphasize the commodity principle in cooperative organization.

### Coordination of Units Needed

It is obvious, of course, that cooperation will not do much for the wheat grower if 5,000 or 10,000 associations try to operate in wheat independently of one another. There is needed a coordination of local cooperative units and a central sales agency. Only by such means can farmers expect to have any effective bargaining power in the wheat market. But a wheat cooperative with a central sales agency that had in its possession from 100,000,000 to 200,000,000 bushels of wheat might help materially in stabilizing wheat prices.

The United States has become great industrially largely through mass production, which facilitates elimination of waste and lowering of overhead costs. Large-scale organization in the business world has effected tremendous economies both in production and distribution, and has enabled manufacturers to supply consumers with what they want when they want it. It seems to me that in this matter agriculture must follow the example of industry. It must have a similar large-scale development of its business organization, managed by competent executives. There are 6,500,000 farmers, each representing a unit of agricultural business. It is therefore not easy to organize agriculture for effective business operations. But the start that has been made in that direction indicates that it can be done.

Natural limits to the extent to which cooperative marketing can be centralized are set by the fact that each basic agricultural product presents problems of its own. It is obviously impracticable to have wheat growers, cotton growers, fruit growers, and livestock raisers all in the same organization. So far as I can see now, there ought to be separate organizations for each leading commodity. But there ought not to be too many competing organizations each striving to handle the same product. When a crop is handled by several hundred small concerns, whether they are cooperative or private, there is bound to be confusion, price cutting when supplies are heavy, market gluts, and other conditions that result in heavy losses for which the producer must pay.

I have already mentioned the possibilities open to wheat growers through the federation of local cooperative organizations. It is necessary to have local farmer-owned elevators. Local cooperative units are necessary for assembling and shipping wheat. Local organizations, however, can not exercise any effective bargaining power unless they follow a limited marketing policy. Such action is, of course, impossible without an overhead selling agency representing them all.

### Building Bargaining Power

What we need, in short, is organization, both local and regional. Our cooperative marketing agencies should be organized on the broadest scale compatible with effective dealing with the special problems presented by the different branches of agriculture. As I have mentioned wheat several times in this connection for purposes of illustration, I may as well amplify my point by further reference to that commodity. There are about 4,000 farmers' elevators in the United States and no fewer than nine wheat pools. These elevators and pools, however, do not conduct any common policy. As a result they have probably little more bargaining power than have individual wheat growers. But if they were federated our wheat growers' organizations would be in a position to exercise a very considerable influence on market conditions. It is not necessary for a cooperative association to handle the whole of a crop in order to have some say as to its price. It is often enough to control merely the surplus beyond what is required for current consumption.

Farmers can unquestionably exercise effective bargaining power through commodity organizations representing a majority of the heavy producers of the crops handled by the organizations. In that way they can prevent disastrous ups and downs in prices, cause a steady flow of products to the best markets, and exert some influence on production. It is important that farmers' organizations should not confine their work merely to regulating the flow of agricultural products to market. They should seek to adjust production as well as marketing to consumption requirements. Effective agricultural cooperation begins at seeding and planting time, and in the case of many crops ends only when the product is turned over to the processor or to the consumer. When farmers' business organizations take this broad view of their functions they can make a real contribution to the stability and progress of agriculture.

### Required Degree of Organization

What proportion of the producers must be organized in cooperative associations to get the best results is a keenly debated question. Enthusiasts will not be content with anything less than 100 per cent organization. As, however, this end is not likely to be reached for a long time, if ever, we shall do well to bear in mind the demonstrated fact that cooperative marketing is not dependent for its success on the inclusion of all farmers in its organizations. Cooperative organization is often measurably effective even when very incomplete. It is true that a cooperative association controlling only part of a given crop may sometimes confer more benefit on nonmembers than on members. It may enable nonmembers to get better prices than would otherwise be obtainable, without saddling upon them any of the expense or risk involved in the operation of stabilizing the market. However, that is a liability which the cooperative movement in its earlier stages can hardly avoid. It will tend to diminish as the farmers become better informed about cooperation and join cooperative associations in larger numbers. Eventually, no doubt, a situation like that seen in the case of certain great industrial organizations will arise, wherein unorganized "independents" find themselves more or less obliged to fall in step with the general marketing policy laid down by the dominant organized group.

### An Objection Answered

It has been suggested that farmers who produce many crops will find it impossible to participate advantageously in cooperative marketing through organizations formed on commodity lines. The idea is that they can not be expected to join a sufficiently large number of different associations. This seems to me a very trivial objection to the method of organization which I am advocating. It would seldom be necessary for farmers to belong to more than two commodity organizations, since few farmers produce more than two different major crops. The average farmer can not expect to do the whole of his business through cooperative agencies, for the present at any rate. A wheat farmer in the Red River Valley of Minnesota, for example, would probably find his interests sufficiently protected by membership in a wheat cooperative. Conversely, a dairy farmer in the same State, with only a small wheat acreage, would probably be content with membership in a dairy cooperative. As a matter of fact, however, thousands of farmers already belong to more than one farmers' marketing organization without getting their affairs unduly complicated.

Cooperative associations reporting to the department at the end of 1925 had on their membership rolls a total of 2,700,000 producers. Allowing for duplication, owing to the fact that many farmers are members of two or more associations, and for inactive members, it is conservative to state that approximately 2,000,000 farmers are now engaged in cooperative marketing. The membership of cooperatives to-day is more than three times as great as in 1915, when it was approximately 651,000. The total business of cooperative associations in 1915 was $635,800,000. In 1925 it reached approximately the huge total of $2,400,000,000.

### Possibilities of Cooperative Marketing

A large-scale efficiently managed cooperative can effect three fundamental improvements in the marketing of farm products: (1) It can standardize grades and handling methods; (2) it can develop an effective merchandising program; (3) it can give the farmer information which will enable him to visualize market conditions six months or a year in advance, and thus assist in making adjustments in his production plans.

The development and use of grade standards has come about largely because of the demands of the cooperative associations. In pooling the products of their members, the cooperatives must have grades so that they can make returns to the growers in accordance with the market value of the product each one produces. The cooperatives have also found that the standard grades make trading easier, reduce wastes, and promote wider distribution and increased consumption.

The cooperative associations can do a better job of merchandising farm products than the individual producer. Merchandising means more than taking orders. The aim of the selling program of a cooperative should be service to its members and its customers. A thorough study of the price and demand history of a commodity and a knowledge of the present and potential supply are essential before the correct selling program can be determined for that commodity. The association must know the supply of the product and of competing products. An association selling oranges must be informed regarding the apple crop, because apples come into competition with oranges. If there is an unusually large crop of Italian lemons, the California lemon growers must take that fact into account in their price and sales policy.

Furthermore, the association must know the markets and the factors that affect prices. When it has collected all this information, the association must use it to guide its price policies; it must determine the markets in which it will attempt to sell, the quantity it will offer each day or week, and the trade channels it will use. Only a large-scale organization can do this job efficiently.

### An Example of Market Information

As an example of information that may be used to guide the marketing policies of cooperatives, studies by the Bureau of Agricultural Economics of the relationship of wheat supply to prices may be cited. The world supply of wheat—especially the supply of the Northern Hemisphere—has a greater influence on price than the supply in the United States, whenever there is a surplus for export. Hard spring-wheat production is frequently sufficient only for domestic requirements, but there is usually a surplus of other classes. The relationship for a period of 25 years of the supply of wheat in the Northern Hemisphere (production plus carry-over) and the supply in the United States to price has been calculated. From these studies it is possible to determine the usual relationship between supply and price during these years and to use the information in estimating probable movements in the future.

Finally, the cooperative associations can furnish the producers information by which they can adjust their production in the light of market requirements. Cooperation must reach back to production, guide the organization of farm enterprises, and direct the production programs of the members. The problem of agriculture at the present time is largely one of coordinating production. To a large extent each of 6,500,000 farmers produces farm products without reference to the plans of his neighbors and without consideration of the factors which will be instrumental in determining whether he produces at a profit or loss.

Cooperation is already having an important effect upon production. Among the fruit growers, undesirable varieties are being eliminated and the quality of the fruit grown is being improved by better cultivation, fertilization, and spraying. The milk producers are delivering a product testing higher in butterfat and lower in bacterial count. Cotton growers, who are paid through their cooperative associations according to the grade and staple of their crop, are making fruitful attempts to plant only standard varieties and to avoid damage which lowers the grade of their cotton.

A few of the milk producers' organizations have been able to go further in influencing production than the examples given. An association in an eastern market, for example, adopted some years ago a " basic price " policy in making payments to its members. By this plan, the quantity of milk delivered by each member in October, November, and December was rated as " basic milk " and paid for at fluid-milk prices. Each member receives the fluid-milk price for the same quantity delivered each month from January to September, but " surplus milk " delivered during these months—that is, the quantity in excess of his average production during October, November, and December—is received at a lower price which is based on the price of 92-score butter in New York City.

### Wholesale Production Shifts

The results of this policy have been a wholesale shift in production. The last three months of the year were formerly months of scarcity, and the early spring and summer months saw large, unmanageable surpluses of fluid milk coming on the market. During 1925, the average deliveries to this association from January to September exceeded those of October, November, and December by only 10 per cent. In other words, the dairymen were able by changes in their practices to maintain practically as large a flow of milk during the late fall and early winter months as during the remainder of the year. The milk supply situation has been stabilized so that seasonal surpluses are no longer a serious factor. Partly as a result of this stabilization, prices to the producers have been among the highest paid in the eastern United States, while prices to the consumer have been from 1 to 2 cents a quart lower than those paid in most large Eastern cities.

### Pitfalls of Cooperative Marketing

Failures in cooperative marketing have not been unusual, considering the number of associations formed and the volume of business transacted. From 1920 to 1925, years for which the department has reasonably accurate records, the largest number of failures reported was 194 in 1923, 1.9 per cent of all associations reporting to the department that year. Failures in 1925 were only 0.3 per cent of the more than 10,000 cooperative associations reporting during the year. The failure of cooperatives which have gone out of business can be traced, in most cases, to a few well-defined causes.

Chief of these, according to reports received from former members and officials of approximately 1,100 defunct associations since 1913, is failure to obtain a sufficient volume of business to make possible economical and efficient operation. The causes which lay behind this situation are often somewhat obscure. The commodity may not be produced extensively enough in the community or region to justify the organization of a cooperative association. For example, a number of cooperative creameries were formed in Kansas, during the nineties, in communities that were not dairy sections and offered no prospect of developing into such in the immediate future. Consequently a large number of failures followed. Again, the sentiment of the producers in the region may not be favorable to cooperative marketing, or there may be antagonism created by the policies of the management, or lack of confidence in the ability of the management.

Members of cooperative associations which fail because of insufficient business very frequently ascribe the failure to poor management. In more than half of the 1,100 suspensions of which the department has record, inefficient management was given as the sole or one of the chief causes of failure. Wisely planned and intelligently directed management is by far the most important element in business success and lack of it the most certain cause of failure. In speaking of management, I want in particular to emphasize the duties and responsibilities of the board of directors.

### Directors Have Responsibilities

One of the serious weaknesses of many cooperatives is found in the tendency of members of boards of directors to shirk their responsibilities. Too frequently the individual member elected to the board looks upon his selection as a director in the light of an honor conferred upon him in recognition of his standing in the community and as carrying with it no responsibility. Such an attitude is unfortunate, and until every director comes to feel that he is accepting the trusteeship for the successful conduct of the business, cooperative marketing will fail of its full measure of success.

Changes in economic conditions at times interfere seriously with the operations of cooperative associations. The shift in demand from cigars to cigarettes, for instance, has seriously embarrassed the tobacco marketing associations in the cigar-leaf sections. Some cooperative creameries have gone out of business because the growth of near-by cities has opened up a fluid-milk market for their members. During and immediately after the war, the high prices paid by condenseries put out of business a number of cooperative creameries and cheese factories, many of which had been operating for 20 years or longer.

### Danger in Price Control

Too often in the organization of cooperative associations the idea has been broadcast that control of supplies by the farmers will enable them to fix the prices of their products. This doctrine has been a factor in the failure of some cooperatives. The price which a cooperative obtains for its products is determined by the supply of the product and the demand for it. Not only the supply in the possession of the association but that controlled by other shippers and produced in other sections of the United States and in foreign countries influences prices. The supply and price of competing products are also factors. Wheat competes with corn and rye as a bread grain; cotton with wool and artificial silk; and potatoes with sweet potatoes and other vegetable crops. The association which attempts to manipulate prices by withholding its products from the market usually discovers that it has created a more favorable market situation for competing sections and products and has possibly sacrificed the crops of its members. The disappointment resulting from the failure of a program that from the beginning was impossible has in some cases set the stage for failure.

A brief analysis of the price history of various commodities will illustrate the difficulties that a cooperative association would encounter in attempting to fix prices arbitrarily. Although all the raisins produced commercially in the United States are grown in a limited area in California, and a cooperative association should control 85 per cent of the output, it could not maintain a profitable price level when confronted by huge domestic production and the growing competition of foreign countries. Much less could this cooperative, apparently ideally situated to control price, maintain, if it were so inclined, an arbitrarily high price level. Plans for monopoly control set up an objective that can not be attained. Such plans obscure the real possibilities and purposes of cooperative marketing, and in the long run are harmful to cooperation and to the development of efficient marketing.

### Success Based on Service

The associations with a record of accomplishment have been successful because of the superior service they have been able to render their members and customers and not because they have been able arbitrarily to fix prices. As one definite example, the experience of a woolgrowers' cooperative association, with headquarters at Columbus, Ohio, may be cited. This association was formed in 1918, and in eight years (1918–1925) has marketed 25,139,000 pounds of wool produced by Ohio, Indiana, Michigan, and West Virginia growers. Its average net returns to its members have exceeded the average of local Ohio prices each year by amounts varying from 2½ cents per pound in 1925 to 8 cents in 1921 and 1924 and 9 cents in 1922. This represents increased returns to its members totaling over $1,500,000 for the eight years, without considering the effect the activities of the association may have had on local prices and buying practices. The members in addition are the owners of a wool warehouse in Columbus which was purchased in 1920 for $125,000.

The success of this association has been due, first, to the education of its members with regard to wool grades, the care of the flock, and the preparation of the clip; second, to the practice of selling direct to the mills. It markets wool throughout the year and supplies each mill the grade of wool that will meet its needs, prepared in such a way that it can be handled with a minimum of waste. These are services to its customers which enable the association to obtain a premium for a large part of its wool.

In the marketing of fluid milk a California cooperative association has made progress, which is typical of a number of successful fluid-milk organizations. This association was formed in 1915, and operated as a price bargaining association until 1920. In that year it acquired 60 per cent of the stock of a retail milk-distributing company at Los Angeles, and now is sole owner of this company.

### Milk Handled Through Subsidiary

At the present time 41 per cent of the milk produced by members of the association is distributed to the consumers through this subsidiary company. From 26 milk routes in 1920, the business had grown to approximately 200 milk routes at the beginning of 1926. The remainder of the milk delivered by members of the association is sold to other distributors, and during periods of surplus a portion is manufactured into by-products. Improvement of the product and the coordination of marketing machinery have stabilized returns to the producers. In 1925, milk to the value of $5,570,032 was handled by the association at a cost of 1.2 per cent.

A cooperative association marketing cotton has found that its chief possibilities lie in giving its customers—the manufacturers—superior service. The spinner wishes to purchase cotton in "even-running lots"—that is, all of the same grade and character. He wants cotton which meets his special needs. The officials of the association quickly recognized that they must first ascertain the needs of their customers, then develop standard "types" which meet these needs, and deliver the exact grade and staple length which the customer desired—not once, nor occasionally, but continuously. This appears to be a simple problem, but it is really very difficult for any agency but a cooperative association to meet it satisfactorily. The association can give its customers "even-running lots" because it has some 200,000 bales from which to select the exact cotton each buyer requires. By its system of classification and records it knows the grade, staple length, and weight of each bale, the warehouse where it is stored, and the grower who produced it. The dealer who sells 100 bales to a manufacturer with the expectation of buying this cotton—1 bale or 10 bales at a time, as it becomes necessary to make deliveries—can not guarantee the uniformity of his shipments with the same assurance as the cooperative association which *knows* it has that exact type of cotton on hand.

### New Cooperative Law

The legislation enacted by Congress has been wisely planned to free the cooperatives from undue restrictions and to assist them in meeting their problems. The Capper-Volstead Act, which became a law in 1922, recognized the right of producers to organize cooperatively, and removed the threat of prosecution under Federal antitrust statutes of cooperatives conducting a legitimate business.

The past year has been signalized by the passage of the act to create a division of cooperative marketing in the Bureau of Agricultural Economics. This bill was drafted after conference with cooperative leaders representing all commodities and all sections of the country. It is designed to enable the department to conduct research studies and furnish service which will aid in the development of the cooperative movement. Research designed to test existing business and marketing methods, education in the principles and practices of cooperation, and such service to the cooperatives as can be rendered by a fact-finding agency are the objectives of the new division.

Research in the business and marketing methods of cooperation, such as the department is undertaking, is not a theoretical abstraction but can be made of practical help and guidance to the associations. The need of the cooperatives for the assistance research can furnish is probably greater than that of private business. Each advance made by cooperative associations calls for a careful study of the conditions under which they must operate. They require a type of research that not only deals with established methods and practices but looks forward to changes which the development of cooperation will introduce.

### Commodity Studies Begun

The division of cooperative marketing is studying at the present time the cooperative marketing of cotton, grain, livestock, fluid milk, and fruits and vegetables. A study just completed of the costs and operating practices of cotton gins may be cited as an example of the work that is being carried on. This study was undertaken in anticipation of the interest which exists among the members and officials of cotton-marketing associations in the formation of local cooperative gins. They will have, as a result of this study, definite information to guide them in forming their ginning associations, and an understanding of the possibilities and problems of this form of organization.

A project dealing with the organization, operating, financial, and selling problems of individual cooperatives was inaugurated early in 1925. This work will be expanded under the provisions of the cooperative marketing act. The demand for studies of this kind indicates the interest among cooperative associations in a close analysis of their business and merchandising operations and in the external factors which affect the prices received for their products. The object in conducting analyses of the business of individual associations is primarily to accumulate a sufficient number of cases to set up operating ratios and standards for cooperatives, and to study by a case system the economics of cooperative marketing. It is essentially a research project, although the development of methods that will enable the cooperative associations to study their own problems is an immediate service.

### Employment of Specialists

The act makes possible also the employment of specialists who are versed in cooperative marketing and familiar with the problems of particular commodities. These men will have two functions; first, to collect statistical and other information made available by the Department of Agriculture and other agencies, and disseminate it to the cooperatives in such form as will be most useful; second, to outline and assist in marketing research and service required by the cooperative associations. These men will have a helpful personal relationship with cooperative organizations, and to a certain extent will be a connecting link between the associations and the men and agencies engaged in research work.

The department expects to cooperate with and assist schools for instruction in cooperation which are being conducted by agricultural colleges and cooperative associations. The growing interest in this instruction is indicated by the increased attendance of members, directors, officers, and employees of cooperatives who spend a week or more at these schools learning the general facts regarding cooperation and the details of financing, accounting, and merchandising methods. The department can make an important contribution by assisting in the development of programs for these schools and by bringing a national viewpoint to those who are considering State and local problems. The dissemination of knowledge regarding the principles and aims of cooperation is one of the major problems of the movement. It is the foundation of sound cooperation.

The department, under the cooperative marketing act, intends to render services which will promote and foster cooperation. The act does not give the department regulatory control over the cooperative associations in any degree. It has never been the policy of the department to attempt to seek such control. Neither does the department intend to undertake any of the functions which the cooperatives themselves were organized to perform. The work of the department will be confined to those research, educational, and service activities which it is peculiarly fitted to perform, and it will be guided in this work by the developing needs of the cooperative organizations.

## AGRICULTURE'S UNCONTROLLABLE EXPENSES

Farmers can do something toward regulating their output and reducing their costs of production and marketing, but many items of farm expense are virtually outside their control. Overhead expense for taxes, interest, insurance, and depreciation is determined largely by factors over which the individual farmer has little influence. This is not to say, however, that nothing can be done toward keeping the fixed charges of the agricultural industry within bounds. Collectively, farmers can accomplish much. I shall refer in detail later to taxation. As a voter, the farmer has some say as to taxation, but his is not by any means always the deciding voice. He often finds himself saddled with a disproportionately high tax burden for public expenditures that benefit him considerably less than they benefit other groups in the population. I shall give some instances of this sort of thing when I take up the general subject of taxation.

Interest charges are another farm expenditure not determined by the individual farm operator. Much has been done in recent years toward reducing the burden of agricultural interest rates for both long and short term credit. Agriculture needs three types of credit. It needs long-time loans on land, short-time credits for six months or less, and production credit running for terms from six months to three years. The establishment of the Federal land banks and the joint-stock land banks has provided admirably for land loans. These banks have loaned more than $1,698,000,000 on terms that have relieved farmers and ranchmen of high interest rates and given them a great incentive to thrift.

### Intermediate-Credit Facilities

Our commercial banking system in general provides short-term credit for agriculture in most regions, although certain districts are still not well served. Facilities for furnishing intermediate credit are now available through the intermediate credit banks which have been set up under the agricultural credits act of 1923. These banks provide a means of advancing all the money that can be prudently employed in the production of livestock or in the marketing of such agricultural commodities as can be insured and safely warehoused. They can loan it, moreover, on conditions that free the producer from worry as to whether his loan may be called before he can finish the undertaking for which he obtained it. Comparatively little advantage, compared with their possibilities, is taken of the facilities offered by the intermediate credit banks. However, the cooperative associations are awake to the usefulness of these institutions.

There is a close relationship between the intermediate credit banks and the cooperative movement. More than half the loans of the banks have been made to farmers' cooperative marketing associations. Moreover, the fact that the cooperatives can tap the resources of the intermediate credit banks has a tendency to make it easier for them to get credit from commercial institutions. That has been demonstrated over and over again. Cooperative associations can get money more easily and on better terms from commercial banks now that they have the intermediate credit banks to fall back on in case of need. The intermediate banks loaned nearly $125,000,000 to cooperative marketing associations last year to finance production as well as marketing. Many cooperative associations have organized credit corporations which can rediscount the paper of their members at the intermediate credit banks. In this way the resources of the banks are made available to thousands of producers who might otherwise have to borrow for production purposes on very unfavorable terms.

## FREIGHT RATES

Transportation charges, although not overhead in the proper sense of that term, nevertheless are often a burdensome, uncontrollable factor in farm business. Farm commodity prices, especially in areas distant from markets, are seriously depressed by high freight rates. It is my conviction, often stated, that we must have substantial readjustments in freight rates. There have been no freight rate reductions of importance on agricultural commodities in the last year. The Department of Agriculture's index of freight rates indicates that they are still 58 per cent higher than before the war. It is instructive to compare this figure with the index for farm commodity prices, which in September stood at only 34 per cent above the pre-war level.

What rail transportation charges sometimes mean to the farmer can be realized from an illustration or two. It costs 26.4 cents to ship a bushel of wheat from Wichita, Kans., to the Gulf of Mexico. It costs 27.8 cents a bushel on the average to ship wheat from the spring-wheat area to the Atlantic seaboard. These freight costs are large relatively as well as absolutely. They place the American farmer at a disadvantage of from 4 to 10 cents a bushel in comparison with the freight costs of his competitors in Canada and Argentina.

### Rate Increase Refused

In the past year a request from the railroads of the western district for a general increase in freight rates on all commodities was refused on the grounds that no financial emergency exists that would warrant such an increase. The Interstate Commerce Commission is continuing its general investigation of the freight-rate structure as ordered by Congress in the Hoch-Smith resolution, which directs such changes to be made as will promote the freedom of movement of agricultural products affected by the depression, including livestock, at the lowest possible rates compatible with the maintenance of an adequate transportation service.

The freight-rate structure of the country has grown up in a haphazard way, which has resulted in a lack of uniformity in rate relationships and adjustments. An example of this is seen in the relation between rates on livestock and fresh and cured meat. Rates have been recently prescribed on shipments between Chicago and New York, establishing rates on fresh meat not to exceed 140 per cent of the livestock rate. As evidence of the need of a general readjustment is the fact that in contrast to this relationship of 140 per cent which was found reasonable, the relationships between these rates from other competitive points varies from 111 to 147 per cent.

A revision of the freight-rate structure on fertilizers in the South has been made, placing rates on a uniform basis throughout the territory and removing any discriminations that may have existed. It is believed that the revision will result in somewhat lower rates in the aggregate.

### Recognize Farm Conditions

The financial needs of the carriers to maintain their roads adequately must be recognized, but the depressed condition of agriculture in many parts of the country must also be recognized. Where the established rates are yielding more than adequate returns it is reasonable to expect that rates on agricultural products suffering from a depression will be reduced.

The railroads in the southern district, for example, are in a prosperous condition, with earnings in excess of what has been determined to be a fair return. The cotton farmer, on the other hand, is facing a year of low prices for cotton. Should it be determined that the cotton farmer may be facing a period of depression, some consideration should be given to the possibility of revising the rate structure in this territory so as to afford him some relief.

Even where railroad earnings do not run in excess of what has been determined to be an adequate return, some relief may be provided for agricultural products suffering from a depression by shifting more of the burden of the rates from these depressed agricultural products to products that are better able to carry the burden.

## HIGHWAY IMPROVEMENT

We have entered upon a period of remarkable development in our highway system, a development conditioned quite largely upon the growing use of motor vehicles. It is important to the Nation that this highway development be so directed as to bring good roads as near as possible to every farmer and at the same time that it be coordinated effectively with other transportation facilities. The program of road building should be in keeping with the needs and resources of the various regions of the country. It is a matter of national concern, and one upon which there should clearly be cooperation between the Federal and State Governments. Detailed information about Federal-aid roads will be given later in this report.

There is no doubt, of course, that the money spent on highways brings a compensating return in reduced expense for the operation of vehicles. This is amply demonstrated by surveys of highway transportation which the Department of Agriculture has made in cooperation with the State Highway Departments of Maine, Connecticut, Pennsylvania, and Ohio. Main intercity roads in these States constitute only one-tenth of their total highway mileage. Nevertheless, there is spent on such roads under the supervision of the State highway departments at least half of their total annual expenditure for highway purposes. They carry a traffic considerably greater than half the highway traffic of the States in question. That owners of motor vehicles believe they benefit from expenditure on highway improvement is indicated by the fact that they now pay in special taxes, without the least objection, an amount which is not less than two-thirds of the annual expenditure of the State highway systems.

Agricultural traffic on these main roads, however, is only a small part of the total. Their traffic is mainly of an intercity character. It neither originates from nor leads to the farm, and therefore helps to improve the condition of the farmer only to the extent that he benefits from whatever general improvement of business conditions the traffic may bring about. In the benefits of main intercity roads, the farmer shares only as he uses them in common with the more numerous users who live in cities and do their business in cities. Clearly, then, it is a mistake to improve such roads by a system of taxation that places the burden largely on farm land. In States in which an effort is made to finance such road improvements in greater or smaller measure by local taxation, there is complaint. The remedy is obvious. Taxation for main road improvement should be on a State-wide basis. There is special appropriateness in the use of motor license fees and gasoline taxes for this purpose.

### Roads to the Farms

But we have more than 2,750,000 miles of roads not included in State main highway systems. For the improvement and maintenance of these roads, revenue may reasonably be derived from taxation of real property. Most of this mileage is devoted to the service of farm land. Indeed, much of it accommodates no one else than a few farmers. Investigations made in Iowa, Wisconsin, and Illinois show that the improvement of such local roads is invariably followed by reduced farm operating expense. Improved roads to the farm cut down wear and tear on vehicles, shorten the time necessary for hauling, and give the farmer access to comparatively distant markets that otherwise he could not reach. In connection with radio and telegraph service, improved market roads enable the farmer to rush his products to town when prices are favorable. This advantage is particularly great in shipping livestock. Livestock raisers who live within trucking radius of their market are in a much better position to profit by upturns in market prices than are those who are obliged to depend on rail transportation. The social benefits of better roads to the farm are perhaps even greater than the economic benefits. Good farm roads lessen the isolation of farmers, and make the farms better places on which to live.

It is extremely important to note, however, that the prevailing weight of farm vehicles, which does not usually exceed that of a 1½-ton truck, makes it unnecessary to improve local roads in an expensive manner. Most of them require no surfacing; very few need more than a coat of gravel or fairly inexpensive material. When local roads are improved beyond this point, there is no proportionate enhancement in the value of adjacent farm lands. It is a common mistake to overimprove this type of road. No road should be improved by the expenditure of public funds in excess of its earning capacity.

## FARMERS' TAXES IN 1926

Farm taxes remain at almost the same level that they reached in 1925. A partially completed survey by the Department of Agriculture reveals the fact that the total taxes collected from farmers in 11 States are slightly higher in 1926 than they were in 1925. The 11 States which have furnished data contain nearly one-third of the farm acreage of the country and present a fairly accurate indication of the situation as a whole.

Drastic reduction in farm taxes can not be expected at the present time. The demands of the users of automobiles for better and more improved roads and the necessarily high costs of education will keep the expenses of the States, counties, and local units close to their present level. The reduction in Federal expenses gives the farmer little direct assistance, although reduction in Federal taxes may be reflected in lower costs for some of the articles that he must purchase.

Aid to agriculture in meeting the tax problem may come from two sources. In those States where agriculture is not the predominating industry it may be that the other industries are bearing less than their share of the tax burden. Where agriculture is the chief industry of the State there is often opportunity for relieving the tax burden by a readjustment of the tax system. Such a possibility should not be overemphasized. So long as Government costs are high the taxpayers must meet the bills. Readjustments of the burden will aid certain groups, but it will not lessen the total amount that must be collected.

### Farmers Bear Undue Burden

Specifically, the farm group may be aided by a general alteration in both the general-property tax itself and in its method of application. As applied in most of the States, the general-property tax must of necessity burden the farmers to a greater extent than it does the proprietors in other industries. The farmers have a larger proportion of their property in a form that can be reached by the assessor than do other groups, and it follows that they pay a larger share in the total expenses of government. An obvious solution for this difficulty points toward an attempt to devise taxes that will force other groups to contribute their share. The State income tax has been one means used to reach incomes that escape the general-property levy. Where the examples of New York and Wisconsin are followed and a portion of the receipts from such a tax, 50 per cent or more in these cases, is returned to the counties and local units, some relief is gained.

The importance of using the receipts from income or other taxes that supplement the general-property tax for purposes other than State expenses deserves emphasis. In 1922 the taxes collected by the States and minor civil divisions amounted to nearly $4,250,000,000. Only 20 per cent of this amount was collected by the States for their uses, the remaining 80 per cent going to the counties, incorporated places, townships, school districts, and other minor divisions. If tax reform is carried on in such a way that it affects only the State taxes it will fail to meet the needs that are greatest. There is in many States a further reason for the distribution to the minor divisions of taxes collected on a state-wide basis. It is becoming common for the State to set certain standards to which the counties, townships, or school districts must conform. In a State where there is uniformity in economic conditions among the various sections, such requirements may not work a hardship on any. Where wealth is unevenly distributed over the State—and it must be recognized that this is the usual condition—it becomes increasingly difficult for the poorer divisions to conform to the standards that have been set up. This situation creates a reasonable basis for the state-wide collection and local distribution of an increasing proportion of taxes.

### Sources of Taxation

It should be noted that the State income tax was mentioned only as an example of a method that has been used by some States. It is not urged that all States should adopt such a measure. The varying economic conditions and characteristics of the sections of the country make no single measure adequate to deal with the situation. The gasoline tax is another that might be cited as an example of a State-collected tax that is adapted either for distribution among the minor divisions or for use by the State in road building and maintenance to relieve the local divisions of some of their expense. This particular tax, with rates ranging from 1 to 5 cents a gallon, has within the last few years been adopted by practically every State. Forty-four of the forty-eight States were using it at the beginning of 1926. It forms a valuable means of collecting part of the cost of roads from those who use them. It again is only one of a number of taxes that are, and should be, used to relieve the pressure on general property.

Out of the four and one-fourth billion dollars collected by the States and their subdivisions in 1922, about three and a third billion came from general property taxes. That is, over 78 per cent of the total collected was levied on a basis which is especially burdensome to the farmer. The fact that so large a portion came from this source indicates its importance and demonstrates the fact that it will continue to be the major factor in the tax system of the States. If figures for individual States, particularly those where agriculture is of major importance, are examined it will be found that the general property tax plays a greater part in many of those States than it does in the country as a whole. In Georgia, Illinois, Louisiana, Oklahoma, and South Dakota it was responsible for from 80 to 85 per cent of the total revenue. In Indiana, Kansas, North Dakota, and Texas between 85 and 90 per cent and in South Dakota 94 per cent of the total revenue was derived from this source in 1922. In view of this importance it is desirable to find means by which this tax may be adjusted.

### Immediate Large Cut Not Possible

The actual amount of the general property tax depends on two factors, the assessed valuation of the property and the rate of the tax. It has been noted that the amount that must be paid by governmental units can not be subject to great or immediate reduction. In certain jurisdictions, however, some relief may be offered by a readjustment of assessments. The sole factor determining assessed valuations can not be income, but this factor should be given increased importance. Through a more flexible system of assessment some of the more striking injustices of the general property tax may be removed. This procedure is not without its dangers, but with intelligent and honest administration, subject to central supervision, it will adjust the burden of the tax more equitably.

Finally, there should be recalled the fact that taxes on agriculture are less likely to be shifted than taxes levied on other groups. The prices of most major agricultural products of the United States are determined on a world basis rather than on a local one. That is, the cost of production of the American farmer plays a comparatively minor part in determining the price he gets for his crops. Production costs of other countries as well as world demand play compelling parts in determining these prices. It follows that the American farmer is not usually able to add his taxes to the prices that he receives for his products and so shift his tax burden to other shoulders. The importance to agriculture of the tax problem is largely increased by this fact.

The primary needs in taxation, so far as agriculture is concerned, are economy of expenditure and readjustment of the tax system so as to reach taxable holdings other than general property and to distribute the burden more fairly among the groups in the States. As economy can not in most cases bring any material reduction in the total costs of government, the second portion of the program deserves increased emphasis. Highway construction must be recognized as a State rather than a local function and financed on that basis. Education, at least where State standards must be complied with, should be paid for in the same way.

## THE FARMER AND THE TARIFF

Many farmers believe that our tariff system benefits industry greatly and agriculture little or not at all. This is the idea behind the demand for legislation to influence farm commodity prices. Such legislation, say those who favor it, is necessary "to place agriculture on an equality with other industries in the matter of tariff protection." The same view of the tariff is held by many persons who disapprove of price legislation. These persons hold that the conditions under which the tariff operates make it practically tantamount to price fixing for the exclusive benefit of industry. They naturally conclude that economic justice for agriculture calls for a downward revision of the tariff.

It is usual to declare baldly, without any qualification whatsoever, that industry gets everything and agriculture nothing out of the tariff. This is obviously not the case. Many farm commodities enjoy effective tariff protection. Among them may be mentioned spring wheat in years when we have a short crop, flax, sugar, wool, butter, and even certain classes of livestock.

### Duties and the Farmer's Purchases

It is incorrect, moreover, to say that everything the farmer buys enjoys the benefit of tariff protection. Many articles bought by farmers are on the free list. This is true of agricultural implements and machinery, harness, boots and shoes made chiefly of leather, cattle and horses imported for breeding purposes, rough lumber, fertilizer materials, gasoline, binder twine, and numerous other commodities. On many other articles purchased by farmers the duty is principally nominal and ineffective. A typical example is the duty of 33⅓ per cent on furniture. This country has a virtual monopoly of the hardwood lumber supply of the world, and the efficiency of American machinery and labor enables the domestic manufacturer to produce and sell furniture cheaper than furniture manufacturers in any other country.

It often is contended, however, that even where an article extensively used by farmers is on the free list the tariff indirectly affects that article because of duties on raw products entering into its manufacture. Agricultural implements are most frequently cited in this connection. It is true that there is a tariff on pig iron, which is bought by implement manufacturers, fabricated, and used for manufacturing purposes. The tariff is, however, only 75 cents per long ton (2,240 pounds). The freight rate from New York to Chicago, near which the manufacture of agricultural implements is localized, is $9 per long ton. Pig iron, on the other hand, can be shipped from the mines in Minnesota to the Chicago district for less than $4 a long ton. Naturally, the Minnesota product is preferred because of the low transportation charges. The situation would be the same if the tariff on pig iron were removed; the $5 freight difference would effectually prohibit the use of the foreign product.

Still more significant, not only agricultural implements in whole but also in part, including repair parts, are on the free list. Hence the domestic manufacturer is exposed to foreign competition as soon as he charges prices sufficiently above the world price to make the American market attractive to foreign manufacturers. As a matter of actual recorded fact, the farmers of the United States, for the bulk of their farm machinery, pay lower prices than do the farmers of other countries.

Another example consists of automobiles. On these there is a tariff of 25 per cent ad valorem, and there are also duties on certain of the materials entering into their manufacture. Does this affect the farmer in his purchase of an automoble? Not at all. The United States, manufacturing more than 85 per cent of all the motor cars produced in the world, invariably undersells foreign manufacturers on cars of the types used by farmers. If there were no tariff on automobiles and no tariff on iron and other products entering into their manufacture, foreign manufacturers would nevertheless be unable to compete. The tariff on automobiles is a tax paid by the very wealthy who are willing to pay a high price for the privilege of owning cars built in Europe.

### All Items Not Balanced

Additional facts could be cited to show the fallacy of the general assertion that the farmer is wholly condemned " to buy in a protected market and sell his products in a world market." Those mentioned, however, will suffice. I am not concerned for the moment to prove that exact justice as between industry and agriculture is brought about by our existing tariff laws. So far as I know, all the items on both sides of the ledger have never been set down and balanced. I merely want to show at this point that the usual methods of condemning the tariff from the standpoint of agriculture are not to be relied on.

It is illogical to consider agriculture as a unit entity and to attempt to appraise the burden carried by this entity as a result of tariff duties on manufactured goods. The farm population must have its purchases segregated into producers' goods, or articles required in the business of farming, and consumers' goods, including the commodities used in all families. Since agricultural producers' goods vary from region to region and from crop to crop, it is misleading to consider them as a unit. If we are to appraise correctly the effects of the tariff on farm-production costs we must find out how it affects different crops.

Statistical material, crop by crop, is lacking for comparison between farm prices received and farm prices paid for producers' goods and for consumers' goods. I distrust comparisons between farm prices and wholesale index numbers. Our lack of comprehensive and trustworthy material on farm prices, incoming and outgoing, makes it difficult for us to define the extent of the disparity existing between farm costs and income. It is therefore impossible to determine to what extent farm costs and farm income are directly or indirectly influenced by the tariff.

### Benefits to Farmer Large

Nevertheless we can be quite sure that the benefits agriculture receives from the tariff are numerous and substantial. These benefits, moreover, are likely to increase, because our agriculture is moving definitely toward a situation in which many of its leading products will be on an import basis. Each year the tariff is becoming more and more effective for agricultural products. Tariff duties on farm products prior to the war were largely hypothetical. Now, with increasing population, with relatively declining farm population, with declining farm acreage per capita, and with increasing efficiency of farming, the tariff is becoming protective for crops formerly influenced mainly by the world market. Already it has become protective for premium products, such as representative flour wheats and other superior wheats. This has the advantage of stimulating the production of premium products and discouraging the production of low-quality products. Powerful forces are carrying us into a position in which the tariff will have its intended effect in the near future on a steadily lengthening list of important farm commodities.

Some examples of direct benefit obtained by agriculture from the tariff may be of interest.

### Butter Imports Cut Down

During the month of May, 1926, following an increase of the import duty on butter from 8 to 12 cents a pound, the imports of butter into the United States amounted to only 103,000 pounds, whereas in the same month last year the imports were 331,000 pounds. During June this year we imported only 100,000 pounds of butter, as compared with 579,000 pounds in the same month last year. The same story has continued in succeeding months.

The long-time trend of our trade in dairy products is definitely toward an increased net importation. The war interrupted this trend, but since 1920 it has been markedly resumed. In 1924 the net importation reached a high point equivalent to 750,000,000 pounds of milk.

Since the enactment of the emergency tariff in May, 1921, the annual average price of No. 1 dark northern spring wheat at Minneapolis has been from 16 to 27 cents a bushel above the level of No. 2 northern Manitoba at Winnipeg (two approximately comparable grades of wheat), except for a few months when our heavy 1924 crop, coupled with a light foreign crop, put us substantially on an export basis.

The United States is the heaviest single consumer of flaxseed. We import as much flaxseed and linseed oil as we produce. The import duty on flaxseed is 40 cents per bushel, which, with the drawback equivalent to some 10 cents per bushel to American crushers who reexport the cake, leaves an effective tariff of about 30 cents per bushel. The monthly average price of flaxseed during the last crop year (1925–26) ranged from 22 to 40 cents per bushel higher at Minneapolis than at Winnipeg.

Wool prices at Boston fluctuate widely relative to London prices, but during the last five years they have, on the whole, reflected fully the fact that we produce annually only about 300,000,000 pounds of wool and import annually considerably more than that amount. The case of sugar needs no illustration. Our flourishing beet industry of the West has been developed behind a protective tariff. Many other illustrations of tariff benefits to agriculture could be given.

### Tariff Should Fully Protect

Under our high-tariff régime, such tariff rates should be placed on farm products, article by article, as will insure the producer the home market. The experiences of recent years have convinced me that the system of basing tariff rates on differences in production costs is inapplicable to agricultural products. It is quite impossible to obtain trustworthy production costs, weighted either for the total crop or for the bulk of it. A certain cost of cultivation and overhead, a certain agricultural effort, may in one year be rewarded with twice the crop that is obtained in another year. Therefore, costs of cultivation can not be relied upon to indicate costs of crop units in a particular year.

In these circumstances I have little confidence in a method of tariff making for agricultural products based on supposed differences in production costs. The only method of setting up a workable and effective tariff for agricultural products is to do what used to be done decades ago for manufacturing industries, namely, to fix rates at such a height as effectively to give the home market to domestic producers.

There is little to be gained from a purely academic analysis of protectionist and free-trade theories in this connection. We have had a tariff so long that our agricultural and manufacturing industries have become as thoroughly adapted to it as they have to our conditions of soil and climate and agricultural resources. A rapid change from tariff protection to free trade would throw our entire economic life into chaos. What we need to study is how our tariff system works out in its distribution of advantages and disadvantages among various economic groups. If a tariff system is discriminatory as to various groups in our own population it should of course be modified. It is important to know, therefore, whether or not our tariff system is discriminatory, and, if so, in what direction and to what extent. Research along this line is, I think, highly desirable.

It is equally difficult to weigh the pros and cons of tariff protection by considering its effect on only a few commodities. The mere fact that the tariff law quotes a certain specific or ad valorem duty on an article does not necessarily mean that the price of that article is increased by the amount of the duty. On many articles the duty could be doubled or removed without affecting the price. This is due to conditions within the tariff wall. Pig iron and furniture, already cited, are illustrations.

### False Method of Reckoning

Nor can one decide that the farmer loses more than he gains from the tariff merely by estimating how much more he buys than he sells under protection. This method of computation rests on the false assumption that the price of the domestic product is always increased by the full amount of the tariff. A farm organization recently figured that the annual net loss to American agriculture from the tariff, based on the years 1917 to 1921, was $301,000,000. It estimated that the tariff in those years added $392,000,000 to the cost of farm products to all consumers and $1,323,000,000 to the cost of the products of all other industries to all consumers. It arrived at its estimate of the net loss to agriculture resulting from the tariff by making the wholly unwarranted assumption that the tariff was fully operative in every case.

### Data Not Broad Enough

Computations purporting to show quantitatively the extent to which farmers' gains from the tariff are offset by losses due to the burdens imposed on agriculture by the tariff on manufactured goods are invalidated, as I have already said, by lack of sufficiently trustworthy and comprehensive statistics. It is obvious that the tariff is not the only factor in the wage scales and labor costs of American industries. Allowance must also be made for the effect of restricted immigration. It is impossible, for the present at any rate, to measure separately the effect of the tariff and the effect of restricted immigration on farm costs and incomes. About all we can say with confidence is that few or no manufacturers are always able to add the amount of the tariff to the prices of their goods in the home markets. They are prevented from doing so either by domestic competition, or by the fact that consumers are generally able to protect themselves in some measure against unfair prices either by turning to substitutes for the overpriced article or by reducing their consumption of it. In the main the value of tariff protection to industry consists less in its effect on prices than in the advantage it gives in the home market. This is true of agricultural as well as of manufactured goods.

It will help us to estimate the significance of the tariff in relation to agriculture if we consider not only how it works now but how it is likely to work in the near future. There is no doubt that tariff protection is most effective on commodities produced exclusively for domestic consumption. When there is a large export surplus of any article, the price of that surplus in export trade tends to set the price for the domestic supply as well. This, of course, is a truism. Frequently, however, its full application to agriculture is overlooked. It is commonly assumed that agriculture is the only American industry operating largely in foreign markets. Manufacturing industry, with its supposed independence of world conditions, is believed to be getting the last possible ounce of benefit from the tariff, unaffected by the difficulty of disposing of its surplus.

### Need for Farm Protection Growing

This may have been largely true in the past. Even to-day industry does a smaller proportion of its business abroad than does agriculture. In the near future, however, the position may be reversed. American agriculture is moving steadily toward a position in which the home market will absorb more and more of its total production, whereas industry, on the other hand, is becoming increasingly dependent on export sales. In a comparatively short time agriculture is likely to have more need of effective tariff protection than industry.

A few figures will illustrate this significant tendency in our economic life. In 1901 our agricultural exports made up 65.2 per cent of our total exports. By 1913 the proportion had dropped to 43.6 per cent. There was an increase during the war to 50.6 per cent in 1919, but after the war the downward trend was resumed. In 1925 our agricultural exports dropped to 44.2 per cent of our total exports. In the year ended June 30, 1926, the proportion was only 40.6 per cent.

Meanwhile industry has been steadily increasing the proportion of its export trade. Alone among the great industrial nations the United States has increased the flow of its industrial exports since the war. Already we are exporting nearly 10 per cent of our manufacturing and mining output, compared with about 13 per cent of the production of our farms. Unquestionably, moreover, the volume of our industrial exports is destined to increase yet more. Industry has acquired an export surplus problem nearly as acute and difficult as that of agriculture. It is therefore less interested in the tariff than it formerly was.

### Tariff Should be Fair

It would be in the highest degree unwise for farmers at this time to launch an attack on the tariff without carefully considering the possibility that in the near future they may need it more than any other economic group in the country. I have said that I can not venture a guess as to where the balance of advantage lies between agriculture and industry at this moment in regard to tariff advantages. That is a point that can only be settled by detailed expert analysis of tariff schedules and commodity prices. I firmly believe, moreover, that in every possible way the tariff should be made equitable as between agriculture and industry. Nevertheless, I am obliged to dissent strongly from the doctrine that the tariff is of no benefit to the farmer at the present time; and I am still more strongly convinced that the relative advantage of tariff protection will swing definitely to the side of agriculture, as the dependence of our farmers on foreign markets grows less and that of our industrialists becomes greater.

On this difficult, complex matter it is idle to advance dogmatic conclusions. In the absence of data showing the incidence of the tariff on articles purchased by the farmer, no estimate is possible as to what the tariff costs him. It is likewise difficult to determine what tariff protection on flax, sugar, wool, dairy products, livestock, and spring wheat is worth to him. We know enough, however, to be on safe ground in rejecting the unqualified assertion that the advantages of the tariff are all on the side of industry. I feel, too, that we have equally good warrant for feeling confident that tariff protection will be increasingly important and, indeed, indispensable to agriculture in the near future.

### Insure Farmers the Home Market

What we should seek in dealing with the tariff on agricultural products is, as I have pointed out, to insure the home market, so far as possible, to the American farmer. He should have effective protection against foreign competition. As I have previously pointed out, labor to-day has, by means of the immigration laws, effective protection in this country. This is manifestly desirable. Among the chief reasons why the United States is better off than foreign countries are that labor is here paid well and that there is little unemployment. This is of direct benefit to agriculture. Even a very little reduction in food consumption per capita, which would come from lowered wages or unemployment, would speedily pile up bigger surpluses of farm products than have oppressed agriculture in recent years. Well-paid labor is thus of advantage to agriculture as affording a large consuming market of high purchasing power.

On the other hand, there is no doubt that the price of what the farmer buys is substantially increased by high wages. The precise effect of high wages on the prices of articles which farmers buy has not been accurately measured, nor for that matter has the exact effect of the immigration laws on protection for labor. We may say with confidence, however, that these items are considerable. Prices are materially higher because labor is well paid, and a principal reason why labor is well paid is that it is effectively protected by the immigration laws.

The remedy of the farmer is not to break down the protection for labor, as this would be disastrous to agriculture, but to seek by means of the tariff the same effective protection against foreign agricultural competition that labor has secured in its field by means of restricted immigration. To this the farmer is beyond any shadow of doubt entitled.

Assured the home market, the farmer may utilize it in the same way that labor has utilized its advantage; namely, by producing with greater intelligence and skill and by bargaining collectively, as I have pointed out in discussing cooperative marketing.

## THE CROPS OF THE YEAR

It will be useful to give here a brief review of the crops of 1926 as estimated by the department in October. Cotton and fruit, as already mentioned, were large crops. There was a good crop of wheat, a relatively short crop of corn, a production below the average of oats, rye, hay, and potatoes, and a production slightly above the average of barley, flaxseed, and beans. Crop yields per acre, in spite of early frosts in the Northwest and excessive rains in the Central States, approximated the average of the last 10 years.

Following a year of heavy abandonment, the area of winter wheat abandoned in 1926 was small, and the acreage harvested nearly one-fifth greater than in 1925. Yields per acre were above average and production was over one-tenth greater than the five-year average. Spring wheat, on the other hand, was adversely affected by drought in the Dakotas, yield was below average, and production was only four-fifths of the five-year average.

The total crop of all wheat was 840,000,000 bushels (October estimate), which was 174,000,000 bushels greater than in 1925 and 38,000,000 greater than the five-year average.

The 1926 corn crop of 2,680,000,000 bushels was 6 per cent below average and was reduced in quality by relatively early frosts and by excessive rains in the North Central States. Frost damage covered a smaller area and was less severe than in either 1924 or 1917, when the corn crop was severely damaged by killing frosts. The Southwest and Eastern States had relatively good crops of corn this year.

An oats crop slightly below average was produced on a slightly increased acreage in 1926. In October the production was estimated at 1,282,000,000 bushels. Extensive field damage at the time of harvest or after harvest affected a considerable portion of the crop, and the quality of it was materially below average. The barley crop is estimated at 197,000,000 bushels, which is slightly above the five-year average crop. Yield per acre was cut by drought and quality was lowered by rain after harvest.

The hay crop of 93,000,000 tons was 3,000,000 below the relatively short crop of 1925 and considerably below the average crop of 101,000,000 tons. Yields of clover and timothy and alfalfa were below average, particularly in the Great Plains from North Dakota to Kansas.

The 1926 cotton crop, from the indications of October 1, promised to be the largest on record. Acreage planted was the greatest ever known, and abandonment was only about average. The yield was fair to good in practically every State. Eight States this year each had a production in excess of a million bales. In 1914 and 1925, when 16.135,000 and 16,104,000, respectively, were produced, seven States each produced an excess of a million bales. In no other year have more than five States each produced more than a million bales. A late season was nearly made up by unusually warm, dry weather in September.

Flaxseed production was reduced by dry weather in the Dakotas. The crop was estimated at 19.5 million bushels, which was smaller than in 1925, but still above the five-year average.

The rye crop was less than two-thirds of average, owing largely to progressive reduction in acreage, but partly also to below-average yields.

Potato acreage was increased only moderately over the relatively small acreage of 1925. Yield per acreage was slightly above average and total production was 351,000,000 bushels. On the whole, the crop was well distributed, most surplus-producing areas having about an average quantity for shipment.

Production of sweet potatoes was 79,000,000 bushels, one-fourth greater than last year, but still slightly below an average crop.

Tobacco this year produced an average crop. Production of cigar-type tobacco was below average. Production of cigarette types was larger than average, but not above the trend of present consumptive needs. Pipe and chewing and export tobaccos were slightly below average, but for most types were somewhat above consumptive requirements.

The apple crop was estimated at 234,252,000 bushels. In only a few States was the crop exceptionally heavy, but production was above average in nearly all sections of the country, and the total crop was the largest in a dozen years.

The peach crop was large in all important States except Oklahoma. The crop of 67,242,000 bushels was about 40 per cent above the average and 5 per cent larger than the crop of 1915, which has been the record year.

The pear crop of 25,000,000 bushels was the largest on record. Grape production again exceeded slightly all previous crops.

Pastures were relatively short until the middle of August. Since that date they have improved greatly and provided unusually succulent fall feed.

Production of commercial truck crops in the aggregate was considerably below 1925, which was a year of generally good yields of these crops. Tomatoes and green peas for canning were particularly short crops. On the other hand, lettuce and spinach crops were large. Commercial truck crops, including early potatoes, made a total of about 7,300,000 tons, compared to 7,600,000 tons in 1925.

## THE WHEAT SITUATION

The world market outlook for wheat this year is better than it was last year, although domestic markets are not paying as much for some classes of wheat. Higher yields in many States, however, will more than make up in returns for the reduction in price per bushel as compared with last year for the United States as a whole.

Prospects are for a world wheat crop about the same as last year. Fortunately the increase in this crop in the United States is largely offset by a reduction in the European wheat crops. Whereas the wheat crop of the United States is 174,000,000 bushels greater than last year, European countries reporting to date indicate a production of nearly 130,000,000 bushels less than last year. Recent reports indicate that the estimates of several European countries are likely to be reduced as the final outturn of the crops become better known. Reductions in other countries have amounted to about 40,000,000 bushels.

Estimates received to date from 32 countries in the Northern Hemisphere indicate a total wheat crop of 2,944,000,000 bushels as compared with 2,939,000,000 bushels produced in the same countries last year. Reports from Russia indicate a crop about the same as last year and exports probably no larger than last year. It is too early to estimate the probable outturn of the crops of the Southern Hemisphere. Reports indicate that areas seeded are somewhat larger than last year. Seedings were made under generally favorable conditions. Average yields in Argentina and Australia would result in crops slightly larger than last year.

Although reports to date indicate a world crop, outside of Russia and China, about the same as last year, the market demand for wheat from these countries is likely to be stronger than last year. An increase in the demand from the Orient may be expected on account of poor crops in parts of Manchuria and China proper. The European demand is likely to be greater on account of a considerable reduction in the production of rye and some reduction in the potato crop. The estimates for rye in 24 countries in the Northern Hemisphere reporting to date total 838,000,000 bushels, a reduction of 143,000,000 from the estimated production of these same countries last year. The extent of the reduction in the potato crops of northern Europe has not yet been estimated but it will probably be sufficient to increase the demand for wheat.

### On Export Basis

Increased production has placed all classes of wheat in the United States this year upon an export basis. Considering the several different classes of wheat separately, it seems probable that the market for durum wheat will be better than last year. The north African wheat crop, a considerable percentage of which is of hard wheat competing directly with durum in the Mediterranean markets, is smaller than last year. Although it can not be ascertained from statistics to what extent hard-wheat production has been reduced, it may be assumed that the production of that class of wheat is at least no greater than last year. There has been a considerable reduction in the production of hard wheat in Italy, which will increase the demand for hard wheats from other countries. With no greater competition to be expected from Russia and some reduction in our own durum crop, the demand for this wheat should be stronger than last year.

The estimated production of hard red spring wheat appears to be just about equal to the amounts consumed annually in the United States. The market for this class of wheat, however, is at present approximately on an export basis, with the price at Minneapolis about the same as the price at Winnipeg. As long as supplies seem sufficient for domestic requirements our markets for this wheat will remain close to an export basis.

The effect of a shift from an import basis last year to an export basis this year is shown by the change in relation of price at Minneapolis to price at Winnipeg. The second week of September of last year, for example, the average cash close price of No. 1 Dark Northern Spring at Minneapolis was $1.59 as compared with $1.37 for No. 1 Northern Spring at Winnipeg, whereas, in the corresponding week of this year the price of No. 1 Dark Northern Spring at Minneapolis was only $1.46 as compared with $1.45 for No. 1 Northern Spring at Winnipeg.

### Exports of Wheat

From the 1925 wheat crop and carryover of old wheat on hand July 1, 1925, the United States exported 63,000,000 bushels of wheat, and flour equivalent to 45,000,000 bushels of wheat. For the manufacture of the flour exported, we imported in bond from Canada 13,000,000 bushels of wheat, and 2,000,000 bushels for domestic consumption on which duty was paid. Thus our net exports in the form of wheat, grain, and flour, amounted to the equivalent of approximately 93,000,000 bushels of wheat. In doing this, however, the accounted-for stocks of wheat were reduced by approximately 22,000,000 bushels between the beginning of the year, July 1, 1925, and the end of the year, June 30, 1926, thus reducing the exports from the 1925 production to 71,000,000 bushels of wheat and flour manufactured from domestic production. In the export statistics no distinction can be made between the new wheat and the old wheat, nor can the exports of flour be distributed by classes of wheat used in its manufacture.

The 63,000,000 bushels of wheat exported as grain may be classed about as follows:

| | Millions of bushels |
|---|---|
| Hard red spring | 10 |
| Durum | 21 |
| Hard red winter | 11 |
| Soft red winter | 3 |
| White | 18 |

A large part but not all of the exports of all classes except Durum was from the Pacific Coast States.

If we did not have a tariff, Canadian wheat would come over the line in greater quantities than it is now coming over, with prices as they are now. In other words our hard spring wheat is now receiving some degree of tariff protection. Winter wheat growers likewise benefit from the tariff. This is true even when the domestic price of wheat is not above the export level. But for the tariff, much wheat from Kansas would be displaced at Buffalo by wheat from Canada.

## THE DAIRY INDUSTRY

On the whole the dairy industry has been in a fairly strong position during the last year. A favorable spread between milk and feed prices has encouraged eastern dairymen. Their view of the situation has been shown in rather high prices paid for cows. Indications are that an increasing number of heifer calves are being raised. Many cows have been slaughtered in the East in antituberculosis campaigns. Conditions have perhaps not been quite so favorable for western butter producers, butter prices having shown relatively less strength than whole-milk prices.

An element of strength in the dairy situation has been a declining rate of increase in production. There was an increase in milk production in 1925 of only 2 per cent over the amount produced the previous year, compared with an average increase of 5 per cent in the last few preceding years. In the early part of 1926 there was a tendency for butter production to resume previous yearly rates of increase. This tendency, however, fell off as the year advanced. After the flush period of summer, the lead established in output was again lost. The trend toward lower production has tended to offset the effect of large stored surpluses.

The 1926 storing season opened with a rather heavy carryover. As the season advanced there was again a tendency toward the holding of a large storage surplus, corrected in part by the downward movement of production. A high record of holdings of butter in cold storage had been reached in the fall of 1924, when 156,000,000 pounds were reported in the warehouses. This situation resulted in large part from unusually favorable weather and pasture conditions. The accumulation, however, was cleared off before the opening of the season in 1925. Holdings of butter in cold storage on September 1 for the 1925–26 season were large (128,000,000 pounds), but they were not the result of an exceptional carryover from the previous season.

### No Foreign Competition

Foreign competition has not embarrassed our dairy industry this year as it did in 1925. Toward the end of that year the foreign situation exerted a depressing influence. There was a possibility of considerable importations of butter. In fact some foreign shipments arrived in spite of an 8-cent tariff duty. Although these imports were not large enough materially to affect the home market, psychological influences due to these imports and to the possibility of others remained in evidence until a change occurred in January in the foreign situation, as a result of which the prospect of substantial importations of butter disappeared. In April the tariff on butter was increased to 12 cents. Since that time butter imports have been of no consequence in the American market.

The dairy industry is not subject to extreme ups and downs. Its turnover is slow and its market relatively stable. Dairymen therefore rarely expect large returns. On the other hand, they are seldom without a fair income. This has been abundantly demonstrated during the last five or six years of agricultural depression, during which the dairy industry has been one of the bright spots in the farming situation. Observers do not expect conditions in the near future much more advantageous than the dairy industry is now enjoying, but there is no immediate prospect of any serious setback.

## EGG PRODUCTION

Egg production during the first two months of 1926 was much above that of 1925 and prices were materially lower. From March to September 1 production held only slightly above 1925. In that period the farm price of eggs was generally well maintained, at times slightly lower than last year, at times slightly higher. All in all, to date the gross return to farmers for eggs seems to have been slightly above that of 1925, which was considered a fairly satisfactory year. Moreover, purchased feeds, except wheat products, were lower than in the preceding year.

## THE LIVESTOCK SITUATION

On the whole the livestock industry prospered this year. Hogs, sheep, and lambs sold readily at remunerative prices. Wool prices declined during the first two-thirds of the year, but toward the end of the summer strength in foreign markets was reflected in the domestic market, and wool prices advanced sharply. The finished cattle market was the least satisfactory part of the livestock situation. More high-grade, heavy-weight beef was produced during the spring and summer than the consuming market could absorb at prices profitable to the feeder. The entire livestock situation can be summed up by saying that a greater tonnage of meat was produced than in 1925, and that the total supply returned to agriculture a somewhat larger amount of money. In other words, a greater quantity of meat moved into consuming channels at a higher average price.

Although finished cattle were not profitable, cattle production as a whole moved into a stronger position. All available evidence indicated a substantial curtailment in basic supplies of beef cattle. With continued industrial activity cattle prices should respond with substantial advances to the more favorable supply position. What happened in the finished cattle market during last summer, disappointing though the experience undoubtedly was to feeders generally, tended nevertheless, to strengthen the prospects of better times. The poor demand for fed cattle was strictly a temporary episode, resulting from the price situation of 1925 plus an abundance of corn. It did not change the fact that basic supplies of beef cattle in the country were at a low ebb.

### Improvement in Fall

There was improvement in the late summer and early fall market in 1926. In that period market receipts of cattle decreased slightly, and the prices of the better grades advanced from $1 to $1.50 a hundred pounds. There were indications, in short, that the temporary market glut was over and that prices were coming more into adjustment with the potential supply of cattle in the country in relation to the probable demand. It is therefore possible to speak of the cattle industry with confidence and optimism in spite of the fact that its returns in the last year have not been wholly satisfactory. The cattle industry has been through the fire since 1920. Of all the major lines of production that were plunged into the postwar depression, cattle production suffered, perhaps, most severely. Its difficulties continued long after producers in many other lines had begun to recover. But the range country has met its trials with courageous self-reliance.

### Cattle Inventory Reduced

Now, we begin to see daylight ahead. The country's cattle inventory has been gradually worked back into line with peace-time requirements—a process involving hardship for many producers and requiring skillful management. Liquidation of cattle has gone far enough to assure some degree of stability for the industry as a whole. The country is sold down very much shorter on steers than on cows. The trend in the market demand is toward the younger, lighter-weight, but high-quality animal. The outlook therefore appears favorable to the cattle raiser so far as the supply is concerned; but the situation has little in it as yet to justify anything but careful, conservative procedure.

Underneath the casual figures of supply and slaughter lies a deeper story of developments in the range country. The events since the war represent only one rather harsh chapter in a longer story of readjustment. We are going through a period of profound transition in the cattle business. The old days of the uncrowded open range are gone. With their passing has gone likewise the old unreckoning, easy-going, speculative scheme of things. We have moved forward into the day of high-priced land and labor, of heavy fixed charges, of stronger competition. We see a great new marketing development, a specialized system built up about the feed lots of the Corn Belt.

### Breathing Spell at Hand

This changing order of things may or may not be welcome. But it must be faced. This is a good time, moreover, to face all facts and take stock of ourselves—now, when the industry is stabilizing again, when a breathing spell is at hand and a favorable period apparently ahead of us. Never, in the judgment of shrewd observers, will the cattleman of this generation have so good a time to get his house in order as within the next five to eight years.

I am an optimist on the cattle situation. The tide has turned and better times are clearly ahead. But future stability in this industry depends greatly on how we utilize these next five years. The man who sees now only an opportunity to pursue an unreckoning, exploitive system will be lucky if he escapes trouble. But for the cattleman who is determined to build up a high-grade herd, to cut his unit costs, and to get his production on a plane of real and lasting efficiency it would seem that the opportunity of a generation lies just ahead.

One of the problems of commerce has always been to develop a common trade language, understood alike by buyer and seller. The department has worked out a set of standard market classes, grades, weight, and age groups for both cattle and beef which in all probability will be promulgated as official United States standards. We have used this system in the conduct of our market reporting service on livestock and dressed meats for the past seven years, and it seems to have given entire satisfaction.

### Western Range Problems

How to make the Western livestock industry more stable is part of the general agricultural problem of the country. No industry which uses the soil for production can be stable unless it is going to stay in the same place and unless the land that it uses is going to maintain its productiveness. Temporary land occupancy and declining range productivity have been outstanding features of western livestock production. The industry has had to move on before the settler, has grazed the open public domain on sufferance, has had to yield possession almost everywhere to those wishing the land for any other purpose, and has, broadly speaking, been confronted with a decline in the carrying power of its vast but diminishing and overcrowded ranges. Provision for permanent grazing use of such lands as will have highest value if employed in this way, for reasonable assurance to the individual stockman who is making use of the land that he will not be arbitrarily or unnecessarily dispossessed, and for insuring that lands employed for grazing will not lose their carrying power is necessary to give the range-livestock industry its fair chance at stable prosperity.

There are two possible ways to go about doing this. One of these is to let economic competition for possession of the land determine who shall have it, and enlightened self-interest solely govern the methods of use. Where the range is privately owned, this takes place. The traditional policy of the United States with respect to its public lands almost to the close of the nineteenth century assumed that private ownership was the best if not, indeed, the only way to get land rightly used. But the conservation movement brought another viewpoint. Under private ownership the right use of mountain lands, it was perceived, is not very likely to come about. Water, timber, and forage are too closely interrelated, and permanency of water and timber supplies is too important to other interests and industries to leave to chance. So some 90,000,000 acres of public lands suitable for grazing along with use for timber and water production are included in the national forests. On these lands the range livestock industry must be given a place, and its stable prosperity must be sought. But the way must be through enlightened public regulation and not by conferring of property rights to or in the land and then depending upon the play of self-interest and economic competition to determine how and by whom the land shall be used.

### New Law Sought

There is a certain degree of grazing use which these lands can be given without injury to timber growth, water flows, or the range itself. There are certain methods of use which make possible the largest returns to the users and to the community. Only as all of these questions are worked out and worked out right can regulation stabilize the western livestock industry along sound lines.

Primarily at the instance of the western livestock industry, the enactment of a law was sought this year defining the place of grazing in national forest management and providing greater assurance for the stockmen against unnecessary changes of administrative policy or arbitrary or unfriendly exercise of administrative powers. After protracted hearings by a Senate committee and full discussion of the subject with this department, a bill was introduced which in my judgment essentially provides what will best meet the real needs of the livestock men with respect to the national forests, and also tends to facilitate sound administration of the forests in harmony with their major purposes of timber production and water conservation.

The same bill made provision for regulated use of the open public range. There are about 180,000,000 acres of unallotted and unreserved public lands of so low value that no law permitting their private acquisition has ever been liberal enough to make patenting them worth while. Of these lands about 130,000,000 acres are grazing lands. That they have to a large extent lost their original carrying capacity, that further deterioration is extensively taking place, that under present laws deterioration is bound to continue, and sooner or later to reduce the grazing to no value at all, and that there is not only the physical waste of the resource but also the further waste due to faulty coordination with other resources employed in livestock production, has been again and again pointed out. In my report of last year I expressed my conviction that the existing policy with respect to land utilization on the public domain has had much to do with the recent troubles of Western agriculture, and called attention to the agreement of opinion among interested persons and agencies that a far-reaching change in that policy is imperative. For these lands enlightened public regulation offers not only the best hope of the livestock industry for more stable conditions, but virtually the only hope. I believe that the enactment of legislation to make such regulation possible is one of the important things needing to be done for the benefit of Western agriculture, and I hope that, in such form as may be found to be most appropriate, the general purposes embodied in the bill now before Congress may be carried to conclusion.

## LEATHER CONSERVATION

Plans for a nation-wide campaign to improve the quality of raw hides and skins used in making leather were outlined by the United States Department of Agriculture and approved at a recent conference by representatives of farmers, cattlemen, dairymen, butchers, hide dealers, tanners, and shoe manufacturers. Millions of dollars are annually lost to producers of the raw material and consumers of finished leather goods through imperfections in raw skins and hides which result from faulty skininng and curing, careless and excessive branding, and the effects of diseases and parasites.

An enormous quantity of leather is used in this country for shoes and harness, 300,000,000 pairs of shoes being bought each year at a cost of more than $1,500,000,000. Production of a better quality of raw material for leather making would avoid serious waste.

In line with the department's plan to eliminate waste and improve the quality of raw material, an advisory committee has been appointed to work primarily on the economic aspect of the several technical problems and to enlist cordial support for the campaign. Other committees will work on the problem of grubs, insects, diseases, and branding; on the problem of skinning and curing; on classification and marketing; and on statistics.

The elimination of grubs, ticks, and other insect pests, and the prevention and cure of diseases will pay the farmer and cattlemen well in increased milk and beef production. The department has long fostered such movements as a means of increasing the profits to livestock men. The leather industry and allied interests will add the force of their publicity and educational campaigns to encourage these practices, first as a means of producing healthier and more profitable livestock, and, second, to secure a better quality of hide.

### Loss From Cattle Grub

The loss due to the cattle grub has been estimated at from $50,000,000 to $100,000,000 annually, a loss which is felt by several industries. Dairymen have estimated that a reduction of 10 to 25 per cent in milk flow is often due to irritation by the grubs. The growth of young stock is retarded and their vitality is reduced through grub infestation, and cattle raisers and feeders suffer losses accordingly. Butchers and packers lose money on hides that have grub holes in them, hides with five or more holes in them being discounted, according to trade custom, 1 cent a pound. The tanning industry as a whole prefers grub-free hides. For certain uses a single hole in the hide makes it unserviceable. The grubs perforate the skin along the back of the animal, thus damaging the portion which is of the greatest value when the hide is tanned, and the extra handling of hides necessary in classifying them as to grubbiness is an economic loss.

Faulty skinning and curing are also responsible for great annual money losses, especially in those hides taken off and cured on the farm and ranch, or by town and country butchers. The department has repeatedly emphasized the fact that this condition can be remedied only by making it more profitable for these men to take more care in skinning and curing. Premiums for quality hides would be an incentive for more care. The practice of hammering down the price of a hide simply because of its " country " origin must be eliminated, if improved methods of skinning and curing are to become effective. " Flat " buying of country hides must go before general improvement can be brought about. It will be the duty of the committee on this subject to work out, through cooperation with the department and other agencies, practicable ways of improving the methods of skinning and curing in the country and to keep this information constantly before the public through the agricultural and trade press.

## SWINE PRODUCTION AND PRICES

Swine producers have enjoyed favorable conditions for the last two years. Although corn was high in price during 1925, hog prices for the most part showed compensating advances. The situation was still more favorable during the first eight months of 1926. Corn was then relatively cheap and hogs continued high. The average price of hogs slaughtered under Federal inspection during the first eight months of 1926 was 70 cents a hundred pounds higher than in 1925, and $3.80 more than the average price for the preceding three years. This favorable price situation was partly due to light supplies of hogs. Receipts at the principal markets during the first eight months of 1926 were approximately 3,250,000 head less than in 1925, and 10,250,000 less than the record run of 1924. The run, in fact, was the lightest for these months since 1917.

From the standpoint of the swine producer, the situation was even more favorable than the figures indicate. Pork production during the first eight months of the year, in spite of the decreased slaughter, exceeded production in the first eight months of 1925 by more than 108,000,000 pounds. This was chiefly due to the fact that the average live weight of hogs slaughtered was 18 pounds per head greater than in the previous year. In other words, swine producers in 1926 marketed much more pork and obtained considerably higher average prices than in 1925.

It is, of course, impossible to discuss the hog situation without considering the corn problem. An analysis of the present relationship between corn and hog prices and of the trend in hog production indicates that swine producers can not expect to maintain indefinitely their present degree of prosperity. Indications are that hog production will be substantially larger in the next year or two and that the increased production will be accompanied by somewhat lower prices. Swine producers should carefully measure the expansion of their operations by production costs and by the prospective demand for pork and pork products. Only in that way can they bring about a balanced situation in which hog production can be kept profitable.

## CORN

During the past year the farmers in the Corn Belt have had a surplus of corn. The price received by the corn producers of the United States for the crop year 1925–26 averaged only about 70 cents a bushel, the lowest since 1921, a year of extreme depression. This price is equivalent to only 45 cents on a pre-war price basis. The immediate effect of these low prices was greatly to reduce the purchasing power of the farmers who produce corn primarily for market. On the other hand, those who had hogs to feed profited by the large corn crop, and most farmers in the Corn Belt fed hogs or cattle.

Corn is not as easily exported as are other cereals; usually less than 3 per cent of the crop finds its way to foreign markets in the form of corn, and even in years of heavy production it seldom exceeds 5 or 6 per cent. Corn is finally exported, however, in the form of pork and pork products. About 18 to 20 per cent of the pork killed under Federal inspection is exported.

The effects of a surplus corn crop are usually felt in two different ways—currently by low corn prices, and a year or two later by an increase in the production of hogs, and consequently lower hog prices. To advise a farmer to raise more hogs because corn is cheap and hogs are relatively high is bad advice, for by the time he has raised more hogs to eat cheap corn, the hogs have become cheap and the corn high. The usual reaction of Corn Belt farmers is to do this very thing. Instead of planting less corn when corn is cheap and holding hog production down to a point where hog prices are on a fairly profitable level, the tendency is to plant about the same acreage of corn the next year and increase the number of hogs.

The production of 2,905,000,000 bushels of corn in 1925 was not the largest crop on record by 300,000,000 bushels. In fact, it was only 55,000,000 bushels above the 10-year average production, and the carry over from the 1924 crop was unusually small. The difficulty was not so much with the size of the 1925 crop as it was with its geographic distribution. Ordinarily about 65 per cent of the corn crop is produced in the 12 North Central States commonly spoken of as the Corn Belt. It is from about 9 of these 12 States that most of the surplus corn of the United States is shipped from the county where grown. Most of the remaining 39 States produce less corn than they use. When they are short of corn to feed, other concentrates are substituted and less grain is fed.

### Increased Hog Production Likely

It is now apparent that the abundance of corn in the Corn Belt with low prices is to be followed as usual by the production of more hogs. The pig survey of June, 1926, showed that farmers intend to materially increase their fall farrowings this year, thereby initiating the first stages of another cycle of increased hog production at a time when hog prices are not sufficiently above the level of the prices farmers pay for commodities to warrant any increase whatever. Corn acreage planted in 1926 was reduced less than 1 per cent. Although there is a larger carry over of old corn and prices are still very low, the worst of the corn surplus situation is probably passed, and it will be only a question of a year or two from this winter when a surplus of hogs will be the topic of the hour.

At this writing a corn crop for the present year of about 2,700,000,000 bushels is indicated. If this forecast is borne out, the crop will be about 7 per cent below last year's large harvest and 5 per cent below the average of the last five years. The demand for corn will probably be better this season than it was last, in view of the prospect that hog production will be increased, although exports of corn are likely to continue small. European demand for American corn has been restricted by the presence of liberal quantities of barley and oats on the European markets and also by the fact that a large surplus of corn has been available for export from Argentina. Crops of feed grains are good in Europe this year, and the competition of Argentine corn will undoubtedly continue.

## SHEEP

The sheep and lamb industry continues to prosper. Expansion of the industry has been going on during the last few years. According to the best available estimates, there were approximately 4,500,000 more sheep and lambs in the country on January 1, 1926, than at the low point of production, which was probably reached in 1922. This expansion has progressed steadily and in general has been conducted intelligently. During the process a fair proportion of each year's production seems to have been fed into the consuming market. Although, as is always true, lamb prices have fluctuated widely and sharply over short periods of time, average prices have been held at a level which has made possible sustained or increased consumption.

Market receipts of sheep and lambs during the first eight months of 1926 exceeded similar movements in 1925 by nearly a million head. Federally inspected slaughter, however, showed an increase of less than 400,000 head, the difference between these two figures being largely accounted for by increased movements of stocker and feeder animals back to the country. This tendency to relieve the pressure on the consuming market has maintained prices at a level which as a rule has compensated the producer for his efforts. The holding back of ewe lambs to increase breeding flocks has also had a tendency to keep supplies within bounds at market centers.

Early in 1926 lamb feeders were confronted with what promised to be a serious problem, arising chiefly from the fact that feeding lambs were generally heavy when put into the feed lots the autumn before and had done well during the winter. More heavyweight, fat lambs were available than the market could readily absorb at prevailing prices, and consequently the market broke rather sharply. A combination of circumstances, combined with efforts on the part of various market agencies and the Department of Agriculture, brought about a material increase in the consuming demand for lamb. Prices righted themselves to the extent that in June a sharp advance occurred, which carried top lambs well about the $17 mark.

### A 10 Per Cent Increase in Lamb Crop

A survey conducted by the department in June indicated an increase of about 10 per cent in the 1926 lamb crop as compared with that of a year earlier. This would seem to indicate a considerable increase in the number of lambs which will normally come to market during the latter part of the year. In all probability there will be a gradual lowering of the market price level as the effects of the expansion which has been going on during the past two years become apparent in materially increased market receipts. There seems to be little if any cause for anxiety, however, provided sheepmen conduct their operations in the light of probable future prices and costs, rather than with their attention fixed on prices which have prevailed in the past during periods of scarcity.

## THE COTTON SITUATION

The present statistical position of cotton indicates a considerable reduction in returns to growers for the crop now being harvested. The large crop of 16,100,000 bales produced last year yielded a return to growers somewhat less than the crop of the previous year, which amounted to only 13,600,000 bales. This year's crop, according to the October 1 forecast of 16,627,000 bales, is greater than that of last year, and stocks at the beginning of the new crop year were so much greater than at the beginning of last year that the total supply for the year is considerably larger than last year.

Prices to producers at the beginning of the season, as of August 15, averaged only 16.1 cents, compared with 23.4 cents last year, and have declined sharply since the beginning of the season. This decline in price brings the southern producers face to face with a cotton-surplus situation. Sixteen cents for cotton is equivalent to only about 11 cents per pound before the war, which is lower than the average price received for cotton in the period 1909–14. The recent low level of 12 cents is equivalent to only 8 cents before the war.

To realize the significance of this fact, it must be noted that there has been considerable increase in the cost of producing cotton on account of the boll weevil, which before the war had spread over only a part of the Cotton Belt. Last year, according to reports from 1,400 farmers in the Cotton Belt, the average cost per pound to producers of cotton lint was about 18 cents.

### Developments Not Favorable

Developments of the last year have therefore not been favorable to cotton growers. Two years ago supply and demand were nicely balanced and prices were satisfactory. Last year the final acreage harvested was increased 11 per cent over that of the year before and the season's crop exceeded the total consumption by a little more than two and a quarter million bales. This year the acreage in harvest is computed at an increase of 2.7 per cent over that finally harvested last year. Weather and insect conditions on the whole have favored the plant and another large crop has followed. This crop, estimated to be the largest ever produced in this country, is now moving to market at prices lower than those of any crop since 1921. Reliable figures on the cost of making the present crop are not yet available. There is little question, however, that present selling prices of cotton at the farm are less on the average than costs of production.

Last year's crop was notable for its unfortunately large percentage of low grades and its small proportion of high and medium grades. Opened cotton was exposed throughout much of the belt to early and prolonged rains and the damage to the quality was extensive. For a time these low grades were in little demand and could be sold only at large discounts. Fortunately, it was found under pressure of necessity, that in many of the mills certain of these lower grades could be satisfactorily substituted in part for some of the higher grades which had formerly been required.

It must be counted as fortunate under these circumstances that other conditions have favored large consumption of cotton. The world used last year, according to the best obtainable figures, some 13,800,000 bales of American-grown cotton. This is about a million bales more than were spun in the previous season and is the largest consumption recorded since the year 1915–16, when industry was striving to meet the necessities of the war. The present marketing

**season which dates from August 1, 1926, finds both exports and domestic consumption running larger than they were a year ago.**

### Compensation for Future

While on the whole the present season must be put down as an unprofitable and a disappointing one to the average individual grower, it may be possible after all to find in it some compensations for the future. By no means the least of these is the fact that the current price should and doubtless will serve to discourage the development and organization of cotton production in the newer cotton areas of the world and reduce as well the American acreage. In recent years, much effort has been put forth in other countries to establish cotton growing on a permanent basis. Although up to this time these endeavors have been notable for the rather negligible success that has rewarded them, they have suggested enough of future competition to attract some attention.

It is observed in periods of low world prices for cotton, that interest in the crop among the cotton growers of foreign countries rapidly subsides and that investment in ginning, handling, and transportation facilities necessary to the permanence of the industry is discouraged. Our crops of this year and last have dispelled much of our own fear of the menace of insects to the future of our cotton industry and stand as a demonstration to ourselves and to the world of the productive power of our Cotton States. One important effect of large supplies and low prices must inevitably be to expand the use and consumption of cotton. It is estimated that the products of cotton are now used for about 10,000 purposes. It seems reasonable to believe that at lower prices, the uses of cotton will be increased and its adaptation to new purposes encouraged.

### Place of Cotton in Export Trade

Cotton growing is the chief branch of agriculture in a large section of our country, and cotton is one of our great national assets, standing first in value among all of our exported commodities. The welfare of the cotton grower should therefore be guarded and fostered as a matter of wide national concern. On this view the department has continued to work. Intensive studies have been carried into the economics of the industry, with a view of learning the extent to which the consumption of our cotton may eventually go and of determining what types and varieties of cotton lie within the field of most profitable production. It has been possible to broaden and energize some of these lines of study by cooperation with southern agricultural colleges.

### Need of Low-Cost Production

A season of low prices enforces the lesson to the farmer of making his production of cotton as efficient and economical as possible by planting only in fields that will grow good crops at low cost and reducing other expenses by practical diversification. The high production costs are on the small crops, grown on land that should be used in other ways. It is estimated that the present volume of cotton production could be maintained on at least a third fewer acres by intelligent application of improved methods, with an enormous saving in costs of production. Farmers who produce economically may be disappointed in their profits but may escape positive losses, even at prices that are ruinous to less competent neighbors.

The possibilities of a fundamental reform of the system of cotton production have been recognized and demonstrated by the work of the department in cooperating with communities of cotton growers that limit themselves to the production of a single variety. In such communities many improvements of production are feasible that otherwise are beyond the reach of the individual growers.

In organized one-variety communities all of the farmers are provided with select seed of pure and uniform quality. From the use of pure seed larger yields are obtained, as well as fiber of better and more uniform quality that can be sold at higher prices. Through the production of commercial quantities of uniform fiber a constructive solution of the marketing problem is made possible. In such communities improved varieties and methods are adopted, and greater skill and efficiency of production are developed. The effects of different conditions and methods of handling the crop are better understood where farmers are familiar with the behavior of one variety, instead of continually changing the varieties, mixing the seed, and depreciating the product, as in unorganized communities. Such a policy, combined with proper diversification, should be adopted in many more cotton-growing communities. Business as well as agricultural organizations would find it to their advantage to promote the movement.

## PRODUCTION OF LONG-STAPLE COTTON

The marketing of the American cotton crop begins with its planting on the farm. Production and marketing are interdependent. The better the product, the more thoroughly it fits demand, the easier it is to market. The world demands good strong cotton of the American upland type, ranging from $\frac{7}{8}$ inch to 1$\frac{1}{16}$ inches in length of staple. We are not meeting this demand as fully as we formerly did. The production of short-staple cotton in the United States has been increasing, and the "bread-and-butter lengths"—the 1-inch, 1$\frac{1}{16}$-inch, and 1$\frac{1}{16}$ to 1$\frac{1}{8}$ inch staples—are becoming a smaller proportion of the crop. It is estimated that more than a million bales, or about 8 per cent of the crop produced last year, consisted of cotton less than $\frac{7}{8}$ inch in length of staple. Manifestly this is not desirable.

Economic pressure on the large cotton-consuming countries has induced them to encourage the production of medium-staple cotton in countries other than the United States. Brazil, for example, is pushing her cotton enterprises. There is, however, no need for immediate alarm over this fact. The Brazilian people need more cotton for their own use. Moreover, there is every probability of an increased demand for cotton throughout the world with the return of prosperity in Europe. At the same time it should be frankly recognized that an increase in the production of good upland cotton in foreign countries will make the production of excessively short-staple cotton in the United States less and less remunerative. Our opportunity lies in adjusting the quality as well as quantity of our output to the world's needs. This applies to cotton just as it does to every other product.

### Quality is Important

Under modern conditions quality is exceedingly important. In every field of agriculture or industry quality goods—goods that exactly meet the public demand—can ordinarily and should bring a premium. European consumers have complained recently that there has been a falling off in strength and uniformity of American cotton—in short, that it lacks some of the quality that they want. There is a belief that the introduction of the small-boll, quick-maturing varieties, high in per cent of lint, is the main cause of the difficulty. These varieties, from the standpoint of lint percentage, may have an advantage as to yield. It is not at all certain, however, that they yield more lint per acre than varieties having a good inch staple. An example to the contrary was recently brought to light when a Southern newspaper announced that the winner of its "more cotton on fewer acres" contest had grown in excess of sixteen 500-pound bales on 5 acres of land, and that the staple of the cotton was $1\frac{1}{16}$ inches. Furthermore, plant breeders have developed varieties of good medium staple that give yields equal to or superior to the varieties producing extra-short staple. They are also equal in earliness of maturity.

The boll weevil, against which our cotton farmers have waged so valiant a fight, need not put an end to the production of long-staple cotton. The development of new early-maturing varieties and the discovery of improved cultural methods of shortening the growing season are making it possible to produce excellent crops of long-staple cotton in the presence of the boll weevil. Indeed, there are additional reasons for growing long staples under weevil conditions. The care and precautions that are required to protect cotton against the weevil also make it possible to produce a better staple. In growing long-staple cotton the growers may find compensation for the increased cost of production or the diminished yield that may be caused by the boll weevil.

### Farmer Not Encouraged

The main reason why the less desirable varieties are grown in large quantities is that the average farmer can not sell better cotton for a better price. The principle that quality goods should bring a premium has been overlooked in cotton buying, so far as the average farmer is concerned. There is a substantial difference in value between a bale of ¾-inch cotton and a bale of $1\frac{1}{16}$-inch cotton. In the hands of a shipper this difference may be $15 or more. Growers who sell their cotton in small lots at country markets, however, often can not obtain any better price for medium than for very short-staple cotton. Good staple and poor often sell for about the same figure, which is based upon the average quality of the cotton sold at the primary market point. Under such conditions the grower has no incentive to produce superior cotton. Indeed, the situation tends to curtail the introduction of new methods, practices, or varieties by the farmer. When the same price is paid for good as for poor fiber at the primary markets, the progressive farmer is penalized and the short-sighted farmer is benefited.

The Department of Agriculture has done what it could to discourage the planting of varieties which yield the very short staples. But the remedy requires the attention of cotton buyers quite as much as that of cotton growers. A marketing system which penalizes the production of better varieties of cotton should obviously be modified. The only secure basis for our cotton industry is in the improvement of the product.

### Cash for Quality Necessary

There is no way to improve the product except by furnishing cash encouragement for quality. Discrimination in buying is just as important as high prices. Upland long-staple cotton brings from 30 to 60 per cent more than middling short staples. Farmers who produce the long-staple kind should in simple justice be rewarded proportionately. It is useless from the standpoint of encouraging quality production merely to get manufacturers to pay more for good fiber. The premium for superior fiber must go back to the farmers. Community production of better cotton would go forward more rapidly if farmers were sure of better markets for good cotton than for short fiber. It is in the interest of the cotton trade to give them this assurance.

## THE PRINCIPAL FRUITS AND VEGETABLES

Bumper crops of nearly all fruits were the rule this year, with quality very good. In October it appeared that the commercial apple crop would amount to 38,500,000 barrels, the heaviest commercial production on record. Western States were expected to have the equivalent of some 14,600,000 barrels, or about 1,000,000 more than the year before, while Eastern and Midwestern producing sections seemed to have about 23,900,000 barrels, an increase of 4,900,000 over the 1925 crop. Record crops were anticipated in the leading States, Washington and New York. Wide distribution was being given the apple shipments.

The peach crop was estimated in October at around 67,000,000 bushels, slightly above the previous highest record established in 1915. Production was about 44 per cent greater than the 1925 crop and than the average for the last five years. Georgia growers had difficulty in obtaining average returns above the cost of production and preparing the crop for market. Shipments from that State reached the unprecedented total of 17,500 cars. California canneries put up a record pack of this fruit.

The pear crop of 25,000,000 bushels was far above average and at least 25 per cent heavier than the year before. Grapes were expected to break all previous records, with a total of 2,360,000 tons. More than the usual quantity of the California product was dried. Not only was the California crop vastly increased, but eastern grapes came back with a heavy yield after the short production of 1925. The Ozark grape region is becoming of commercial importance.

Potatoes did somewhat better than last year, but a total crop of 351,000,000 bushels, as indicated in October, would still be 45,000,000 less than the five-year average and 74,000,000 bushels below the exceptionally large crop of 1924. Per capita production appeared to be around 3 bushels, which is below normal requirements. Acreage was increased only about 2 per cent, and average yields of 108 bushels would be very little better than the average for the five years, 1921–1925. The midseason potato supply was heavier than in 1925, when drought reduced the crop, causing this year's prices for a few weeks to be lower than those of the preceding season. It is hardly expected that the extremely high returns of 1925–26 will be repeated this season, even though the main crop is moderate.

### Sweet-Potato Production Greater

Sweet potatoes were coming back to normal after several years of light production. October estimates indicated 79,000,000 bushels, which would be a crop of little above midway between that of 1925 and the five-year average of 84,000,000 bushels. Improvement was noted in practically all the States which lead in the production of sweet potatoes.

More main-crop onions and cabbage were being produced than the year before. Midseason cabbage and onions, however, found a very dull market, partly because of the abundance of home-grown supplies. Melons were a good crop, but prices were unusually low. Cantaloupes produced well except in California, and such truck crops as lettuce and celery were increased. It is questionable whether greater production of lettuce can be marketed with a profit to growers. Car-lot movement of 38 fruits and vegetables during the calendar year 1925 filled about 980,000 cars.

## FOREIGN MARKETS

Foreign demand for some of our agricultural products was stronger in the fiscal year 1925–26 than in the preceding year, while for other products it was somewhat slack. The value of the exports of agricultural products, excluding forest products, was 17 per cent less than for the previous year but remained larger than in any other year since 1920–21. On the basis of 1909–1913 prices, the volume of agricultural exports declined 20 per cent.

The agricultural share of our exports of the last fiscal year was the lowest in our history except in the war years 1916–1918. In value the exports of agricultural products exclusive of forest products amounted to somewhat less than 41 per cent of all exports, compared with 48 per cent last year and 32 per cent in 1916–17, the lowest previous record.

The reduction in volume of exports in the past year was due largely to a short wheat crop and to a greatly reduced production of pork. Our wheat crop was so small that our exportable surplus was greatly reduced. Large crops of feed grain in Europe and cheap corn from Argentina reduced the demand for our feed crops so much that we exported only 23,000,000 bushels of corn, at an average value of 92 cents a bushel, out of a very large crop.

Having reached the low point in a hog-production cycle, our exportable surplus of pork products was likewise considerably reduced. The exports of bacon and ham from the United States declined considerably in volume but the value of the shipments was fairly well maintained. Declines were registered in the exports to practically every important market and particularly in the shipments to the United Kingdom. Lard exports also showed marked declines. Shipments to all important European markets fell off, but Latin-American countries, which are assuming more importance in our lard trade, all took larger quantities except Cuba.

The demand for cotton was not so good as last year. The exports were 227,000 bales less at a price so much lower that the value of our exports of cotton was only $918,000,000 compared with $1,061,000,000 the previous year. Had Japan not come into the market and taken a much larger quantity than usual, there would have been a considerably larger reduction in foreign takings. Depressed economic conditions and a weak export market for cotton goods considerably reduced the demand in the United Kingdom and Germany.

### More Tobacco Exported

More tobacco was exported from the United States at higher prices last year than in 1924–25. The increase in the volume and value of the exports of bright flue-cured tobacco, the principal cigarette type, was particularly noteworthy. This type last year made up over 60 per cent of the total exports of leaf tobacco. The United Kingdom continues to be the leading market for American leaf tobacco, taking 35 per cent of the shipments from this country last year, while China was the next largest market taking 18 per cent. The increase in the shipments of cigarette types of tobacco to China is the feature of the United States exports of tobacco.

Fruit constitutes the only important class of agricultural products, outside of tobacco, to show any appreciable increase in exports during 1925–26 over the preceding year. The total value of the fruit exports, including fresh, dried, and canned, was $105,000,000 last year as compared with $85,000,000 in 1924–25.

In spite of unfavorable conditions in the United Kingdom, the principal market, the exports of apples from the United States showed an appreciable increase over the preceding year. This increase in volume and value of exports seems more remarkable considering the fact that in England there was a large amount of publicity charging excessive arsenic spray residue on American apples. This accomplishment in the face of agitation against American apples must be attributable in part at least to the diligent work of the department's representatives in the principal European markets. By keeping in touch with the market and keeping European importers informed concerning American supplies they were able to minimize the agitation against American apples. They were able at the same time to convey to American growers' organizations and exporters the critical necessity of taking double precautions to ship clean fruit abroad.

### German Market Improved

Market conditions in general are improving in Germany and the immediate outlook for raw cotton and foodstuffs is better than it has been at any time since the war. The improvement in the German market for dairy products is a very important factor in the world's dairy markets. In the past year Germany has taken, and is continuing to take, large quantities of Danish and Siberian butter. This has been an important factor in keeping foreign butter from our markets. Denmark is finding a better market in Germany near at hand than in New York after transportation and duty. Australia, New Zealand, and Argentina are finding outlets in England for their butter, at prices better than they could receive in New York after paying the duty, because British markets are being relieved of considerable amounts of Danish butter which has gone to Germany.

Conditions of foreign demand in other countries are in general about the same as last year. England is still experiencing a depression on account of the coal strike. Recovery of general prosperity and purchasing capacity will necessarily be slow. Economic conditions in France, Italy, and many of the smaller countries are unsettled. Efforts of the Governments in France, Italy, and Belgium to strengthen the currencies, if successful, may be expected to improve prosperity in the future, but may result in a temporary check upon business activity, and hence a temporary restriction upon those markets for American raw cotton and foodstuffs.

### Larger Exports

The United States is producing this year larger exportable surpluses of wheat, cotton, and apples. Whereas last year our net exports of wheat, including flour, amounted to only 93,000,000 bushels, we are likely to have available for export this year nearly 200,000,000 bushels of wheat. We need foreign markets for a considerable part of the increase of 27,000,000 bushels in our commercial apple crop, as also for the increase of more than a million bales in our cotton crop. Fortunately for our farmers, Europe exclusive of Russia, according to latest estimates, is harvesting a wheat crop 140,000,000 bushels less than last year and a rye crop 131,000,000 bushels less than last year. The north African wheat crop is also 14,000,000 bushels less than it was last year. It seems, therefore, that the foreign demand for our wheat will be better than it was last year. Although favorable conditions in the Southern Hemisphere to date indicate possibly greater competition from that source, we ought to be able to dispose of our exportable surplus of wheat without depressing the world wheat market.

Some reduction in apple production in northern and northwestern Europe has left a market for more of our apples. Reports to date indicate that the foreign production of cotton may be less this year than last, but not sufficiently less to effect a material increase in the demand for our cotton. In fact, we produce such a large proportion of the world's crop that the size of our crop practically dominates the world market.

Prospects for European markets for corn, oats, and barley as feed grains are not so good as last year. Europe has harvested a large crop of oats and is harvesting a fairly good corn crop. Adding the three crops together, the present prospects are that Europe exclusive of Russia will have an increase of at least 5 per cent in the tonnage

**of these crops. Argentina is planting a new corn crop and it is too early to determine how much competition one may expect in the European markets from this source. The crop that was harvested there last April and May was the largest that that country had produced since 1914, and some of that crop will compete with this fall's United States crop in European markets.**

### Pork Production Stimulated

Larger feed-grain crops and consequently lower prices will undoubtedly stimulate an increase in pork production in Europe just as last year's large crop is inducing farmers to plan to produce more hogs in the United States next year. Conditions for marketing our pork products in Europe should remain favorable for a short time, but increased pork production in this country is likely to be met by increased competition in foreign markets.

The total foreign trade of the United States in dairy products has been declining since the abnormal trade of the war period, in spite of a steady increase in domestic production. Figures for the year ended June 30, 1926, indicate a continuance of that decline and also illustrate the tendency of imports into the United States to exceed exports by an increasing margin. This situation, however, is always open to the possibility of being reversed with the acceleration of the tendency toward increases in domestic production. While world production since the war has increased continuously up to the record year of 1925, demand during that year and in 1926 has been sufficiently well sustained to keep world prices of dairy products at relatively high levels.

In general it may be said that there is no immediate prospect of a weakening in foreign competition in agricultural production. Production in Europe is steadily recovering from the effects of the war, while expansion in Australia, Argentina, and Canada continues.

## OUTLOOK REPORTS

A demand among farmers for more complete and up-to-date economic information led the Department of Agriculture in 1923 to begin preparing and issuing statements on the outlook for the production and marketing of the principal commodities. These reports met with such a favorable reception that the work has been expanded and made a regular part of the program of the department.

In February of each year a comprehensive report is prepared covering the outlook for all the commodities on which sufficient information is available. During the summer of each year special reports on the outlook for hogs, sheep, and cattle are prepared and a report on the outlook for wheat production is issued just prior to the time of planting winter wheat. The general report on the agricultural outlook for 1926, issued in February, contained statements on 31 different commodities, in additon to statements on the domestic and foreign demand situation, agricultural credit, and farm labor and equipment. This report covered a greater number of commodities than any of the reports that had been issued up to that time.

Necessarily, the outlook reports present a national point of view. They should be carefully considered by producers in every region to determine whether the general suggestions given apply to a greater or lesser extent to that region. In making his plans each farmer must bear in mind not only the probable conditions of the market and the prices he may expect for his product, but also the possible lines of production in which he may safely engage considering the conditions under which he is farming and the characteristics of his own farm. Both the requirements for production and the probable returns from the product should be considered in making decisions as to what to produce and how much to produce.

### Blanket Recommendations Useless

Since conditions vary widely in different parts of the country, no blanket recommendation applicable to all the producers of a given commodity can be made in statements which present the national point of view. If the outlook for the production of some commodity is good, it does not necessarily follow that all the producers of that commodity would profit by increasing their production. Neither does it follow that it would pay all the producers of a particular commodity to curtail their production when the outlook is for a lower demand or increased supplies from foreign countries.

For this reason many of the State colleges, through their experiment stations and extension services have adopted the plan of preparing and issuing statements for farmers within their field. These statements are based in part on the department's report and in part on the possibilities of producing the different commodities within the State concerned.

Twelve of the State colleges sent representatives to Washington in February of this year to be present at the time the annual outlook statements were being prepared in the department. These State representatives thus became thoroughly acquainted with all the information which formed the basis for the outlook statements and were in position to prepare localized statements more directly applicable to the conditions within their States. It is hoped that all of the State colleges will be in position to send representatives to Washington to be present at the time of the preparation of the outlook reports for 1927 and subsequent years.

### Reports Widely Distributed

The general reports of the department and the more localized reports of the State colleges are made available to producers by all known means of dissemination. Two hundred thousand copies of the report on the outlook for 1926 were mailed direct to farmer correspondents of the department within 10 days after completion of the report. Advance copies were sent to all of the farm papers in the country and condensed statements were furnished to the press and transmitted over the radio. The extension forces of the State colleges disseminate the information through their publications and through local meetings of farmers, at which the reports are presented and their application to the particular locality discussed. These reports have been of great value to cooperative marketing associations. Many of these associations have been active in disseminating the reports among their members.

The general outlook report issued in February is followed by a report on farmers' intentions to plant spring crops. This information gives producers an opportunity to make adjustments in their plans should there be a tendency to overplant or underplant particular crops. A report on intentions to plant fall crops is issued in August. Frequent surveys of breeding intentions with regard to specific classes of livestock are giving producers more information upon which to base their plans.

### Outlook Crop Forecasts Accurate

Considering the recent development of this work and the lack of complete information on many points that must be considered, the conclusions presented in the outlook statements have been remarkably accurate. In even the earliest reports nearly 90 per cent of the outlook statements on individual commodities turned out to be correct, and in the 1925 report and the 1926 report subsequent events proved that more than 95 per cent of the statements were correct.

It is the intention of the department to expand this work so as to cover a larger number of commodities, to concentrate on the collection of more economic information and further analysis of statistical data needed to furnish a better basis for subsequent reports, to obtain wide dissemination of the reports, and to assist the State colleges in every way possible in preparing and disseminating localized statements that apply especially to the farmers in different areas and regions.

## AGRICULTURAL READJUSTMENTS

Because of continually shifting conditions with respect to the production of and demand for particular commodities, careful studies are made by the department as a basis for assisting farmers in interpreting the significance of these changes. During the last year numerous studies have been conducted in Louisiana, southern Mississippi, New Hampshire, Kansas, and Idaho with a view to providing local farmers with a more adequate basis upon which to plan their production and marketing programs. In all of these studies attention is given to the adjustment of farming to meet the needs of local markets in order that emphasis may be placed upon those lines of production which are more profitable than others. Markets outside the area studied are also considered, and the necessity of keeping production in line with market requirements as to quality and quantity is pointed out.

A study in Louisiana and southern Mississippi brought out the fact that the agriculture of the New Orleans trade territory is now in a transitory stage of development away from highly specialized cotton, sugar-cane, and rice plantations. This transition is of necessity slow but it is enabling small farms to be better able to withstand depressions. The survey also indicated that a profitable increase of cotton production would result from a greater use of the richer delta and bottom lands for the crop and the use of some of the worn-out hill lands of the State for reforestation and grazing purposes. It was shown that there is need for considerable improvement in cotton-marketing methods. Market facilities for handling fruits and vegetables produced on farms in the region studied are inadequate, and this situation, together with insufficient market news, is responsible in part for the failure of local farmers to produce a larger portion of the food products consumed in New Orleans.

In a similar study for New Hampshire it was found that local producers could profitably expand the production of some commodities, such as potatoes, provided they were grown in acreages sufficiently large to make the use of efficient machinery and production methods possible. The possibility of producing more commodities for the use of the summer hotel and tourist trade was pointed out. In cooperation with local agencies, similar studies have been made in other States. A study of dairy farming in the Shenandoah Valley of Virginia emphasized the fact that the incomes of dairy farmers in that area can be materially increased by keeping cows with more dairy blood, by feeding better-balanced rations, and by modifying cropping systems so as to produce the roughages needed by dairy cows and increase the crop production per acre without additional expense. I need not emphasize the value of such studies in revealing neglected opportunities.

## THE PEACH INDUSTRY

One of the most difficult problems in adjusting agricultural production is involved in planting tree fruits. In order to put before producers of the country the facts regarding bearing and nonbearing trees, commercial varieties, competitive districts, price trends, and costs of production, the department with the cooperation of State agencies recently made a survey of the commercial fresh-peach industry of the United States. This study included 26 different States, and reports as to the age and variety of peach trees in commercial orchards were received from about 21,700 growers located in all the important producing regions.

In 22 commercial peach-producing areas in 12 States the cost of developing peach orchards by the usual methods followed was determined. The costs of producing peaches and the usual methods and practices in producing peaches in most of the areas were also ascertained. The selection of proper varieties was found to be an essential factor in the development of a successful commercial peach orchard. Costly mistakes have frequently been made by growers in planting varieties which were not adapted to their market conditions. In some instances it has been found advisable to remove or top-work trees because the variety was proving unprofitable.

While many varieties of peaches are grown for marketing as fresh fruit, only a relatively small number of these were found to be of widespread commercial importance. The Elberta, by far the most important variety east of the Rocky Mountains, is grown in practically all commercial districts. Other varieties which are of commercial importance as fresh fruit are Carman, Hiley, and Belle. These mature earlier in the season than the Elberta. Parts of the information obtained in this study have been used by several States in preparing State publications on this subject. This study of the peach industry brings out conclusively the necessity for peach producers to make preparations for disposing of an increased production of peaches during the next few years.

## MARKET NEWS

Use of market news economic information by extension workers continues to grow rapidly. More than a dozen States now have well-organized economic services, to which the department supplies a large volume of fundamental information. The demand from the news press, farm papers, farm organizations, and radio-broadcasting services has likewise increased.

The department's 7,500 miles of leased telegraph wires is the chief means of transmitting information between the various branch offices to Washington and from one branch office to another. This information includes shipment reports, arrival and price data, and statements regarding local conditions in producing sections and terminal markets, and other valuable facts. The information is compiled and given wide publicity from Washington and the branch offices and field stations by means of mimeographed reports, radio, telegraph, telephone, bulletin boards, and the press. The products covered by daily telegraphic reports include 34 of the most important fruit and vegetable crops of the United States.

On fruits and vegetables alone the total number of mimeographed market reports distributed during the year from Washington and the branch offices was approximately 12,150,000—an increase of 12 per cent over the preceding year. A constantly augmented demand for these reports as a basis for settling railroad claims testifies to their accuracy. The mimeographed reports also furnish a basis for statistical studies and research work. Many dealers and shippers maintain complete files of the reports for reference.

In providing market news on livestock 16 branch offices are maintained. At the close of the year preliminary arrangements had been made for opening 6 new offices, made possible by an increase in the appropriations at the last session of Congress. These offices will be located at Buffalo, Cleveland, Pittsburgh, Cincinnati, Indianapolis, and St. Joseph. They will enable the department to serve a large group which heretofore has been served only partially and indirectly.

### Scope of Service Widened

Approximately 5,000,000 mimeographed reports dealing with market news on livestock were distributed during the year to subscribers in all parts of the United States and in a number of foreign countries. This represents a material increase over the distribution of such reports in the preceding year despite the fact that market reports are broadcast by radio and disseminated by other agencies. Everything is done to keep the mailing lists at a minimum. Daily wool-market reports are distributed to the press, and to cooperative associations and other interests which give the reports distribution through their own publications.

The grain and hay market news service has been made more effective by timely compilation of the market statistics necessary for the proper understanding and interpretation of the constantly changing conditions in the grain and hay markets. Contacts for the collection of market information have been extended so as to cover all of the important United States markets. Probably the most important of these reports received are those giving a summary of the week's developments in the grain and hay markets. These are forwarded from all markets by telegraph on Friday and used in the preparation of the weekly grain and hay market reviews issued each Saturday morning. At the close of the fiscal year ending June 30, more than 300 newspapers with a total circulation of over 5,000,000 were publishing the reviews regularly.

## PRESS SERVICE

New information on the science and economics of agriculture is continually being gathered by the department through research and study in field and laboratory. Such knowledge would be of little value to the public were it not made available for wide practical use. Early and wide dissemination of agricultural news is facilitated by the department's press service, in the Office of Information, which maintains "open house" to all press representatives, editors, and contributors to all kinds of publications using agricultural information. This results in reaching practically all of the 22,000 or more publications—daily newspapers, weekly and semiweekly newspapers, farm journals, trade and technical magazines, and miscellaneous publications—in the United States, and in ultimately reaching millions of readers. Serving the wants of the writers who call at the press service headquarters results in the featuring of much agricultural information in articles of length and comprehensiveness, many of them illustrated.

Information of strictly a news nature, relating to the agricultural situation, regulatory measures, or scientific developments, is made immediately available through the department's press service to some 200 press representatives in Washington, and also is mailed in mimeographed form to all interested publications. Stories of this kind for the year totaled more than 800. In addition, there were 110 restricted or exclusive releases, some of them prepared in response to special requests from editors and contributors to the press.

Supplementing the news releases is the printed weekly "Clip Sheet," which carries stories of timely information on agricultural practices, progress of research projects, and other news of department activities. This service is mailed to more than 12,000 publications serving a large circulation, most of which is rural. More than 250 special stories of like nature, with photographs, were prepared for syndicate services supplying a large number of papers.

### College Editors Help

Particularly satisfactory results have come from the maintenance of close contact with the agricultural college editors who, through the use of much department material in their State releases, have spread information on the department's work.

Toward the end of the fiscal year a special information service was begun for country weeklies under the title, "Page, line, and paragraph." It consists of useful and seasonal information on agriculture and home making in articles varying in length from one line to a typewritten page. It goes each week to 7,000 weekly newspapers. That this service is well received and fills a long-felt need is shown by the large number of commendatory letters received from editors and clippings from papers sent to the press service.

Agricultural news is regarded by the press as of increasing importance, and more and more space is being devoted to it. This is a healthy sign. The steady appetite for material on the department's work is indicated by the number of clippings taken from newspapers, farm journals, general magazines, and trade publications, only about 600 of which are sent to the press service. The number of clippings of all kinds runs usually from 2,500 to 3,000 a month, and has gone as high as 4,000.

## RADIO

Early in 1926 the number of rural radio sets in the United States reached nearly 1,000,000. To furnish the users of these sets with timely agricultural information, the department has inaugurated a comprehensive radio program covering the full range of its activities. A new section in the Office of Information, known as the radio service, has been established to originate programs; to make contracts with commercial stations as an outlet for these programs; and to adapt timely subject matter for radio presentation. Ninety broadcasting stations, representing every section of the country, lend their facilities regularly to the department for an average of half an hour daily.

The department's farm programs are brief digests of the most timely, pertinent facts woven into story form, and covering a wide range of topics. The fall and winter broadcasting schedule of the radio service includes 20 special program features each week. The United States Radio Farm School, which has already brought requests for a half million enrollment cards, is conducted from 25 stations. Lessons take the form of experience talks and imaginary inspection tours. Radio " schoolmasters " at the different stations conduct the classes. All lesson material is dramatized so as to catch and hold the interest of the listeners. Printed lessons are mailed to all enrolled students.

Another outstanding service, released from 50 stations, is called " Noonday Flashes." This program enables a million farmers to listen in daily on a conversation between a county agent and a farmer who discuss current problems. "Aunt Sammy," a new radio friend and neighbor for the 5,000,000 farm women of the Nation who have an opportunity to tune in, is heard from 40 stations. The service known as the " Housekeepers' Chat " is a 15-minute period devoted five days a week exclusively to up-to-date information on subjects of interest to women.

### New Farm Features

Special farm features scheduled for the 1926–27 season from 50 stations include "A Weekly Letter to Dad," which a son at college writes home telling about his studies in agriculture; "Autobiographies of Infamous Bugs and Rodents," a 10-minute specialty about " Pests that Are Bothering Now," as told by the insects and rodents themselves; " Chats by the Weather Man; " " Primer for Town Farmers; " "An Interview with the Agricultural Economist "; and a weekly " Farm News Digest."

Services through the various offices of the Bureau of Agricultural Economics to radio broadcasting stations have been maintained and expanded. The outstanding development of the radio market news service during the year is the extension of a leased wire to station KFKX at Hastings, Nebr. This powerful station will carry marketing information to the Great Plains States, into many sections not heretofore reached by the Government service. Congress provided for extensions of leased-wire service through the agricultural college at Ames, where reports are broadcast by the college station. A "drop" has been opened at Oklahoma City where, through cooperation with the State board of agriculture, reports are broadcast for the Southwest. With the development of more college and university radio stations additional contacts have been made for the use of market material. Marketing information is now being used by stations at Ohio State University, Columbus; Purdue University, Lafayette, Ind.; and the South Dakota station at Brookings.

## WORLD CROP AND MARKET INFORMATION

An increasing demand for the latest information regarding crops in the world's chief producing countries and market conditions in our important foreign markets is evidenced by the many direct requests made of the department's foreign service. The rapidly increasing use of economic information by farmers and by cooperatives, merchants, and other agencies of the farmer in the process of producing and marketing the Nation's supply of farm products indicates a growing understanding of the close relation that exists between the agriculture of the United States and the production and market requirements of foreign countries.

Foreign competition and demand must be taken into account both in planning production and in marketing farm products. In recent years approximately 13 per cent of the net product of the agriculture of the United States has been marketed in foreign countries. Considering only that part of the production that is sold off the farm, over 16 per cent has been sent to foreign countries. Approximately 50 per cent of the cotton crop must find a market abroad annually, facing increasing competition from Brazil, India, China, and new cotton-growing regions in both South America and Africa. Last year nearly one-third of the wheat crop was sold in foreign markets. Producers of pork, tobacco, and apples, three other great industries, have to depend to a considerable extent upon foreign markets for an outlet. Prices received by farmers for all these products depend not only upon the production in the United States and foreign countries but also upon foreign market requirements as to quality and quantity, and the purchasing power of foreign consumers.

## FOREIGN COMPETITION IN UNITED STATES

The producers of many farm products have to meet foreign competition in our own markets. The United States imported agricultural products, exclusive of forest products, valued at $1,918,000,000 in the year ending June 30, 1926. Many of these imports compete directly with American-grown products—for example:

Sugar $232,000,000, wool and mohair $125,000,000, hides and skins $94,000,000, tobacco $60,000,000, dairy products $31,000,000, and flaxseed and flaxseed oil $40,000,000. The farmers who have to market their products in competition with these imports are vitally concerned with production and prospects of production of these products in foreign countries as well as the foreign demand which is an important factor in determining at what price these products will be offered in the United States.

The department is developing a world crop and market reporting service that is furnishing producers with timely and helpful information. With the assistance of the International Institute of Agriculture, American consuls, Department of Commerce agents, and representatives of the Department of Agriculture in Berlin and London, and Italy, information is being collected as to production in all parts of the world and a beginning has been made in reporting market conditions in foreign countries. Reports of prices and market conditions in British and continental markets for our apples, wheat, cotton, tobacco, pork, and other products are received daily by cable and radio from foreign countries, and the information after careful interpretation is broadcast by leased wire, radio, and other channels of the department. Mailing lists arranged by commodities are maintained, to which a special release service is provided. "Foreign Crops and Markets" is being widely reprinted by trade journals, newspapers, farm papers, and farmers' cooperative marketing organs.

Another important step in bringing American producers and European consumers together has been taken in sending a well-trained fruit-marketing specialist to study European fruit markets for apples and citrus fruit. This survey of European fruit markets has brought to the attention of producers and shippers in this country many ways in which the European market requirements can be better met. Reports on these markets are helping to avoid much waste from shipping the fruit too green, not suitably packed for the ocean voyage, not put up in a manner to attract foreign buyers, varieties not suited to the market, sizes too large or too small, or in such great quantities as to overload weak markets.

Without additional personnel or increased expenditure, in the past year the department has increased greatly its foreign service. This has come about largely as a result of the natural development of the organization and through the more effective assistance of the cooperating agencies, the Consular Service, the Bureau of Foreign and Domestic Commerce, and the International Institute of Agriculture. The increasing and systematic use of data relating to foreign production and market possibilities is taking an important place in planning our farm adjustment and marketing program. The many special requests from producer interests for work in analyzing and developing foreign markets which are received in the department indicate the need for expansion of this service.

## GRADING OF FRUITS AND VEGETABLES

Rapid progress has been made in the standardization of grades for fruits and vegetables during the last year. Grades have now been recommended for 35 different fruits and vegetables. The use of national grades for fruits and vegetables has been extended through their adoption as official standards by the States. Thirty States have now officially adopted one or more of the United States grades. In many cases the use of these grades is compulsory for those crops standardized under the provision of the State law.

Great progress has been made during the four years that the shipping-point inspection service has been in operation in securing the adoption of recognized standards for fruits and vegetables. Supervising inspectors have reported better knowledge on the part of shippers of established standards and more effort to comply with the best grading practices. Insistence by several organizations on the shipment of graded products only has kept on the farms products of low quality which otherwise would have gone on the market in competition with the higher quality offered by the better growers and shippers. The inspection service has also helped cooperative associations in dealing fairly with their members.

Rice standardization investigations for the purpose of perfecting the United States grades for milled rice and for rough rice were continued. Improved standards for these commodities are being developed. A detailed study of California rice and of rice grading, handling, and marketing conditions is being made.

### Rice-Grading Schools

In cooperation with extension leaders in the Southern States rice-grading schools have been conducted in the principal rice centers of Arkansas and Louisiana. At these schools rice-grading demonstrations were made, and moving-pictures and lantern-slide lectures pertaining to rice grading and to improved methods of handling rice were given. As a result, the Arkansas Cooperative Rice Growers' Association installed a complete rice-inspection laboratory and several rice mills installed new rice-testing equipment.

A mechanical device, known commercially as the Smith shelling device, for removing the hulls from samples of rough rice for testing and grading purposes has been perfected by the department. By use of this device it is now possible to determine the milling yields and qualities of rough rice, and also the percentage amounts of red rice and damaged and chalky kernels in rough rice. This makes uniform and accurate grading of rough rice possible. The device is in regular use for commercial inspection purposes by one of the principal rice-growers' cooperative associations.

Official standards for shelled corn, wheat, oats, rye, and grain sorghums were in effect during the entire fiscal year. Official standards for feed oats and mixed feed oats became effective September 1, 1925. In addition, official standards for barley were promulgated on May 26, 1926, to become effective August 24, 1926.

Requests have been received from many sources, including the governors of North Dakota, South Dakota, Montana, and Minnesota, for a complete Federal service in testing of wheat for protein content. Further legislative authority will be necessary, however, before these requests can be met.

No changes or modifications of existing standards or grades for American upland cotton were made during the fiscal year, but five standards for upland cotton of extra white color were promulgated at the urgent request of producers and handlers in the irrigated sections of the Southwest whose cotton was not readily classified by existing standards. These standards become effective August 1, 1927, but prior to that date they may be used as tentative or permissive standards.

Seventeen States in which hay production or consumption is of importance had adopted United States hay standards as official State standards at the close of the year. Other important hay States are now giving serious consideration to the adoption of the standards. In 39 States agricultural colleges are employing United States hay standards in the teaching of hay grading and field crops to students of agriculture.

### Standards for Soy Beans

New standards for soy beans under a joint Federal-State inspection service in North Carolina proved their practicability and value. Assistance was given to cooperative egg-marketing associations in Ohio and Nebraska in establishing grades for their market eggs. In each case the United States standards and grades for eggs were adopted. The results obtained indicate that the United States grades are practical and especially well adapted for use by cooperative organizations in handling and marketing graded eggs. The United States grades for eggs were demonstrated in Nevada, California, Oregon, Washington, Utah, Montana, Nebraska, Kansas, Missouri, Illinois, Indiana, Ohio, Michigan, and Alabama.

After extensive study, numerous conferences with the trade, and a thorough test in market reporting, grade descriptions for market classes and grades of slaughter, feeder, and stocker cattle were prepared for publication. Tentative grade standards for these classes were formulated and submitted in connection with the proposed standards for beef grades at public hearings held at Portland, Oreg., Chicago, and New York City. Progress was made also in drafting specifications for grades of calves and vealers and sheep and lambs.

In cooperation with several of the State agricultural experiment stations, a study was begun to determine, among other things, what makes quality in beef. Approximately 1,000 cattle fed by the experiment stations were graded as feeders, later as slaughter cattle, and afterwards as carcasses of beef. Finally cooking tests were made and the cooked meat graded by experts. In connection with these experiments standard grading charts were devised by which it is possible to apply a mathematical weighting to each grade factor, thereby facilitating scoring and making more accurate grade comparisons. The results so far indicate a rather close correlation between the grade of the live animal and the grade of the carcass.

After eight years' practical use in market reporting and three years' use as suggested standards in commercial transactions, standards for grades of carcass beef were formally promulgated June 3 as official United States standards, effective July 1, 1926. These standards provide for seven grades each of steer and heifer beef and six grades each of cow, stag, and bull beef. Interest in standardization is very active among livestock producers.

### Tobacco Classifications

A classification by types of all American-grown tobacco was made. This classification has met a distinct need not only of the producer but of the tobacco trade as well.

Twenty-nine distinct types of American tobacco are recognized. Grades have been prepared for all the leading types with the exception of Burley. Study was given to this type, however, and at an early date tentative grades for Burley tobacco will be issued. A special report has been prepared on the sizing of tobacco, which may finally result in the use of a common sizing system for American-grown tobacco, not only in the United States but also in foreign countries.

### Barley Standards

The preparation and establishment of standards for barley presented a difficult problem by reason of the difference in conditions obtaining in the Middle West as compared with the Pacific coast area. Public hearings were held at several of the important barley markets at which producers, dealers, and all other branches of the industry were afforded opportunity to present their views. Following this, official standards were established, divided into classes on the basis of the section where grown. These standards became effective August 24, 1926, and it is believed that they will work out satisfactorily to all interested parties.

## INSPECTION OF FRUITS AND VEGETABLES

The service covering the inspection of fruits and vegetables and the certification as to their quality and condition has made satisfactory progress both at shipping points and at the receiving markets. The total number of inspections of fruits and vegetables made at receiving points was 32,531 cars, an increase of 197 cars over the preceding year. The total number at shipping points was 165,529, an increase of 34,442 cars. In addition to the inspections made for commercial interests, 38,889,636 pounds of fruits and vegetables were inspected for the Navy Department; 2,608,363 pounds for the Marine Corps; and approximately 8,600,000 pounds for the laid-up fleet and for various steamship lines. Substantial savings are effected for the Federal Government through the inspection service.

There has been a material increase in the number of export inspections of boxed and barreled apples in New York City. Exporters are depending more and more upon the Federal certificate as an aid in closing their financial transactions at the time the fruit is delivered to the steamship companies. The greatest increase in number of shipping-point inspections made was in California, this being due largely to a great increase in the number of grape inspections, 36,069 cars having been inspected in 1925–26 compared to 18,783 in 1924–25.

An increased willingness has been shown in practically all sections to accept certificates on cars which failed to meet the grade requirements. Shippers are finding that they can sell cars which are slightly under grade at only a slight reduction if they support their statements of the quality of such cars by Federal-State certificates. Reductions in price on slightly off-grade cars are usually much less if made at the shipping point than if made after the product has passed into the hands of the buyer.

### Hay Service Extended

Prior to this year the hay-inspection service has been limited by the fact that Federal standards were available only for timothy, clover, and grass hay. On July 1, 1925, standards were recommended for alfalfa and alfalfa mixed hay, prairie hay, Johnson and Johnson mixed hay, and mixed hay. On September 1, 1925, these recommended standards, together with those for timothy, clover, and grass hay were made the official standards of the United States for the inspection and certification of such hays. The publication of these additional standards caused an immediate increase in the demand for Federal hay inspection, particularly in the Western and Southern States.

Inspectors employed exclusively by the department have continued to assist other Government agencies by inspecting hay for them. The Federal specifications board adopted the Federal standards for timothy, clover, and grass hay some time ago as master specifications for all Government purchases. In November, 1925, they adopted in a similar manner the standards for alfalfa hay, prairie hay, Johnson hay, and mixed hay. In January a conference was held at the hay standardization laboratory in Washington, which was attended by representatives of nearly all Government departments interested in the purchase of hay. The standards were explained at this meeting and the various departments were offered the benefit of the inspection service. Considerable changes in methods of purchase were made in several of the departments as a result of this conference. This will result in financial saving to the Government and improvement in the quality of hay received on contracts.

## MOVEMENTS OF POPULATION

The movement of farm people away from farms and the reverse movement of city people to farms when thoroughly understood constitute an important index of the agricultural situation. A study of these movements of population during the last five or six years throws considerable light on the present trend of rural events.

Information obtained from many sources indicates that in 1920 there was a net gain in total farm population of approximately 500,000 over the preceding year, when according to the United States Census reports there were 31,614,269 persons living on farms. The prosperity of farming at that time apparently restrained the customary flow to cities of young people between the ages of 20 and 25. Moreover, the annual movement of prosperous retired farmers to town was offset by the arrival of city people drawn to farming.

The year 1921, however, was marked by striking drops in prices for farm products and saw the beginnings of an unusual movement of population to the cities. Although many persons who were tempted to leave farming stayed on farms, in the hope that soon the tide would turn and prosperity flow farmward, some were forced out of agriculture. The result was that the net increase of farm population that year fell from 500,000 to 200,000.

In 1922 a department survey indicated that the net movement of persons to cities reached the 1,000,000 mark, which entailed a net loss in the farm population of 460,000 persons.

In 1923 the drift of population to cities continued in full force, probably reaching its height and causing a net decline in the farm population equal to or possibly somewhat exceeding that of 1922.

Another survey of the situation was made by the department in 1924. It showed that while forces tending to drive people to cities were still in operation (more than 2,000,000 persons moved to cities in 1924) other forces were sending back from cities to farms a larger number than formerly. This return movement in 1924 totaled 1,396,000 persons, and reduced the net loss to the farm population to 182,000.

### The Cityward Movement

The movement of population from farms to cities, towns, and villages in 1925 is estimated to have totaled 2,035,000 persons. The reverse movement to farms is estimated to have been around 1,135,000 persons. There was consequently a net movement away from the farms of 901,000 persons. Births on farms during 1925 were estimated at 710,000 and deaths at 288,000, leaving a natural increase of 422,000, which reduced to 479,000 the loss due to the cityward movement of population.

The large movement back to farms in 1924 and in 1925 doubtless included some persons who had sold their farms in recent years, but were obliged to take them back on account of the failure of promised payments. It doubtless also included many farm owners who found after a year or so that they could not afford to live in the city on the rentals of their farms. In the return flow of population to the farms there were likewise many laborers and former farm tenants, who had failed to find their expectations fulfilled in the cities.

In normal times there is a constant interchange of population between the country and the town. As farmers retire to cities, so city people retire to farms; laborers move back and forth from farm to city and from city to farm; and a stream of youth of both sexes goes permanently from farms to cities. All agencies seeking to promote the general welfare, whether rural or urban, should work toegther to reduce to a minimum the inevitable dislocations due to this interchange of people. Yet, looking at it from another point of view a reasonable movement one to the other benefits society. It is the extent of such excess movement from farm to city which is desturbing.

## PACKERS AND STOCKYARDS ADMINISTRATION

The Packers and Stockyards Administration is a separate unit of the department organized to carry out under the direction of the Secretary the purposes of the packers and stockyards act. The purposes of the act are in a general way to promote fair, impartial, open, and competitive conditions in the livestock and meat-marketing process of the country. The act provides that the rates and charges made at the public markets shall be just, reasonable, and nondiscriminatory, and prohibits any market agency or dealer from engaging in any unfair, unjustly discriminatory, or deceptive practice at a public market. Provision is also made for the correction of any unfair, unjustly discriminatory, or deceptive practices by packers in the manufacture and distribution of packing-house products in commerce.

Seventy-eight stockyards have been posted by the Secretary as coming within the jurisdiction of the act. Approximately 5,600 market agencies and dealers and 850 packers are also subject to regulation. All market agencies and dealers operating at public stockyards are required to register and carry adequate bonds to cover their obligations. The stockyard companies and market agencies are required to file schedules of their rates and charges. If a schedule is filed that appears to be unreasonable or discriminatory, the policy of the administration is to secure an adjustment informally where possible. If this can not be accomplished, formal proceedings are held to determine the reasonableness and lawfulness of such rate or charge.

### Many Actions Started

During the fiscal year 19 formal dockets have been initiated and action has been taken with respect to 11 other cases which were pending at the beginning of the year. Of these cases 7 involve the general schedule of stockyards rates and charges, 2 involve the general schedule of commission charges filed by all the market agencies operating at their respective markets, 13 involve trade practices, and 9 involve insolvency. During the year 5 of these cases were closed by being dismissed without prejudice, in 9 cases the registrant was suspended, and in 4 cases a "cease-and-desist" order was issued.

Special attention has been given to the bonding of the market agencies and dealers. New forms of bonds have been prepared covering the different classes of business of the registrants. A complete physical valuation has been made of all the properties of the Denver Union Stockyards Co. At a number of the yards improved scales have been installed. Attention has been given to the testing of the scale equipment, and weighing instructions have been issued and forwarded to the weighers at all markets.

By an act of Congress, approved May 5, 1926, the packers and stockyards act was amended to provide that in any State where the weighing of livestock at a stockyard is conducted by a duly authorized department or agency of the State, the Secretary may register it as a market agency for the weighing of livestock received at such stockyard. In accordance with the provisions of this amendment the Railroad and Warehouse Commission of the State of Minnesota has registered as a market agency and is furnishing the weighing service at the South St. Paul stockyards.

## ALFALFA AND RED-CLOVER SEED TESTS

The wide differences in agricultural adaptability within the United States of alfalfa and red-clover seed produced in different foreign countries, to which reference was made in my report of the previous year, have received constantly increasing attention. It is clear that the information regarding the country producing seed of these two crops is of unusual importance to the American planter. Trials with alfalfa, red clover, and seed from various countries are under way, in most instances in cooperation with State agricultural experiment stations, although many years' experiments will be required to determine accurately the adaptability of seed of different origin to different sections of the United States.

Determining the winter hardiness of alfalfa varieties or strains imported from different countries is necessarily slow. Up to the present time the results available have shown that alfalfa seed from Turkestan is of little value for the greater part of the United States, particularly in those humid sections where alfalfa is an important crop. Seed from South Africa produces plants that are not sufficiently hardy for the Northern States, and, in the majority of tests, plants grown from seed from Argentina have suffered seriously in the United States over the first and second winter.

In considering the adaptability of red clover to different regions of the United States, three general regions may be distinguished: First, the region in which severe winters prevail, with low temperatures and with little snow or with great fluctuations in temperature; second, the region in which anthracnose or similar clover diseases are not important factors and in which the winters are somewhat milder; and third, regions in which the winters are not severe and in which anthracnose or other clover diseases are of major importance. Clover from domestic seed, including that grown in Canada, is more resistant to severe winters than any foreign clover so far tested, and in regions of severe winters only American-grown clover seed should be used. Seed of disease-resistant types of domestic clover should be used, if possible, where anthracnose or similar diseases prevail.

### Seed Act Amended

The widespread interest in these results on the part of farmers, seedsmen, and others more or less directly concerned resulted in an amendment, April 26, 1926, to the Federal seed act (formerly designated the seed importation act), which requires that all seed of alfalfa and red clover imported into the United States be colored, so that the purchaser may know whether he is buying seed of domestic or foreign production.

The general scope of this amendment and the regulations promulgated for its enforcement may be briefly sumarized as follows: Whenever the Secretary of Agriculture, after a public hearing, determines that seed of alfalfa or red clover from any foreign county or region is not adapted for general agricultural use in the United States, entry of such seed is prohibited unless at least 10 per cent of the seed be stained a red color. This 10 per cent red coloring is required for Italian red clover seed effective September 2, 1926, and for alfalfa seed produced in Turkestan and Africa effective September 25, 1926. Moreover, all alfalfa and red clover seed for which the country of production can not be shown is prohibited entry unless at least 10 per cent of the seed be stained red. Except as provided in the foregoing, entry of alfalfa or red-clover seed into the United States is prohibited unless approximately 1 per cent of the seed is colored violet, if produced in Canada, or green if produced in any other country. The amendment also provides that any seed in interstate commerce that is willfully misbranded may be confiscated by the Secretary of Agriculture by a process of libel.

## SOY BEANS

No single agency has done more to develop the soy-bean industry in the United States than has the Department of Agriculture. Introduced from the Orient many decades ago, the soy bean only recently attained a recognized place in the cropping system of American farmers. As late as 1917 less than 500,000 acres were devoted to the growing of soy beans for all purposes. In 1924 there was a total of 2,500,000 acres, of which about 1,000,000 acres were used for hay, 1,000,000 acres for pasture and ensilage, and 500,000 acres for seed. This increase in the acreage devoted to soy beans in the United States is largely due to the development of better-adapted varieties. Previous to 1898, there were not more than eight varieties of soy beans generally grown in the United States, and of these only two, the Ito San and Mammoth Yellow, are now grown to any extent. In 1924, the last year for which data are available, the total value of the seed of all varieties of soy beans grown in the United States was estimated at $23,917,500. Of this total $12,675,540 must be credited to new varieties introduced by the department. The total value of the soy-bean hay crop in 1924 was $18,360,000, and of this value the new varieties were responsible for a little more than half.

There is no way of estimating the value of the soy beans used for pasture, ensilage, and soil improvement, but it is probable that at least 25 per cent should be added to the above figures as the value represented by these uses of the crop. In estimating the contribution made by the new varieties, not all the States growing soy beans are represented. Data were obtainable only from the principal soy-bean States.

### Older Varieties Supplanted

The extent to which new varieties have supplanted the older ones in certain States is apparent when the following facts concerning soy-bean hay and seed only are considered. The Biloxi makes up 43 per cent of the total production in Louisiana; Black Eyebrow, 25 per cent in West Virginia; Haberlandt, 32 per cent in Kentucky; Laredo, 25 per cent in Mississippi; Manchu, 45 per cent in Iowa; Midwest, 50 per cent in Indiana; Mandarin, 42 per cent in South Dakota; Morse, 28 per cent in Missouri; Virginia, 55 per cent in Virginia; Wisconsin Black, 40 per cent in Wisconsin; and the Wilson, 53 per cent in Pennsylvania and 52 per cent in Maryland. The results obtained from the search for new varieties appears to have justified the work and compensated for the expense many times over. Of the total production of soy-bean hay and seed, 53.7 per cent is represented by varieties introduced and developed by the department.

## SUDAN GRASS

This valuable grass sorghum and annual hay plant was obtained in 1909 from northern Africa, through the efforts of C. V. Piper, then agrostologist in charge of the office of forage crops of the department. It was immediately successful, particularly in the southern Great Plains, and in 1918, nine years after its introduction into the United States, the value of the annual crop of Sudan grass was conservatively estimated at $10,000,000. Like the sorghums, it has proved able to survive periods of drought, and its fondness for hot weather during its growing period has resulted in its extensive use as a summer pasture, not only in the Great Plains but also in the Corn Belt. The acreage has practically doubled since 1918, and is becoming more or less unvarying around 1,000,000 acres sown annually. It is appreciated as an emergency hay crop and summer pasture grass in Iowa almost as much as in Texas, and the interest in it is increasing as far east as Ohio. Although the value of a pasture crop is exceedingly difficult to appraise. there is justification for the belief that the annual crop of Sudan grass in recent years is easily worth $16,000,000. It has supplanted millet to a considerable extent as a catch-crop, on account of its ordinarily higher yields and the greater palatability of the Sudan grass hay. Seed of it is now abundant and fairly cheap, and this grass promises to continue as one of our regular forage producers, returning each year in this one item many times the entire annual expense of forage investigations in the the department.

The introduction of Ladino clover was accomplished in Idaho about 1915, and since then about 40,000 pounds of Ladino clover seed have been produced and there have been established about 1,000 acres of the very best kind of dairy pasture. The total value of this new industry, although comparatively small, may be said to have added some $13,000 to $15,000 a year to the income of Idaho farmers.

## ABACA IN TROPICAL AMERICA

The so-called "hard" fibers furnish the entire supply of raw material used by American manufacturers for making binder twine, and the greater part of the raw material used for all other kinds of cordage except that made from jute and cotton. In addition to large quantities of miscellaneous hard fiber cordage between two and three hundred million pounds of binder twine are consumed annually on the farms of this country. The American farmer is, therefore, our largest consumer of hard fibers.

The four fibers that furnish practically all of our supply of this raw material are henequent, sisal, abaca, and istle. The imports of these four fibers in 1925 amounted to 215,758 tons valued at $43,434,169. The henequent is obtained principally from Yucatan, the sisal from Netherlands India, the Colonies of East Africa, and the Bahama Islands, the abaca from the Philippine Islands, and the istle from the northern part of Mexico. None of the hard fibers are produced in commercial quantities within the continental United States.

Special attention has been given during the last year to the establishment of abaca production on a commercial scale in tropical

America. The entire world supply of abaca fiber, with the exception of a few hundred bales, is produced in the Philippine Islands. With a decreasing supply of labor, and increasing competition from coconuts and other crops, the Philippine production of abaca is barely holding its own and is not keeping pace with the world demand for this fiber. Two diseases of abaca, that have appeared in recent years, threaten to reduce still further the production of abaca. In view of these conditions, it is apparent that effort should be made to encourage the growing of abaca in tropical regions other than the Philippine Islands.

### Difficult Shipping Problem

Abaca, when propagated from seed, does not come true to type, which necessitates propagation either from rhizomes or suckers. The shipment of plant material of this character from the Philippine Islands to the American Tropics has proved to be a difficult problem, and shipments of abaca plants made in 1923 and again in 1924 failed to survive the long journey. During the calendar year 1925, with the cooperation of the War Department, the Navy Department, and the United States Shipping Board, arrangements were made for the routing of a freight steamer direct from the abaca-producing province of Davao, in southern Mindanao, to the Canal Zone. Provision was also made for the storage and handling of growing plant material on this ship.

During the months of July and August, 1925, 1,438 selected abaca plants, representing six different varieties, were accordingly collected on five different plantations in Davao. This material, which included rhizomes, suckers, buds, and growing plants, was packed in a number of different ways, and was shipped from Davao August 21. The shipment was en route 44 days. On arrival the Canal Zone plants were reshipped to the northern part of the Republic of Panama, where arrangements had been made for planting them in an isolated plant quarantine section. About 50 plants were subsequently taken to the plant introduction gardens at Summit, in the Canal Zone.

Of the total shipment of 1,438 plants, 1,052 plants, or 73.2 per cent were alive when the shipment arrived at its destination. There was a relatively heavy loss after the plants were planted in the plant quarantine station. At the close of the year about 500 plants were growing and in good condition.

## DEMAND FOR RUBBER INFORMATION

Rubber has become an essential to agricultural production and marketing of crops, as well as to urban industries. About three times as much rubber is used in the United States as in the rest of the world. The present development of our civilization could hardly be maintained without rubber. The precariousness of being so completely dependent upon the East Indies for an indispensable product is being recognized.

Interest in the possibilities of rubber production is intensified by the large areas of unused or partially used land in the United States, especially in the southern and southwestern regions, where it is hoped that rubber production may prove feasible. If suitable plants were discovered, and methods of utilization devised, the well-known disparities in the cost of labor between the oriental regions and the United States might be overcome, as we now grow cotton, rice, sugar, and tobacco in competition with the oriental countries.

Large areas of land now of little value in tropical America may be utilized for the production of Hevea rubber if suitable methods can be devised. Experiments to determine such possibilities are being made in numerous localities in the Canal Zone and in neighboring districts of the Republic of Panama, as well as in Haiti and southern Florida. On account of different conditions in tropical America, the methods that are used on the large rubber plantations of the East Indies have not appeared practicable, but other methods may be developed which will make production possible without contract labor and also avoid the large initial outlay and overhead charges of the East Indian plantation system. Careful experiments are needed to show the range of conditions under which it is possible for the trees to grow and to produce rubber, and to demonstrate a practical method for bringing the trees through the early stages of the development with the smallest requirement of labor and expense. The first result of these experiments is to show that the range of adaptation of Hevea, the Para rubber tree, is much wider than has been supposed.

### Hevea in Tropical America

Experiments with Hevea and other rubber-producing plants are going forward in Haiti, in the Canal Zone, and in the Republic of Panama. Seeds and young plants of Hevea from Haiti were taken to Panama, and are being tested in numerous localities. The tapping of mature Hevea trees in Haiti has been carried into the second year with yields distinctly larger than at the corresponding periods in the first season. Compared with records of individual trees in Ceylon and elsewhere in the East Indies, the range of variation is much the same, and also the average production per tree. Thus there is no question of the feasibility of commercial production of rubber in Haiti, if a suitable system can be established. A small shipment of the crude rubber was sold in New York at the full market price of East Indian rubber.

Seedlings of Hevea are tolerant of shade and specially adapted to forest undergrowth conditions, so that planting in the open is not necessary. Slower growth of the plants in the early stages does not interfere with a vigorous and normal development of the trees after they have become well established. The use of cover crops like the pigeon pea, or Congo bean, may be desirable for controlling weeds or grass, shading the soil, and gradually establishing the desirable condition of the forest leaf-litter covering; also the closer planting of the rubber trees may serve the same purpose. While the tapping size might be reached somewhat later in close-spaced plantings, the cost of establishing plantations might be less and the outlook for sustained production might be improved, since the bark surface would be greater. Also the removal of low-yielding trees could be accomplished with less difficulty or need of replacement.

### Promising Rubber Plants

Several of the tropical rubber-producing species thrive in southern Florida and appear to be so well adapted to local conditions that extensive cultivation might be possible if satisfactory methods for extraction of the rubber could be devised. The Assam rubber tree (*Ficus elastica*) and the purple-flowered rubber shrub (*Cryptostegia grandiflora*) are widely distributed and grow very well in many localities in the southern half of Florida. *Cryptostegia madagascariensis* has also been introduced into Florida; this species has been studied in Mexico and Haiti and is known to produce rubber of fair quality. The collection of rubber plants now growing at the plant-introduction garden Chapman Field, near Miami, includes numerous species of Alstonia, Asclepias, Carissa, Carpodinus, Castilla, Cerbera, Cryptostegia, Euphorbia, Ficus, Funtumia, Hevea, Jatropha, Landolphia, Manihot, Mascarenhasia, Parthenium, Pedilanthus, Plumeria, Rhobdadenia, and Urceola.

Rubber plants that are natives of dry regions are being tested in California, in the coast districts as well as in the interior valleys. Several dry-country rubber plants are known in Mexico, while others are reported in South America, Africa, and Madagascar. Special attention is being given to one of the native species of milkweed (*Asclepias subulata*), which appears to be the most promising for waste lands and for producing the largest quantity of rubber-bearing material readily and cheaply.

## FOREIGN PLANT INTRODUCTION

Methods for safeguarding the country against foreign crop pests in connection with plant-introduction work are being steadily improved. All plant material from foreign sources is brought to Washington, D. C., and subjected to rigid inspection and to treatments if required. Much of the material goes into quarantine and some is detained under special safeguards. Material that is released to go to one or more of the plant-introduction gardens is under surveillance all the time it is being grown and propagated. Just before distribution a final inspection is given. These protective measures are developed cooperatively by the Bureau of Plant Industry and the Federal Horticultural Board.

Several years ago one of the agricultural explorers of the department discovered a remarkable cherry growing in the Ecuadorian Andes. This fruit is closely related to our wild black cherry. It occurs all the way from Mexico southward. For a long time only seed could be obtained, but two years ago some budwood was introduced and successfully established under glass at the Bell (Md.) plant-introduction garden. Four small trees from this budwood came into bearing this year. The fruit is of good size and very fair quality. The Capulin cherry, as this fruit is called, is believed to be adapted to our Southern States; at least it will be given extended trial there. It is essentially a warm-country cherry. A cherry for the home gardens of the South and for local markets would be a valuable acquisition. The fruit of the Capulin as grown here is about three-fourts to 1 inch in diameter and of a pinkish-red color. It is borne in racemes, like our native black cherry.

Bamboos are attracting much interest in this country, especially since the recent publication of a small bulletin on their growth and uses in the United States. The timber bamboo is one of the most striking forms. About 8,000 plants of this species were distributed in the spring of 1926. Cooperators are being encouraged to put out and care for small groves of from a quarter acre to an acre. It is important to make certain of a future supply of plants. The plants must be propagated by division, as seed is not available. Besides the timber bamboo, which finds many uses on the farm and in commerce, numerous other species are being tested and propagated—mainly at the plant introduction garden of the Bureau of Plant Industry, near Savannah, Ga.

## TUNG-OIL TREE INTRODUCTION

Commercial plantings of the tung-oil tree, a recent introduction of the department from China, have now reached a total of about 1,500 acres. The new industry is centering in north-central Florida, and is being fostered by interests connected with the paint and varnish industries, in which tung oil is an important factor. Most of the bearing trees are young, and consequently the seed crop small. All available seed is still being used for planting purposes. While there is at present an ample supply of tung oil from China for the needs of American manufacturers all that is received is more or less adulterated or otherwise inferior in quality and there is a need for a commercial supply of the pure oil. The imports during the calendar year 1925 amounted to 101,550,000 pounds, with a declared value of $11,385,000.

Interest in the Chinese elm (*Ulmus pumila*) has increased each season since its first introduction, and very favorable reports have been received from all sections of the country. Because of its rapid growth and its resistance to drought and alkali special interest has attached to its usefulness in the Great Plains region, where there is great need for a shade tree also suitable for use in windbreaks. No other tree has met so successfully the requirements of this region. The ever-increasing demand for it has resulted in its being offered by a number of nurserymen in that section, and there is little doubt but that hundreds of thousands of these trees will be planted as rapidly as they become available.

## RIPENING OF DATES

From the elaborate pollination experiments on dates it has been determined that the type of pollen used will make possible either the very early ripening or mid-season ripening or late-season ripening of the particular variety of dates that are pollinated. Not only the time of ripening but the size and flavor of the mature date are determined to a very large extent by the kind of pollen that is used.

The extent to which this may apply to fruit crops other than the date is now under consideration. It is possible that the same principle may be applied to secure more or less control of the quality of other fruits. In so far as the production of dates is concerned, this discovery is of unusual importance because of the material extent of the control of fruiting habits of the different varieties of dates now being grown in the Southwest.

## SUGAR BEETS

Distinct advances have been made in the investigations into the curly-top of sugar beets, which is perhaps the most serious disease with which beet growers have to contend in the western areas. A mild form of the disease first observed at Bakersfield, Calif., in 1924, was studied and found to be caused by virus that had previously passed through certain wild hosts, subject to the disease, before being transmitted to beets by the insect *Euttetix tenella.* This remarkable discovery of attenuation of the virus is believed to be the first instance ever recorded of such a phenomenon in a disease of plants.

Additional data on the control of the sugar-beet nematode by rotation of crops was obtained at Salt Lake City, Utah, and this method is now unhesitatingsly recommended as the only practicable one under present conditions in Utah, Idaho, Colorado, Wyoming, Montana, and California.

An investigation of the best conditions for storage of commercial beets was brought to a conclusion at Salt Lake City. It had been previously brought out that enormous losses of sugar occur in the piles at beet dumps and in factory bins on account of the physiological activities of the beets which go on, although at a diminished rate. The principal recommendation resulting from this investigation is to shade the surface of piles with a moisture-holding inexpensive covering; which should be sprayed with water during dry weather. It was proved that this lowers the temperature and cuts down ventilation, which reduces respiration and the resulting loss of sugar.

## WHITE PINE BLISTER RUST

Blister rust was found in the Northwest in the fall of 1921, when it was discovered at Vancouver, British Columbia, and shortly afterwards at Mount Vernon, Wash. Subsequent investigations indicate that it was introduced from France in 1910 on a shipment of young white pines that were planted near Vancouver. Field conditions favored its rapid spread and it became thoroughly established on western white pine in the coastal region of British Columbia. Following the discovery of the disease in the West, the department in 1922 and 1923 undertook a cooperative survey to determine the limits of infection and the possibilities of natural or artificial barriers delaying the advance of the disease into uninfested regions.

The season of 1923 was notable principally for the spread of infection southward through the dry belt of central British Columbia and through the Lake region of eastern British Columbia. Infection on cultivated black currants was found to be generally scattered over the dry belt and extended as far south as the central part of Okanogan County, Wash. Infection in eastern British Columbia was found to have extended southward to Grand Forks, British Columbia; Danville, Ferry County, Wash.; and to Nelson, British Columbia. It was also found that numerous Ribes were each year infected in the Puget Sound region of western Washington. Their proximity to native white pines made it probable that these pines were becoming infected.

### Idaho Pine Threatened

In general, at the end of the 1923 field season, the Idaho white pine belt was directly threatened with invasion from the Northwest, through the dry belt and from the north through Nelson, British Columbia, and near-by points. Also, the increase of infection in western Washington constituted an ever-increasing menace of infection in western Oregon.

In 1924, the department in cooperation with the affected States and local agencies began a control program projected over a period of 10 years which aimed at delaying the spread of the disease and at developing and applying practical control measures. During the two years the program has been under way, good progress has been made in carrying out such measures as were considered worth while and in developing suitable control practices.

During 1925 two important developments in the spread of the rust were noted. First, western white pines were found to be infected at Nelson, British Columbia. This pine infection resulted from Ribes infection found at that point in 1923 and is significant in that it constitutes a focus from which Ribes infecting spores can be disseminated over long distances, thus greatly increasing the risk of initial infection of Ribes in northern Idaho. Second, the disease was found in the coast region of northwestern Oregon at Pacific City, Wheeler, and Knappa. This spread undoubtedly denotes the presence of infected pines in the Puget Sound region of Washington some distance south of the Canadian border. It constitutes a direct thrust of the disease toward the sugar-pine regions of southwestern Oregon and California.

### Blister-Rust Control in the East

Steady progress in blister-rust control in the East has been made since the beginning of the control program in 1922. The developmental work prior to 1921 resulted in 1,036,903 acres of land being cleared of 14,491,503 Ribes, of which 91,718 were cultivated bushes. At the same time, the average per acre cost of eradication was reduced from 72 to 18 cents. From the beginning of the control program in 1922, a total of 29,988,089 Ribes, of which 204,451 were cultivated bushes, have been eradicated from 3,217,140 acres of land at an average cost of 18 cents per acre. Since 1918 a total of 44,479,592 Ribes of which 296,169 were cultivated bushes, have been destroyed on 4,254,043 acres of land.

The majority of owners of cultivated Ribes destroyed their bushes without compensation. During 1925, 59,458 cultivated bushes were uprooted, yet the State had to pay for only 2.2 per cent or 1,300 plants. A total of $514.55 was paid in compensation for cultivated Ribes to 49 owners. During the four years the program has been under way the cooperating States, towns, and individuals have made available a total of $723,451.02 for cooperative control work.

The blister-rust situation in the Middle Atlantic and Lake States differs materially from that in New England and New York. The southward advance of the disease into northern New Jersey and northeastern Pennsylvania has been comparatively slow. The difference in the behavior of the disease in this region is probably due to the influence of host associations, and perhaps other factors not definitely known at present. Wild Ribes are moderately abundant, but the pine host is so scattered that field conditions are unfavorable for the rapid spread of the disease. Cooperative scouting in New Jersey during 1925 resulted in the finding of infected cultivated black currants in Monmouth, Passaic, Warren, and Sussex Counties. Similar scouting in Pennsylvania showed the rust present in Wayne County at Callicoon, Rileyville, and Damascus, where it had occurred in former years, and at Laurella, a new location. In two instances the disease was on cultivated black currants, in the third on pines and black currants, and in the fourth on pines and wild gooseberries. The southward spread of the rust is being carefully watched, and steps will be taken, in cooperation with the States concerned, to secure the application of control measures to valuable pine stands as the need arises.

## BARBERRY ERADICATION

The campaign for the eradication of the common barberry for the purpose of reducing stem-rust losses of small grains has been in progress eight years. This year's results show that a great many barberry bushes still exist in the barberry-eradication area. Some of these bushes are in areas not yet reached in survey and eradication, for barberries are numerous in the old established farming communities of the counties not yet covered in the first survey. Others are bushes overlooked in surveys, and these cause the greatest concern. The second-survey results show that a comparatively large number of plantings were missed on the first survey. These are scattered well over the entire area.

In spite of the extreme care used in the second survey, a check survey in a county picked for the purpose showed that a comparatively large number of barberries may be missed even on second survey unless every foot of the area is inspected. All areas of escaped bushes must be completely inspected, and care must be exercised to insure that the extreme limits of these areas are reached. Numerous seedlings may continue to develop each season in the vicinity of locations from which fruiting bushes were removed. The missed bushes and the continuously developing seedlings are hidden centers of stem-rust infection. Patience in searching for bushes and seedlings, the following up of all reports of the early and heavy development of stem rust in local areas, and the eradication of bushes found will aid materially in the control of stem rust.

In the eastern winter-wheat producing States of the eradication area, stem rust of wheat is controlled as soon as the barberries are eradicated from an area. It may be that stem rust developing early in southern climates under certain conditions is spread widely by winds to the spring-wheat producing States. However, in 1925 142,550 barberry bushes and 701,796 seedlings were found in the counties surveyed. In the second survey in Minnesota, 1,124 bushes were found on 134 properties in 10 counties. In North Dakota, 110 bushes were found on 15 properties in 5 counties. In South Dakota, 446 bushes were located on 66 properties in 10 counties, and in Iowa, 1,125 bushes on 145 properties in 8 counties. Similar results were obtained from the second survey in the other States. Granted that much rust may develop from untraced sources, it is nevertheless true that wherever very severe local stem-rust epidemics have continued to recur year after year, a careful survey usually reveals one or more plantings of barberries. Records of hundreds of these epidemics are filed in the offices of State officials, and many cases of the reduction of rust by eradication of local barberries are testified to each year by farmers and field men.

### Many Bushes Still Exist

Thousands of bushes and seedlings, no doubt, still exist in the 13 States of the eradication area. A preliminary survey of a few townships in border counties in Kansas and Missouri in 1924, and a further check for stem rust in the spring of 1925, show that many plantings of barberries exist there. Some of these when examined were spreading stem rust to grains and grasses, others apparently were not.

There are eradication laws or regulations under which barberry bushes may be eradicated not only in the 13 States of the eradication area, but also in Missouri, Oregon, Washington, West Virginia, and Tennessee. Interest in the eradication of barberries is manifested locally in Pennsylvania. In the part of Virginia where *Berberis canadensis*, a native barberry, spreads stem rust to local grain crops local eradication of this native barberry is in progress. North Carolina scientists are showing interest in the spread of stem rust from *B. canadensis* in that State.

## SOIL SURVEYS

The hitherto unknown characteristics of many soils in the United States have been determined by the Bureau of Soils in the last fiscal year. Survey projects were either begun or completed in 29 States, covering a total of 28,508 square miles, an area equal to more than half of Iowa. This means that during the last fiscal year definite knowledge has been gained of an additional 18,245,120 acres of soils—the Nation's most important agricultural resource—regarding their present and potential productiveness, the type of agriculture for which they are best suited, methods of soil improvement, crop adaptation, and their proper management.

An intensive field study was made of the important soil types of north-central Indiana, with a view to determining the relation between the distinguishing soil characteristics and soil productiveness and management. This marks the beginning of an entirely new and important line of soil investigation. Soil mapping and classification are now pursued in harmony with the dynamic or genetic conception of soils—a conception which recognizes the development of distinguishing soil characteristics under the influence of climatic and biotic forces, and not according to the old idea of classification on the basis of the physiographic position of soils. The facts collected in the study of the Indiana soils show that when soils are classified according to these natural, distinguishing characteristics they correspond to the soils to which the farmers have given distinction in local descriptive names, in their estimates of average yields per acre, in their soil-management practices and in their estimates of relative land values.

### Alkali Soils in Illinois

Soil studies, in cooperation with the University of Illinois, have brought to light a wide distribution of certain "alkali" soils in southern Illinois, hitherto not known to occur east of the Great Plains. These soils, from the surface downward, are similar to the so-called "Szik" soils of Hungary, the "Solonetz" soils of Russia, and to the "slick spots" which occur in regions of low rainfall in the United States. These peculiar soils, in their development, owe their distinguishing characteristics to the presence of certain salts which are common in the dry regions of the West, but which were not known to exist so far east as southern Illinois. Such a distribution of alkali soils affects to a marked degree the type of crops that can be grown in the affected area.

## EXCLUSION OF PLANT PESTS

The protection of American agriculture from new insect pests and plant diseases is one of the more important activities of the department. It is known that our chief insect and disease hazards are of foreign origin, and that the importation of plants and plant products without inspection or safeguards of any kind has been the means of entry of practically all of these imported pests. Since 1912, under the enforcement of the plant quarantine act, the rapid stream of entry of such pests has been largely stopped. This desirable result is being obtained by the enforcement of some 22 foreign quarantines restricting, controlling, and safeguarding by inspection the entry of the plants and plant products known to be carriers of specific plant enemies. For the enforcement of these orders, the department is maintaining an inspection service at the principal ports of entry in the United States, the utility of which is daily attested by the interception of new and important pests.

Under the authority given in the plant quarantine act to control and prevent the spread of new plant enemies that have gained more or less local foothold in the United States, some 17 of these are now under domestic quarantines, among which may be mentioned the pink bollworm of cotton, the Japanese beetle, the European corn borer, the gipsy moth, and the white pine blister rust. These domestic quarantines also include those necessary to prevent the spread of pests to the continental United States from the Territories of Hawaii and Porto Rico. The most important of these quarantines is that intended to prevent the entrance of the Mediterranean fruit and melon fly into the mainland of the United States.

### Control of Pink Bollworm

It may be here noted that the pink bollworm has not reappeared in the important cotton regions of central and eastern Texas and in Louisiana, where it was formerly widely established, indicating the continued success of the eradication and control measures. The effort to confine the gipsy moth to its known distribution, covering now much of the New England States, has been accomplished by the maintenance, for the last two years, of a defense belt extending along the Champlain-Hudson River section. It is generally recognized that the spread of the gipsy moth into the mountainous regions of central and northern New York would make it very difficult, if not impossible, to prevent the rapid spread of this serious forest and orchard pest throughout the United States.

In the case of the Japanese beetle and the European corn borer, natural and local spread can not be prevented, but control measures enforced with respect to these pests have effectively prevented their long-distance spread. The Japanese beetle has spread during the year into two new States, namely, New York—in the immediate vicinity of New York City, in the Hudson Valley and on Long Island—and the southwestern corner of Connecticut. The white-pine blister rust has appeared in Oregon, evidently spreading from its known western locations in British Columbia and Washington. New quarantine control measures for this disease have been adopted and are now being enforced. It is hoped that these will give greater protection against further spread to important white-pine areas in the Western United States not yet invaded.

### Eradication Sometimes Impossible

It is recognized that such pests and diseases are introduced and firmly established over considerable areas, their eradication is impossible and their spread, probably ultimately throughout their possible range in the United States, can not be prevented. The control efforts which the department is carrying on are intended to retard the spread of these pests and to reduce losses pending effective local control.

Authority granted in the appropriation act for the fiscal year 1927, to inspect domestic fruits and vegetables and other plants and plant products offered for export to meet the sanitary requirements of foreign countries, became effective July 1, 1926. Such inspection is now being given. This is a new service but is expected to be self-supporting under authority granted to make reasonable charges for inspection.

The decision of the Supreme Court of March 1, 1926, in the case of the Oregon-Washington Railroad & Navigation Co. versus the State of Washington, in effect, ruled that, with the Federal plant quarantine act in force, "State action is illegal and unwarranted," and invalidated upward of 200 State quarantines. This situation necessitated an amendment of the plant quarantine act to make it possible for any State to take necessary protective action with respect to any subject which has not been specifically taken up under Federal quarantines.

A joint resolution was therefore drafted, amending section 8 of the act to give such powers to the several States. This amendment received the sanction of Congress and was approved by the President April 13, 1926. The amendment also authorizes the Secretary of Agriculture to cooperate with any State, Territory, or district in the enforcement of any such quarantines and, further, gives authority for any State to exercise its police powers with respect to any articles shipped in violation of a Federal plant quarantine. The amendment of the act providing for Federal and State cooperation in quarantine activities should greatly harmonize and strengthen such activities in the future.

## ANIMAL INDUSTRY

The year just completed has been one of excellent progress in bettering conditions for the production of domestic animals. Methods for the eradication and control of animal diseases have been highly fruitful of results. Efforts to improve the quality of livestock by better breeding have shown gains both in public interest and in actual betterment of stock. In regulatory work also there has been a growing spirit of cooperation from individuals, transportation companies, the meat trade, and livestock organizations. This work has to do largely with supervising the importation and interstate movement of animals, inspection of meat, and supervising the manufacture of biological products.

It is gratifying to report that the United States again is free from the dangerous foreign malady, foot-and-mouth disease, which gained entrance in 1924 and recurred in 1925. Fortunately the ravages of the disease were confined in both outbreaks to limited areas in two States—California and Texas. Following a period of very close supervision over the regions affected—and especially of the rough, mountain ranges in California where deer had become infected—the department withdrew its last quarantine restrictions June 10, 1926.

The appearance of foot-and-mouth disease in Mexico near the end of the fiscal year was occasion for renewed precautions and vigilance. The department is optimistic, however, regarding the ability of the United States to maintain its freedom from the plague and to eradicate any infection which may ever gain entrance. Public sentiment supports the aggressive measures used in combating the malady by quarantine, slaughter, and burial or burning of infected carcasses. Success in eradicating the outbreaks of 1924 and 1925, and of establishing complete freedom from the disease in 1926, has been due largely to excellent cooperation among livestock owners and county, State, and Federal officials.

### BOVINE TUBERCULOSIS DECLINING

In the nation-wide effort to eradicate tuberculosis from livestock, results have been unusually gratifying. During the fiscal year 109 counties completed a series of tuberculin tests showing that infection had been present to the extent of not over one-half of 1 per cent. With the disposal of reactors and establishment of other safeguards the counties were recognized as virtually free from bovine tuberculosis. This number is greater than the total of all previous years and brings the total list of such counties to 198. The acceleration of progress in establishing county-wide areas free from tuberculous cattle supports the belief of department livestock officials that the task of eradicating bovine tuberculosis from the United States is feasible, though still of great magnitude and likely to require many more years.

During the progress of the present systematic campaign, which began late in 1917, the extent of bovine tuberculosis in the United States has declined from about 4 per cent to 2.8 per cent. These figures are estimates based on more than 25,000,000 cattle tested. A reduction in per cent means a large corresponding reduction—

when applied to all cattle in the country—of economic losses and of menace to the livestock industry. More than that, the decline of the disease in cattle means that the menace to the human race, and especially to small children, is gradually being removed. The experience of inspectors engaged in field work has revealed scores of cases in which there was an intimate relation between tuberculosis among livestock and of people on the same farm, or who used raw milk from tuberculous cattle. Public sentiment is strongly behind the campaign to eradicate tuberculosis while the degree of infection is still low—which fortunately is the condition in most localities. Prompt and aggressive measures will save many human lives, reduce losses of animals, and put the stock-raising industry on a safer, sounder basis.

Liberal appropriations for the work made this excellent progress possible. The testing is done only by trained and qualified men and under a system which insures economy of operation. The number of cattle tested during the year was 24 per cent greater than during the previous fiscal year, yet the demand for the work exceeded facilities for testing, and 4,000,000 cattle were on the waiting list for testing when the year closed. As further indication of public interest, a survey made during the year showed that over 1,200 cities and towns in the United States now have municipal ordinances requiring the tuberculin testing of cattle furnishing milk for consumption. The ordinances, the survey showed also, were being fairly well enforced except in about 1 per cent of the cases.

Meat-inspection records for the year show a gratifying decline in tuberculous infection among hogs. Of the domestic animals besides cattle and hogs, poultry also are susceptible to tuberculosis. A survey showed that fowl tuberculosis is serious in several areas, especially around the Great Lakes and westward. Suitable field measures, combined with distribution of explicit directions for reducing losses, are the means being taken to improve the situation.

## HOG-CHOLERA LOSSES

With the present widespread knowledge concerning the preventive-serum treatment for hog cholera the swine industry can be protected from heavy or sudden losses caused by that disease. As in the previous fiscal year the toll of hog cholera during the fiscal year ended June 30, 1926, was unusually low. In fact, there has been no period of exceptional prevalence since 1913–14, which was before the discovery of the cause of hog cholera and the development of means to immunize hogs against it.

The experience of nearly two decades indicates that modern methods of prevention and improved farm sanitation can stop the periodic waves of hog cholera, which before 1914 caused sudden and staggering losses and were disheartening to swine growers throughout the country.

During the fall of 1926 a situation arose which demonstrated clearly the importance of keeping swine immunized against this highly contagious disease. Owing to the slight extent of cholera in recent years, a very large proportion of swine owners discontinued the practice of immunizing their herds. As a further result the commercial production of serum declined in proportion.

Both of these conditions—large numbers of susceptible animals and shortage of serum—were responsible for extensive outbreaks in several hog-growing States until serum production again met the requirements of the industry.

## ERADICATING CATTLE TICKS

The work of eradicating cattle ticks from the areas in the South where ticks are still present continues to gain ground. Cooperative tick-eradication activities during the year resulted in the releasing of 18 counties and 9 parts of counties from Federal quarantine on account of tick fever. The areas released were: In Alabama, two counties and one part of county; in Arkansas, two counties and two parts of counties; in Florida, six counties and four parts of counties; in North Carolina, seven counties; and in Oklahoma, one county and two parts of counties. In the area previously released, 72 counties in which some tick infestation still existed were rendered entirely tick free. At the close of the fiscal year 723 of the 984 counties originally in the quarantined area were released. Of this number 601 counties were reported as entirely tick free.

During the fiscal year 1926 Texas, or tick, fever was, by act of Congress, placed in the list of contagious, infectious, or communicable diseases of livestock. The act of Congress creating the Bureau of Animal Industry in 1884 provided by a special provision "that the so-called splenetic or Texas fever shall not be considered a contagious, infectious, or communicable disease within the meaning * * * of this act."

To understand the apparent inconsistency of this special exemption it should be remembered that in 1884 little was known of this cattle malady, which became known as Texas fever because it often followed the introduction in northern pastures of cattle from Texas. It should be remembered also that the 1884 law antedated by about five years the bureau's discovery that the cattle tick was the carrier of this disease.

Following this discovery and particularly since systematic efforts at tick eradication have been undertaken, the repeal of this provision has been frequently recommended. But it was not favorably acted upon until the present year, when an act approved June 28, 1926, repealed the provision in section 6 of the 1884 law permitting the movement of tick-infested cattle for slaughter. The present law provides "that until May 1, 1928, cattle infested with or exposed to cattle-fever ticks may be shipped in interstate commerce for immediate slaughter after one dipping in accordance with such regulations as the Secretary of Agriculture may prescribe." After May 1, 1928, only tick-free cattle will be permitted in interstate commerce.

## SWINE SANITATION

Besides the diseases mentioned, which are of major importance, there has been progress also in reducing the toll of certain others both by regulatory and educational methods. The system of swine sanitation, developed by the Bureau of Animal Industry a few years ago in Illinois, is now being widely and effectively used throughout the Central West. It has not only greatly reduced losses of pigs from roundworms and associated ailments but has improved the vigor and growth of pigs raised according to the system.

Extensive experiments for the control of stomach worms of sheep completed during the year at Vienna, Va., point to the ineffectiveness of pasture rotation alone for preventing losses from this pest. Though of some benefit, the mere changing of pastures as frequently practiced is much less effective than dosing the sheep periodically with a dilute solution of copper sulphate.

During the year the department began extensive investigations of animal parasites at two field stations in the South—McNeill, Miss., and Moultrie, Ga.—there being special need for a better understanding of Southern parasite problems.

## QUALITY IN LIVESTOCK

The importance of high quality in domestic livestock has been continually urged by the department. Well-bred animals are the basis of a profitable livestock industry and an ample supply of good-quality meat and products. A definite method used for the last six years for increasing the use of purebred sires now has approximately 17,000 followers enrolled to use purebred sires exclusively in their livestock-breeding operations.

During the year Union County, Ky., after five years of persistent effort, has succeeded in banishing all scrub and grade bulls and establishing itself as the first county in the United States to use purebred bulls exclusively, there being 145 within its boundaries at the close of the year. The stallions, jacks, and boars of the county were purebred also so far as known, but effort has been centered on the improvement of cattle, owing to the large production of beef there. The accomplishment is especially noteworthy since it marks the success, on a county-wide basis, of an activity heretofore limited to progressive individuals or associations made up of specially interested persons.

Forty-three other counties in various States are likewise making outstanding progress and bettering their livestock. In each of those counties 100 or more owners have agreed in writing to use purebred sires for all classes of animals raised. The greater earning power and better selling price of well-bred stock continue to be apparent.

Through arrangements with the management of Sni-a-Bar Farms near Kansas City, Mo., the department obtained and published some of the results of an extensive demonstration conducted for 10 years in the improvement of an ordinary herd of cows by the use of purebred bulls. The marketing data and other results furnish convincing evidence that good breeding is a dominant factor in the production of high-quality beeves and that good feeding and management will not return best results unless the element of good breeding is present also.

## MEAT INVESTIGATIONS

In accordance with plans made during the previous year, important research is now in progress to determine factors which influence the quality and palatability of meat. The experimental work takes into consideration numerous factors, including age, sex, breeding, grade, and feed. Nineteen States cooperated with the department in the first year's work. In technical studies of the kind undertaken the necessity for accurate measurements was apparent early in the work for determining and expressing quality in meat other than by personal judgment. The development of equipment included machines for measuring color accurately and for determining the tenderness or breaking strength of muscle fibers. Slaughter records in connection with meat research include not only studies of carcass weights, dressing per cent, and quality of meat, but also weight of organs both full and empty, length of intestines, and numerous other details.

### Soft-Pork Problem

Earlier investigations to determine the causes of " soft pork " and the opportunities which may exist for correcting the conditions producing it were continued in cooperation with 13 State experiment stations. The condition appears most noticably when hogs are fed certain rations, such as those containing peanuts, soy beans, and other oily feeds. Formerly soft pork was regarded as a problem chiefly of the South and dependent in large degree on rations containing peanuts. Developments during the last year's experimental work now show clearly that other feeds, notably soy beans, are likewise important, and that soft pork is a problem to be reckoned with wherever hogs are produced. The experiments are resulting in systems of feeding by which any of the softening feeds may be used to some extent, without necessarily producing soft carcasses.

## ANIMAL PROTEINS

The chemical and physiological studies of meat and meat-food products have furnished new knowledge concerning the nutritive value of proteins in animal tissues. The supplemental value of certain meat proteins to that of vegetables is especially of interest. The protein of beef, for instance, enhances to a remarkable degree the nutritive value of protein in wheat, bolted wheat flour, corn meal, oatmeal, and rice; that is, when consumed in combination with beef proteins cereal proteins are much more efficient for promoting growth than when the latter are fed alone. In the same way certain animal products, such as tripe, calves' sweetbreads, beef blood, and beef serum, which are of low biological value when fed alone, are greatly improved in value when fed with the proteins of beef muscle or beef liver.

Other biological studies have revealed the mode of action of disinfectants. This work, which is highly technical, shows which chemical members of various series of compounds have the chief power of destroying bacteria. Several products studied proved to be of exceptionally high bactericidal power. Research of this kind has its practical uses in the treatment and eradication of diseases and in increasing the effiectiveness of disinfectants.

## LIVESTOCK EXPERIMENTS

Three years of experimental work conducted in Texas and New Mexico have shown that calves can be fattened in a comparatively short time on the feeds produced in the Southwest. Experiments in West Virginia, which apply also to surrounding territory, have shown that cattle to be marketed off grass in the fall can be wintered satisfactorily—so far as gains are concerned—on almost any combination of feeds produced in the Appalachian region. Silage, cottonseed meal, and straw proved to be a more desirable winter ration than hay and grain.

Studies of wool production under western range conditions showed that length of staple is one of the most important factors influencing the weight of wool per fleece. The breed used in these experiments was the Rambouillet, and owners of such sheep should find it profitable to breed for fleeces of longer staple.

A five-years' comparison to determine the advantages of early or late lambing under New England conditions strongly favored the latter. Net profits for ewes that lambed late (May and June) were more than twice as great as for ewes that produced lambs early (February and March). The principal reason for the advantage was the lower cost of feeds. Late lambs and their mothers did well on cheap pasture, whereas the early lambs and their mothers required expensive feed.

### Poultry-Breeding Work

Poultry-breeding work conducted at the department experiment farm at Beltsville, Md., resulted in increased production and a larger proportion of hens which laid 200 eggs or more annually. In poultry-feeding tests the benefit of cod-liver oil in rations of chicks raised in confinement was apparent. Removal of the oil from the rations of such chicks resulted in greatly increased mortality and poorer growth.

An important undertaking of the year in poultry work besides the experimental activities was the formulation and development among States of a uniform plan of accreditation and certification of hatcheries and breeding flocks. The essential purpose of the undertaking is the establishment of inspection and supervision, thereby enabling purchasers of fowls, of baby chicks, and hatching eggs to obtain stock free of disease and of the quality represented. The department also instituted cooperation with the management of official egg-laying contests with respect to the adoption of uniform rules and regulations.

## MEAT INSPECTION RENDERS WIDE SERVICE

Of the various regulatory services which the department conducts for the benefit of the American public, Federal meat inspection is one of the most important and extensive. During the year this service was maintained in 896 establishments in 251 cities and towns throughout the country. It covered the inspection of more than 68,000,000 food animals both before and at the time of slaughter. The supervision extended also to the preparation of a wide range of food products derived from such animals. The service as now conducted extends to about two-thirds of the food animals slaughtered in the United States, the remaining one-third being local or intrastate slaughter not subject to Federal supervision under the Federal meat-inspection law. During the year, Federal inspection of meats made possible the exportation of about 1⅓ billion pounds of meat and meat products to foreign countries which require certificates of inspection. This Federal activity thus aids in furnishing an outlet for a surplus of meats grown on farms and ranches of the United States.

### Small Proportion of Condemnations

The general condition of food animals coming under Federal inspection has been reasonably good, the proportion of entire animals or carcasses condemned being less than one-half of 1 per cent. Parts of carcasses failing to pass inspection were more numerous, amounting to about 1.6 per cent of the number of animals inspected.

Meat-inspection records for the year continue to draw attention to a distressing condition at meat-packing centers, namely, the large number of animals which Federal inspectors find dead or in a dying condition. The numbers of such animals for the year are: Swine, 37,103; cattle and calves, 10,367; sheep and goats, 8,763; making a total exceeding 56,000 head of stock. Besides representing a large loss of meat and food products, the unfortunate condition of the animals entails much suffering and reflects on a branch of commerce which has earned widespread recognition for its highly perfected organization and efficiency in other respects. The total of 56,000 dead or dying animals found at market centers is, of course, a very small proportion of the livestock receipts, but the figure appears to be needlessly large and capable of reduction by the combined efforts of all persons shipping and handling livestock.

### Supervision of Biological Products

The inspection of biological products intended for sale in interstate commerce was attended by a noteworthy increase in the number of certificates which the department issued for their exportation. A total of 467 certificates—more than a third greater than last year—were issued to accompany shipments to 22 foreign countries. These products, which include serums, viruses, and toxins, are important in the prevention, diagnosis, and treatment of various livestock diseases. Federal inspection of their manufacture deals largely with supervision that insures purity and potency. The quality of biological products made under Federal inspection continues to be satisfactory and in conformity with the high standard established for them.

## BAIT FOUND FOR PEACH MOTH

Steady and remarkable progress along many lines has been made by the Bureau of Entomology during the last year. An attractive bait for the peach moth has been found. It has also been found that in its overwintering stages in the soil this destructive insect can be destroyed by two thorough cultivations. Furthermore a thorough study of the life history of the insect in Georgia indicates that the peach moth will not be a serious peach pest there.

The problem of the plum curculio in the peach orchards of Georgia appears to have been solved, although only a few years ago much consternation was aroused by the ravages of this insect.

Because of the general adoption of control measures worked out by entomologists of the department in cooperation with State experiment stations, the Hessian fly has been held to a minimum since 1919, and one of the best wheat crops in years has been harvested this year. The control of the Hessian fly has saved millions of dollars to the wheat growers, both in quality of their product and in yield per acre.

The European corn borer has been held to territory not much greater than that which it inhabited last year. No severe damage has been suffered in the United States. Based upon our thorough investigations of the biology of this insect, agricultural engineers have been able to develop farm machinery which mechanically destroys the corn borer while at the same time it performs the necessary harvesting operations at little or no increased cost. The efforts of the department through the effective cooperation of State organizations in thus retarding the spread of this injurious insect have resulted in the saving of millions of dollars.

A demonstration carried out to determine the effectiveness of the department's recommendations against the rice weevil, in which a small island off the coast of Georgia was the field of operations, has shown that this insect can be controlled economically.

In southern California investigations have shown that, with the proper field control practices, bean-weevil injury can be almost completely eradicated. Heretofore the loss from this insect has been very great, mounting into the hundreds of thousands of dollars.

### Contact Spray Developed

A satisfactory contact spray has been found which can be used successfully against the Japanese beetle. Better soil insecticides have also been developed for use against the larvae of this destructive insect, and the advantages of geraniol as an attractant for the beetles have been more apparent. It seems probable that the department in its active work in delaying the commercial spread of this pest will have gained the necessary time for the development of control measures before the enormous damage is done which this insect has threatened.

Many thousands of parasites of both the European corn borer and the Japanese beetle have been brought in good condition from Europe and the Orient, and from Europe department experts have also sent parasites of the alfalfa weevil, the European earwig, and the European elm-leaf beetle.

The Gipsy moth has been held within its old boundaries of spread and the large New Jersey colony of the insect is under thorough control and approaches extermination.

Poison dusting from airplanes has been effective against the cotton boll weevil and the cotton leaf worm and is now being tried out with considerable success against the alfalfa weevil.

An extraordinary outbreak of the cotton flea hopper occurred in the early summer of 1926 and great damage was threatened. Investigation showed that a fair degree of control may be reached by the proper use of sulphur on the cotton plants.

White ants or "termites" cause millions of dollars damage to the wood of buildings each year. Methods of control have been formulated and specifications prepared for use in the creation of termite-proof buildings. These plans have been placed before municipal engineers for adoption in their building codes.

An important result of careful studies is the finding that the western pine beetle has a tendency to select the slower-growing trees. This shows a possibility of eliminating the susceptible trees through selective logging operations.

## INVESTIGATIONS IN MILK PRODUCTION

Increasing the efficiency of dairy cows so that the same amount of milk and butterfat can be produced from fewer cows at less cost is the quickest way of increasing the net income of the American dairy farmer. The average yearly production of butterfat per cow in this country is about 180 pounds. This is much too low. With such an average it is apparent that many farmers are not realizing a profit from the dairy business. Investigations by the department point to the possibility of increasing this average perceptibly within the next few years by laying special stress on certain fundamentals in dairy-herd management.

It has been found that the inherent ability of cows to produce milk varies to a great extent. One cow of certain parentage may possess the ability to produce large quantities of milk and butterfat economically, whereas another from the same parents may be entirely lacking in this ability. Another problem is that of the proper feeding of dairy herds. Why does one cow utilize feed to better advantage than another? Why does one kind of feed produce better results than another? The problems of dairy cow nutrition which involve not only the protein, carbohydrates, and fats in the feed, but also the calcium, phosphorus, and other minerals, as well as vitamins, are far from being solved.

Investigations now underway in the Bureau of Dairy Industry deal directly with these problems. Results so far indicate that through the finding of dairy sires that are pure for the transmission of high milk and butterfat production, it will be possible to mate animals so as to be reasonably sure the offspring will be high producers. These pure sires are being located through the testing of large numbers of cows and their daughters. When all the daughters of one bull invariably produce more than the dams of those daughters, almost regardless of how low or how high the production of the dams may be, it seems highly probable that this sire may be pure for the transmission of high production. Such a bull would be regarded as a proved sire and should be kept in use as long as he is serviceable. Many such bulls have been found and in finding them many inferior bulls have likewise been located. There is as much advantage in destroying the latter as in making the fullest use of the former.

### Great Dairy Improvement Possible

Great improvement in dairy herds can be accomplished through a more general use of purebred sires. Fewer than half of the dairy bulls now in use are purebred. By eliminating scrub bulls and replacing these with purebreds, a distinct advance can be made in increasing dairy production. The department is now undertaking to extend the use of purebred dairy bulls through cooperative bull associations and through organized scrub bull eradication campaigns.

Improvement in dairy production is also possible through better feeding of dairy cows. This includes the balancing of the ration so as to furnish not only sufficient protein, carbohydrates, and fat, but also mineral matter and vitamins. It has long been known that heavy milking cows need an abundance of mineral matter in their diet. This may be supplied through the proper selection of feeds, and the use of a liberal amount of legumes. However, it makes a difference how these legumes are cured.

Investigations by the department show that when cows get brown stemmy alfalfa which has been exposed to the rain or to too many days of hot sun, they often can not assimilate more than 5 per cent of the lime contained in it. Accordingly, they must draw on their bones for a large part of the lime needed in their milk. This results in decreased milk production, and possibly difficulties in rearing their young.

On the other hand, when cows get green leafy alfalfa which has been cured without getting wet by the rain and without too much exposure to the sun, they are able to assimilate about 20 per cent of the lime contained in it. They do not need to draw on the lime contained in their bones in order to supply what is needed for the milk or for reproduction.

Another closely related problem concerns uncertain breeding and temporary sterility among dairy cows and heifers. To determine whether or not this condition was caused by a shortage of vitamins in the ration, shy breeding cows and heifers were fed fairly large quantities of sprouted oats and wheat germ, these two feeds having been reported to contain vitamin E in abundance. After receiving sprouted oats for periods ranging from 10 to 114 days, a number of such animals were pronounced pregnant.

### Utilization of Dairy By-Products

It is imperative that more attention be given to the efficient utilization of the by-products of butter and cheese manufacture. Over 28,000,000,000 pounds of skim milk, buttermilk, and whey is produced in this country each year. Of this amount 22,000,000 pounds is skim milk from the manufacture of butter. In this great volume of by-products is nearly 900,000,000 pounds of protein and 1,400,000,000 pounds of milk sugar. All of this is in a form available for human food, but under the present conditions the greater part of it is fed to farm animals. Although by this means it is converted into human food in a different form there is a very material loss in the process. The 2,500,000,000 pounds of edible dry matter in the dairy by-products fed efficiently to hogs would be converted into only 400,000,000 pounds of edible dry matter in the form of pork, or if fed to chickens would produce only 110,000,000 pounds in the form of poultry.

The department is undertaking investigations which are planned to reduce this loss by converting skim milk, buttermilk, and whey into convenient form for combining with other foodstuffs. Special attention has been given to the properties of dry skim milk in bread making and to methods of utilizing the proteins of whey. A process has been developed and established in commercial practice for converting skim milk into a stable product which can be used efficiently for poultry feeding. It is hoped, however, that eventually the uses of skim milk in human food may be developed so fully that only the small part essential to the proper development of young animals will be retained on the farms.

## DUST-EXPLOSION PREVENTION

Progress was made in work to prevent dust explosion in industrial plants. Dust-explosion regulations have been developed in cooperation with the National Fire Protection Association for flour and feed mills, sugar-pulverizing systems, cocoa-pulverizing systems, pulverized fuel installations, terminal grain elevators, and starch factories. These regulations embody the precautionary measures developed for the prevention of dust explosions and fires in representative industrial plants. The regulations have been adopted by the National Fire Protection Association and also by the National Board of Fire Underwriters, and have become the standards for insurance and State officials.

The development of the use of inert gas for the prevention of dust explosions is an achievement which should prove of particular interest to manufacturers of dusty products who have a dust explosion hazard in their plants. Feed manufacturers will benefit particularly from the work of the past year because the first tests and demonstrations have been made with feed-grinding equipment. Although it has been known for years that inert gas could be used to extinguish or prevent fires, the actual application of the principle had not, so far as is known, been tried with feed-grinding equipment.

### Inert-Gas Method in Use

Equipment to provide inert gas for preventing explosions during the grinding of sulphur and hard rubber is already in actual operation in a number of plants and the tests made in the department during the past year indicate that it will be possible to provide in practically all feed-grinding plants insurance against dust explosions by means of inert gas.

The presence of static electricity on belts and operating equipment is a great dust-explosion hazard. It is one of the most difficult hazards to control, and up to the present time no satisfactory mechanical method has been developed to prevent its formation. Electrically-grounded combs and brushes on belts merely dissipate the charge after it has been formed and increase the hazard if the ground wire were to become broken. For this reason no grounding method for static electricity can be regarded as an absolutely effective control measure. Encouraging results are being obtained in tests on a waterproof, dry surface, rubber-belt composition. Laboratory tests on a leather-belt dressing have been so successful that plans are now being made to try it out on an industrial scale.

## DETECTING FROZEN ORANGES

Research work was conducted to determine the chemical changes that take place in oranges during freezing in order that methods may be developed for detecting and separating out the frozen oranges. It is highly important both for the producer and the consumer that frozen fruit be eliminated before shipments are made to market. Unfortunately, frozen oranges can not be detected merely by inspection. If some certain method for sorting out all frozen oranges can be devised, it will be of immense benefit to the fruit-growing industry and also to the consumer. If separated out in time at point of production, the frozen oranges can be used in the manufacture of by-products.

### DETERMINING MATURITY OF FRUITS

One pressing problem confronting the growers of fruits is to know at exactly what stage of maturity to pick the fruit in order that it may reach the market in the best possible condition. If the fruit is picked too early it never attains its finest flavor and the market for the fruit is impaired by the unsatisfactory flavor. On the other hand, if the fruit is not picked until too late it is very likely to start deteriorating before it reaches the consumers.

Losses from this cause are especially large when the fruit is shipped long distances. It is not practicable to determine by physical examination alone when the fruit has reached that degree of maturity which is best for picking. Some chemical test is necessary. The Bureau of Chemistry laboratory at Los Angeles has made a study of the chemical factors that are affected by degrees of maturity in various fruits in order to devise tests by which the growers can determine when the fruit should be picked.

In previous reports the results of work on tests to determine the maturity of cantaloupes and oranges have been outlined. These tests for maturity have been applied commercially to oranges for a number of years and to cantaloupes for two or three years. They have saved growers from great losses. During the year work has been completed on maturity standards for raisins and the results published. A tentative standard has been worked out for maturity in pomegranates and has been tested through one crop. Work to develop maturity tests for other fruits is under way.

### CHEAPER EMULSIONS FOR CONTROLLING INSECTS

Lubricating oil emulsions and miscible oils are used principally for the control of San Jose scale, citrus white fly, and citrus scale insects. In recent years their use has increased greatly. The formula for making lubricating-oil emulsions, which is now most generally employed, requires heat or a large proportion of soap. In the preparation of the boiled emulsion the use of heat is both time-consuming and expensive, and in the case of the cold emulsion formula, calling for the increased proportion of soap, the cost of the product is greatly increased.

As the result of a comparative study of this problem by the Bureaus of Chemistry and Entomology, a modification of the method of making cold-mixed emulsions was developed which gives a product that is apparently as stable and as effective as the best boiled emulsions, and one that can readily be made by the orchardist. The proportion of soap is the same as, or less than, that used in the present formula for boiled emulsions, so that the cost of the product is materially decreased. This emulsion may be made and shipped in paste form containing only 8 per cent of water. The packing and shipping charges will thus be much less than if the ordinary concentrated emulsion were shipped. Last spring one grower made and used several thousand gallons of this product against San Jose scale with satisfactory results.

A soap-cresol-oil emulsion was also developed which contains less cresol, the most expensive ingredient, than the usual miscible oil and is therefore less expensive. When diluted for spray use it has the small-drop size and stability in hard water characteristic of miscible oils, and spraying experiments indicate that it is equally as toxic to insects as the product made by the old formula.

## NUTRITIVE VALUE OF WHEAT BRAN

Previous studies on the proteins of wheat bran conducted in the Bureau of Chemistry have shown that these proteins differ essentially from the corresponding proteins of the other parts of the wheat kernel. They contain much larger quantities of the so-called nutritionally essential amino acids than are contained in the endosperm proteins. Wheat bran contains more than twice as much of these important amino acids as are present in the same weight of white flour.

In the light of these results obtained from a chemical investigation of the proteins of wheat bran, feeding experiments with albino rats were undertaken to further study the nutritive value of the bran proteins, and also to ascertain to what extent these proteins are available for assimilation when animals are fed, not the isolated proteins, but the crude bran.

Although wheat bran has long been recognized by practical feeders of animals as having high nutritive value, nevertheless there has been almost no experimental work done to determine the nutritive value of the proteins of wheat bran in which the bran supplied all the protein in the diet. It is generally conceded that bran is fairly well digested by ruminants which have digestive tracts adapted for the accommodation of coarse, bulky material such as hay and fodder. As for its food value for animals other than ruminants, particularly as a food for man, many conflicting views are expressed, ranging from the statement that bran is wholly without food value to statements that it is an excellent food, and that it is digested by man as well as by domestic animals.

### Bran Well Utilized

The feeding experiments, in which about 70 albino rats were used, have shown that the proteins of bran are well utilized by rats and that the ability to digest the proteins in crude bran is not limited to ruminants as is frequently asserted. Rats have lived for nearly two years, a period which corresponds to about two-thirds of the normal span of a rat's life, on a diet containing no protein other than that supplied by crude bran. During the period of early growth they grew at a rate better than normal, but after arriving at the early stages of maturity, development practically ceased.

In a similar diet in which the protein was furnished by white flour instead of bran the animals gained during the first 100 days only one-half to two-thirds as much as the rats on the bran diet. Those receiving the white flour grew slowly, yet their rate of growth was so uniformly maintained that at the end of 254 days most of them weighed even more than did the rats that had been receiving the bran diet for the same length of time.

It appears that wheat bran contains in abundance certain factors required for the growth and development of young animals, but does not satisfactorily meet the animal's nutritional requirements after it has reached maturity. Rats fed the bran diet have produced offspring, but they had little success in rearing them. Fecundity was low. The high efficiency of the bran ration for promoting early growth, and the less satisfactory results obtained with it in connection with subsequent growth and reproduction are a striking example of how the nutritional requirements of an animal vary with the changing stages of development coincident with advancing age. This also emphasizes the need of giving consideration to this phase of nutrition in connection with the practical feeding of domestic animals for animal production.

## THE FEDERAL FOOD AND DRUGS ACT

Progress was made in promoting the purity and truthful labeling of food and drugs through the enforcement of the Federal food and drugs act. This year is the twentieth anniversary of the enactment of the law. The department looks upon this act as a corrective measure rather than a punitive one and, in enforcing it, endeavors to render assistance to the industries in improving their products. For instance, a survey made a few years ago revealed that canned blueberries from Maine contained excessive quantities of maggoty berries. Several shipments of these were seized in various parts of the United States. The canners and growers of blueberries thought it impossible to reduce materially the quantity of maggots in blueberries. The blueberry-canning industry was threatened with ruin, since maggots in canned food constitute a violation of the food and drugs act. Blueberries are the chief crop of one county in Maine, and the livelihood of many people was threatened.

Staff specialists were sent from the department to study the situation, in collaboration with officials of Maine. As a result of the study, an apparatus was devised by means of which it is possible to eliminate the maggoty blueberries. The first season after this device was invented, it was used by a few canners with marked success. The next season, a still larger number used it and put up a product that met the requirements of both Federal and State food laws. Practically all of the principal canners have now adopted means that insure a legal product. Federal and State food inspectors patrolled the canneries to assist in eliminating maggoty berries and to see that the canned product met the requirements of the law. The educational methods followed by the Federal and State food officials have been effective both in saving an industry from great losses and in enabling consumers to obtain an unobjectionable product.

### Deterioration in Sardines

Inspection of the sardines packed in Maine in previous years revealed that a considerable portion of fish which had undergone a form of decomposition known as " belly blown " was included in the pack. Numerous shipments of decomposed sardines were seized and extensive educational work to demonstrate methods for putting up a good pack was carried on. A survey was made to ascertain if educational work done among the sardine packers during the last few years had been effective. Packing plants were visited five or six times. It was found that the educational and regulatory campaigns had accomplished commendable results. Notwithstanding rather comprehensive sampling, no goods of last season's pack were found of a character warranting action under the Federal food and drugs act.

When individual concerns persist in violating the law, or when violations involve deliberate fraud either through adulteration or misbranding, the full penalties of the law are invoked to correct the trouble. For several years a bad situation existed in the salmon-canning industry in that a few canners persisted in putting up decomposed fish. An extensive campaign was carried on to stop this practice. Several seizures were made and a number of hard-fought contests in the courts resulted ultimately in verdicts for the Government. This has demonstrated to those packers who are not disposed to put up a sound and wholesome pack that it is incumbent upon them to revise their methods of operation and market an article which will comply with the law. The department has had the whole-hearted support of the better element of the industry, which through pressure on offending members has assisted in the process of reform. Examination of a large number of shipments of canned salmon during the last season has shown that great improvement has been made in this industry, and that the great bulk of the canned salmon shipped in interstate commerce now meets the requirements of the law.

## VITAMIN CONTENT OF OYSTERS

Notwithstanding the fact that oysters constitute the most valuable fishery product of the United States, nothing previously has been ascertained regarding their content of vitamins A, B, and D. Work was therefore undertaken to determine the value of oysters with reference to these diet factors. An additional interest is connected with this investigation inasmuch as a large part of the food of oysters consist of diatoms and minute organisms—marine forms of life to which have been traced the origin of the fat-soluble vitamins found so abundantly in certain fish liver oils, such as that of the cod.

Fresh, medium-sized oysters obtained in the open market were frozen and ground. Graduated dosages of the frozen material were tested for its vitamin content by means of feeding experiments with albino rats according to methods in general use for vitamin determinations. The results of these experiments show that oysters are rich in vitamins A and B. Quantities of fresh oyster equivalent to half a gram, calculated on a dry basis, caused prompt resumption of growth when fed daily to rats that had declined in weight as a result of deficiency of vitamin B in their ration. Even smaller quantities were found to practically meet the requirements of rats for this vitamin. Similar quantities of oysters have been efficacious in curing an eye disease in rats caused by a deficiency of vitamin A.

## MANUFACTURE OF SIRUP AND SUGAR

Work was continued on a procedure for producing unsulphured cane sirup of good quality from low-purity cane juice. Important progress was made. This work will permit heavy milling and greater extraction of juice in the manufacture of this type of cane sirup and will reduce the loss resulting from low juice extraction. When used in conjunction with sugar production it will be possible to use the higher-purity juice for sugar, the lower-purity juice representing higher extraction being used for making sirup. This will make for greater economy in the commercial utilization of sugar cane under domestic conditions.

As a part of this investigation, a method for producing a new product called "cane cream" has been devised and production of this product on a semi-factory scale will be undertaken during the season of 1926. Cane cream, which is also made from lower-purity juice, has a consistency similar to that of confectionery fondant, with a characteristic cane flavor. It can be made of widely varying consistency, and can be used in a variety of ways, such as in sandwiches, on griddle cakes, and in preparation of cake icing. The cost of manufacture is moderate, and the use of lower-purity juices for producing cane sirup and cane cream will make possible greater efficiency and economy in the manufacture of sugar from higher-purity juices when used in conjunction therewith. The fabrication of these products is part of a general plan for the production of specialties which is believed to be of great economic importance for the cane-sugar industry.

Considerable progress was made in an investigation of the fundamental conditions governing clarification of cane juice in the production of raw and plantation granulated sugar. Because of lack of full understanding at the present time of the various factors which control clarification of juice, the elimination of nonsugar substances from juice in sugar manufacture is conducted with a varying degree of efficiency, and the maximum clarification possible is far from being consistently attained. It is known that the exact combination of conditions required for maximum clarification of cane juice varies greatly, depending on such factors as variety of cane, soil, kind of fertilizer used, degree of maturity of cane, whether the cane has been burnt or not, and length of time the cane has been cut. Methods are being devised whereby the juice can be tested from time to time and suitable adjustment made in clarification conditions, so as to obtain uniformly the maximum efficiency possible with the clarification process used.

A method has been worked out whereby the clarification of acid digestion liquors in the manufacture of glucose and corn sugar may be considerably improved. This is of much importance, in view of the fact that uneliminated colloidal substances interfere with the growth of corn-sugar crystals. If the crystals are too small, difficulty is experienced in separating them from the mother liquid by centrifuging. Greater elimination of colloidal substances is therefore desirable, corn sirup of greater clarity resulting. This improvement is of distinct benefit to the rapidly growing corn-sugar industry, which in 1925 produced almost 600,000,000 pounds of this sugar.

## FEDERAL-AID ROAD CONSTRUCTION

Continuing the Federal-aid road work, which has now been in progress for 10 years, the department, cooperating with the several State highway departments, brought to completion during the last fiscal year road-building projects involving the improvement of 9,417 miles. This brings the total mileage improved with Federal aid during the 10-year period up to 55,903 miles.

At the close of the fiscal year construction was in progress on 10,962 miles, and projects involving 2,470 miles had been approved for construction. Thus the cooperating Federal and State authorities have so far undertaken or completed the improvement of 69,335 miles, all of which, with the exception of a few hundred miles completed prior to 1921, is included in the interstate system of 182,135 miles known as the Federal-aid highway system, designated in that year in accordance with the Federal highway act.

The Federal-aid highway system is a real interstate system, designated in the first instance by the several State highway departments and approved by the Federal authority. The manner of their designation by those whose knowledge of traffic conditions is most intimate justifies the presumption that the roads constituting this system are the most important through highways in the country. Nearly a third of this important system has already been improved to a degree commensurate with present traffic demands under the Federal-aid plan, and the work currently in progress will raise the proportion well beyond a third. As reports of the State highway departments indicate that at least an equal mileage has been improved by the States without Federal assistance, it is probable that nearly three-quarters of the system is already improved or in course of improvement.

Ten years ago when the Federal-aid road work was begun there were only five States in which there was an improved road across the State. To-day 25 States have continuously improved highways entirely across them in at least one direction and 16 of these have completed such trans-State arteries in two directions.

### Status of Transcontinental Roads

A recent survey of the status of improvement of the Federal-aid highway system shows that there is now one transcontinental road which is 97 per cent improved. This is the road from Washington through St. Louis, Texarkana, and El Paso to San Diego. Of other roads crossing the continent one which runs from Atlantic City to Astoria is seven-eighths improved; another from Norfolk to Los

Angeles is 68 per cent improved; and one from Boston to Seattle is 73 per cent improved.

It is the primary purpose of the Federal-aid highway legislation to expedite the improvement of such interstate roads; and the rapid progress that has been made in the last 10 years toward that end is in large part the result of the Federal participation.

The projects completed during the fiscal year 1926 include 2,161.3 miles of roads graded and drained, 627.3 miles surfaced with sand-clay, 3,274.1 miles surfaced with gravel, 58.2 miles of waterbound macadam, 553.2 miles of bituminous macadam, 179.6 miles of bituminous concrete, 2,464.3 miles paved with Portland cement concrete, and 78 miles with brick. These with the bridges completed, aggregating 21.3 miles in length, make up the total of 9,417.3 miles completed during the year and added to the length of the corresponding types completed previously bring the total up to 55,902.8 miles, as shown in the following table:

*Mileage of Federal-aid roads completed up to June 30, 1926, by types of construction*

| Type of construction | Miles completed to June 30, 1926 | Type of construction | Miles completed to June 30, 1926 |
|---|---|---|---|
| Graded and drained | 9, 653. 6 | Portland cement concrete | 11, 976. 5 |
| Sand-clay | 4, 926. 2 | Brick | 752. 0 |
| Gravel | 22, 547. 3 | Bridges | 121. 5 |
| Water-bound macadam | 1, 123. 3 | | |
| Bituminous macadam | 3, 176 3 | Total | 55, 902. 8 |
| Bituminous concrete | 1, 626. 1 | | |

## Cost of Completed Roads

The total cost of the roads completed during the fiscal year was $206,139,220, of which the Federal Government paid $90,294,107. These sums were expended on the 9,417 miles of new construction and on 1,193 miles of roads previously improved to raise the type of the prior improvement in accordance with traffic demands. The total Federal disbursements to the States during the year amounted to $87,754,534. This was the amount paid for work on all projects during the year.

The total of Federal-aid funds apportioned to the States from July 11, 1916, to June 30, 1926, was $671,375,000 which is $3,686 for each of the 182,135 miles included in the Federal-aid highway system. That the apportionment per mile of the system to the States of the several geographic divisions is substantially in accordance with the relative need for highway improvement as expressed by the number of motor vehicles per mile of the system, and with the relative character of the Federal-aid roads that have been constructed as indicated by the percentage of high and intermediate type surfacing, is shown by the following table:

*Relation of Federal-aid apportionments and motor vehicles per mile of Federal-aid system and percentage of high and intermediate type surfaces constructed in the several geographic divisions*

| Geographic division | Average apportionment per mile of Federal-aid system | Number of motor vehicles per mile of Federal-aid system | Percentage of high and intermediate type surfacing |
|---|---|---|---|
| Middle Atlantic | $7,165 | 343 | 98.3 |
| New England | 5,175 | 223 | 75.8 |
| East North Central | 4,240 | 187 | 71.9 |
| Pacific | 4,186 | 193 | 36.7 |
| East South Central | 3,810 | 61 | 28.2 |
| South Atlantic | 3,793 | 85 | 38.7 |
| Mountain | 3,705 | 32 | 10.2 |
| West South Central | 3,187 | 74 | 27.8 |
| West North Central | 2,475 | 62 | 14.3 |

## FOREST-HIGHWAY CONSTRUCTION

Within and adjacent to the national forests there have been designated as forest highways 13,459 miles of important roads, of which 10,954 miles are in the 11 States of the Mountain and Pacific groups. Approximately 8,041 miles of these highways which either coincide with or are possible extensions of the Federal-aid highway system are designated as class 1 or class 2 highways according as they lie entirely within the forests or extend to outside towns. The remaining highways, including about 5,418 miles, are largely of local service and are designated as class 3.

Particularly in the Western States the forest-highway construction has been an important adjunct of the Federal-aid road work. As the national forests lie in general along the mountain ranges, the improvement of highways across them is necessarily expensive because of their rugged topography, their inaccessibility, and the shortness of the working season. Yet these forest links constitute vital connections in the main transcontinental and interstate routes, especially where they occupy the principal mountain passes. By virtue of these conditions the liberal appropriations made by Congress for road construction in the national forests are of importance not only in the development and protection of the forest areas and their immediate locality but are of benefit to the entire country, in that they make possible the construction of essential interstate and transcontinental highway connections.

The mileage of forest roads brought to completion by the Bureau of Public Roads during the fiscal year was 622.5 miles, which added to that previously completed brings the total at the close of the year up to 3,045.6 miles. These figures are subdivided by States in the following table:

*Mileage of forest highways completed by Bureau of Public Roads, by States*

| State | Completed during the fiscal year 1926 | Completed up to the close of the fiscal year 1926 | State | Completed during the fiscal year 1926 | Completed up to the close of the fiscal year 1926 |
|---|---|---|---|---|---|
| | *Miles* | *Miles* | | *Miles* | *Miles* |
| Alaska | 30.7 | 146.4 | New Mexico | 44.3 | 164.1 |
| Arizona | 89.2 | 216.6 | North Carolina | | 16.4 |
| Arkansas | 2.3 | 56.8 | Oregon | 133.5 | 464.9 |
| California | 56.4 | 202.6 | South Carolina | | 5.3 |
| Colorado | 32.1 | 211.4 | South Dakota | | 34.8 |
| Florida | 6.2 | 64.2 | Tennessee | | 12.2 |
| Georgia | | 8.6 | Utah | 16.3 | 259.0 |
| Idaho | 44.4 | 383.6 | Virginia | | 6.5 |
| Minnesota | 19.4 | 34.6 | Washington | 29.6 | 184.1 |
| Montana | 66.9 | 303.3 | Wyoming | 39.6 | 173.8 |
| Nevada | 9.4 | 94.2 | | | |
| New Hampshire | 2.2 | 2.2 | Total | 622.5 | 3,045.6 |

## HIGHWAY RESEARCH

For the better discharge of its obligations in connection with the administration of the Federal-aid and forest-road work the department has conducted for a number of years a series of researches into the design and construction of highways, the economics of highway transportation and construction, and the materials of construction best suited to resist modern traffic. The department has taken the lead in this field of research and its efforts, supplemented by those of the State highway departments and engineering experiment stations, have laid the foundation for the rational and economical methods of highway administration, design, and construction that have been developed within the past five years.

## ALKALI-RESISTANT CONCRETE PIPE DEVELOPED

After five years' research in cooperation with the University of Minnesota and the State department of drainage and waters, methods have been developed by the use of which concrete drain pipe can be made that can be satisfactorily used in alkali soils in which the content of sulphate of magnesium and sodium is less than 2,500 parts per million. With extreme care in manufacture, even more severe conditions can be satisfactorily overcome. This work of the department and its cooperators makes possible the use of concrete tile for farm drainage in large sections in which previously the use of concrete pipe has been impossible because of deterioration resulting from attack by alkali.

## EXTENSION WORK

At the end of the fiscal year 4,965 persons were engaged in cooperative extension work, of whom 3,513 were located permanently in the counties. Of these, 2,221 were employed as county agricultural agents or assistant agents, 882 as home demonstration agents, 135 in boys' and girls' 4-H club work, and 275 in negro extension work. These county workers were assisted by 764 full-time and 218 part-time subject-matter specialists located at the State agricultural colleges. Supervisors, assistant supervisors, and administrative officers numbered 470. Funds from all sources available for cooperative extension work during the fiscal year 1925–26 amounted to $19,853,726, an increase of about $240,000 over the previous year. Of the total funds, 62.2 per cent was allotted for extension agents in the counties; 5.7 per cent at the State agricultural colleges for administration; 10.8 per cent for supervision of county extension forces; 19.5 per cent for the employment of subject-matter specialists to supplement the county workers; and 1.8 per cent for activities of the Federal Extension Service in general supervision, administration, and coordination.

Farmers and farm women conducted about 770,000 extension demonstrations, and farm boys and girls in 4–H clubs about 590,000, a combined increase of about 225,000 demonstrations over the previous year. Improved practices were adopted on farms and in farm homes in nearly 4,000,000 instances during the year as a result of extension influence. More than 200,000 farmers and farm women gave valuable aid to the paid extension staff as volunteer local leaders in the promotion of extension activities. Effective training for extension agents and volunteer local leaders was emphasized during the year. Increased attention was given to the development of a wholesome and attractive life in the open country.

The department continued to cooperate with the State extension services in studying the effectiveness of various phases of extension work in the field. The studies made in 1923–24 in typical areas of seven counties of four States indicated that extension effort had brought about the adoption of one or more improved practices on three farms out of every four and that, on the average, 3.4 improved practices were adopted on each farm reached. These studies were broadened during the year to include special surveys of junior extension work in Massachusetts, local leadership in New Jersey and South Dakota, negro extension work in Georgia and Arkansas, and alfalfa extension in Wisconsin.

### Progress in Smut Control

Outstanding work was done during the year by extension plant pathologists in influencing farmers to adopt the copper carbonate treatment for the control of stinking smut of wheat. Twenty-five States reported successful results in the use of copper carbonate in preventing loss from this fungus. One State found the treatment so satisfactory that about 90 per cent of the total wheat acreage was sown with treated seed.

Under the Clarke-McNary reforestation act, $50,000 was available during the year for assisting farmers in the management of woodlands, the reforestation of waste lands, and the more satisfactory utilization of woodlot products. This fund has been allotted to the State extension services at the rate of $1,500 to each State providing at least an equal amount for the employment of an extension forester. At the end of the year 25 States were cooperating on this basis.

In home demonstration work the number of demonstrations conducted by farm women increased 36 per cent over the previous year. Clothing, foods, nutrition, home management, house furnishings, and home health and sanitation were leading lines claiming the time and attention of extension workers with farm women and girls. In addition to productive and management activities, opportunities for recreation and self-development were sought and created by farm women through their extension organizations. This was evidenced by the numerous community and county recreational and social events which were held, such as contests, camps, and pageants.

## BOYS' AND GIRLS' CLUBS

One of the important functions of the State agricultural colleges and the department is to keep farm boys and girls in touch with the best in rural life and develop leadership, community responsibility, and good citizenship. This is largely accomplished through 4-H clubs organized by the extension service. In 1925 there were 41,286 of these local clubs in which 565,046 farm boys and girls were enrolled. The largest enrollments were in work with poultry, corn, swine, cotton, home gardening, dairy cattle, clothing, food preparation, nutrition, beautification of home grounds, food preservation house furnishings, and home health and sanitation.

Large as this enrollment is, only one in twenty rural boys and girls between the ages of 10 and 18 is receiving the instruction, training and helpful guidance to which all are entitled. Many farm boys and girls are not attending school. To reach a larger proportion of the boys and girls in the country, a program for the systematic development and expansion of 4-H club work has been adopted. This program contemplates encouraging county agricultural and home demonstration agents to interest more boys and girls in 4-H club activities where this is possible without decreasing their work with adults, or to employ an assistant agent or club agent to give their full time to farm boys and girls.

Agricultural exhibits were presented during the year at 46 State and interstate fairs, and at about a dozen minor exhibitions. A large and comprehensive exhibit of the various activities of the department was prepared for presentation at the Sesquicentennial International Exposition in Philadelphia, a special appropriation having been made available for that purpose.

## NEW MOTION PICTURES MADE

The department is making large and satisfactory use of motion pictures in presenting many phases of its work to the public. Approximately 25 new pictures have been made each year for the last few years, and the department now has films in circulation on more than 200 subjects. The Office of Motion Pictures has available 1,485 copies of the various department films, many of which are in constant use by its extension and research workers. Some of the most effective work in promoting campaigns for the eradication of plant and animal diseases, such as white-pine blister rust, bovine tuberculosis, and the southern cattle tick, has been done through the use of motion pictures. In the tick-eradication campaign two motor trucks equipped with projection apparatus have been constantly engaged in presenting the advantages of tick eradication in rural communities, in many of which motion pictures have not been previously shown. This work has been so effective in creating favorable sentiment that plans are now under way for the making of a new motion picture on tick eradication, those previously made having been so widely shown that new material is needed.

For the past few years demonstrators have been at work on several of the Federal reclamation projects, particularly for the purpose of encouraging livestock production. These men have been maintained entirely from Federal funds, but during the last year arrangements have been made with State extension officials for their cooperative employment, in most instances as members of the State extension service. This plan has served to coordinate their activities with those of other extension workers and has brought to the reclamation projects the additional services of specialists from the State colleges of agriculture. Funds released by the taking over of portions of salaries and expenses by State and county agencies have been utilized in the employment of extension agents on additional projects where this service has been much needed. The demonstrators in the past have been very helpful in promoting the development of dairying, poultry raising, the production of sheep and swine, the growing of forage and pasture crops, and the giving of advice on other agricultural problems. A notable example in the development of dairying is found on the Newlands project in Nevada.

## THE PURNELL ACT

Striking testimony of confidence in the efficacy of organized agricultural research was afforded by the passage of the Purnell Act for the more complete endowment and maintenance of the State agricultural experiment stations, which went into effect July 1, 1925, and added $960,000 to the $1,440,000 previously received by the stations through the Hatch and Adams Acts, and will ultimately (in 1930) increase the Federal endowment of the stations to $4,320,000 annually.

During the first year of the operation of the Purnell Act over 600 new research projects dealing with problems of primary importance to agriculture and rural life were successfully undertaken by the stations with notable broadening and strengthening of their field work and improvement of the cooperative relations of the department and the stations.

The Purnell Act was the first Federal legislation to give explicit authority for work by the experiment stations in agricultural economics, rural sociology, and home economics. The stations had previously done a considerable amount of substantial research in these fields, but lack of means and trained personnel had prevented the development of such research to the extent that its importance merited.

### Research in Economics

While not neglecting the fundamental questions of efficient production, the newer work recognizes more fully the importance of finding solutions for the economic and social problems of the farm and the farm home. Clear evidence of this is found in the fact that half of the new projects undertaken under the Purnell Act deal with such problems. It is believed that the better-balanced program of research thus made possible will contribute to greater efficiency and profit in the operation of the farm and to the development of a more satisfactory rural home life. Altogether, the first year's experience under the new act has been very satisfactory.

The expectation that the operation of the Purnell Act would lead to a considerable expansion of the already large cooperative relations between the stations and the department, especially in the relatively new fields of agricultural economics, rural sociology, and home economics, has been fully justified. The department and the stations are now cooperating in approximately 500 formal projects and in a large number of less formal ways. This means more efficient, less wasteful, and more speedy methods of attacking, and finding practical solutions for, some of the larger problems affecting farming and the farm home.

## NITROGEN FIXATION

During the last year contact with the nitrogen-fixation industry has been maintained by the Fixed Nitrogen Research Laboratory. The industry has been served through the usual channels of publication, and the laboratory has been conducting various investigations in order to furnish further fundamental data.

A number of technical men have left the department to enter the synthetic ammonia industry.

Progress in nitrogen fixation in the year 1925–26 has been encouraging. About half a dozen industrial plants are now in operation in various parts of the country and others are planned or under construction. The combined capacity of these plants is now nearly sufficient to furnish all of the ammonia needed in the country for the refrigerative and chemical industries. The point appears to have been reached where the decision must soon be made as to whether this industry will expand into the field of nitrogen fertilizer on a large scale. While this step encounters competition from by-product ammonia, agriculture seems likely to profit by this competition through price reductions.

A synthetic-ammonia plant, mentioned in the last annual report as having been installed to use the process developed at the Fixed Nitrogen Research Laboratory has now been in full operation for more than a year. The mechanical design as well as the catalyst and other features have proved satisfactory. While cost data have not been available, it is estimated that the cost of production has been low.

### Making Ammonia Fertilizer

The laboratory has continued during the present year to investigate the important subject of urea synthesis. Now that it is known that ammonia can be synthesized at a favorable cost, the next most important step is to be able to convert it economically into one of the various forms suitable for fertilizer use. Urea is one of the most attractive of the possibilities, since carbonic acid, the only other chemical needed besides ammonia, can be very cheaply obtained. The problem consists in working out a continuous process that will be sufficiently economical. The investigation is still in the stage where the different unit operations are being studied, and it is too early to predict what the result will be when the entire cycle is put into operation.

The engineering division of the laboratory has just completed the design of a laboratory compressor to operate at 1,000 atmospheres. The compressor will be used in studying catalytic processes at very high pressures.

## FIRE-WEATHER FORECAST SERVICE

Weather is a factor of large importance in the preservation of forests. Fire is the greatest menace to forestry and losses each year from this cause are enormous. Information in advance of weather conditions tending to the inception and spread of forest fires or to the putting out of fires already in progress is of inestimable value to protective agencies of the forests by enabling them to increase lookouts, assemble fire-fighting forces, and take other measures to stop any fires that may start.

In recognition of the need for an intensive fire-weather forecasting service a special appropriation, a part of it becoming immediately available, was made by Congress during its last session for the organization of such a service in some of the large forested sections of the country. To that end a conference, participated in by officials of the Weather Bureau, the Forest Service, State forestry organizations, and representatives of privately owned forests, was held in April at Portland, Oreg., to devise plans for the work. This purpose was accomplished and fire-weather warning districts were established for California, Oregon, Washington, northern Idaho and Montana, and southern Idaho, with headquarters, respectively, at San Francisco, Portland, Seattle, Spokane, and Boise. A trained meteorologist and forecaster was assigned to each district and arrangements made for providing service before the advent of the summer fire-hazard season.

Additional meteorological substations were established in the forests from which weather reports were obtained daily for use in connection with the forecast work and a system was organized whereby the forecasts and warnings were expeditiously distributed by telephone, telegraph, and radio to the protection agencies in the forests. The value and efficiency of the forecasts were demonstrated in connection with the exceptionally numerous and serious forest fires which occurred in the Western States.

Plans also were made for establishing as soon after July 1 as possible similar fire-weather forecast projects for the forested areas of Minnesota, Michigan, and Wisconsin and for the Adirondacks and New England.

## WEATHER MAPS BY RADIO

In the latter part of the fiscal year arrangements were made by the Weather Bureau to conduct experiments for the transmission of weather maps to ships at sea by means of radio. For many years bulletins containing weather observations from land and ship stations have been broadcast twice daily for the benefit of ships in addition to general weather information, forecasts, and warnings.

Many masters enter the data on special base charts provided them for the purpose and prepare weather maps which are of great value in navigating ships. The purpose of the experiments is to transmit maps which are far more complete and accurate than can be made by ship masters. The experiments are now in progress and the project gives promise of success.

## FRUIT-FROST WORK

Because of heavy frost damage to citrus fruits in California during the winter of 1924–25, many fruit growers in that State who had not heretofore protected their orchards by heating installed heating equipment during the year, and demand on the frost specialists of the Weather Bureau for cooperation and advice was unusually heavy.

Eight specialists were assigned to duty during the frost-danger season in the citrus and deciduous fruit districts of the Western States, and there were urgent requests from fruit interests for additional service in these sections, as well as in other portions of the country. This service has become one of the most valuable conducted by the bureau.

It was not possible to meet the many requests made for extension of a specialized fruit-frost service. Accordingly, to assist fruit growers to the greatest extent possible a cooperative arrangement was made with the California State College of Agriculture whereby local representatives of that institution in a large number of counties served as meteorological observers in cooperation with the Weather Bureau district forecaster at San Francisco. Special frost warnings were thus made available to fruit growers in many parts of the State.

## WEATHER-CROP WORK

An outstanding feature of last year's work was the establishment of more than 50 additional telegraphic weather-reporting stations in the western and northwestern portions of the Cotton Belt. In recent years the area of cotton production has expanded into new territory, which was not covered by daily weather reports in these sections. This expansion was made possible through a special appropriation by Congress for this purpose, and affords daily weather information not heretofore available from important cotton-growing sections.

Weekly weather and crop bulletins are issued by the bureau showing weather conditions prevailing in different sections of the country as affecting crop growth and farm operations. The need for similar information as to weather conditions in other agricultural countries of the world has long been felt, so that the American farmer could keep in intimate touch with progress of world crops. Efforts were made during the year to obtain brief weekly weather and crop summaries from all the principal agricultural countries, and cooperative arrangements have been made so far with Canada, England, Argentina, India, and Australia, whereby reports from these are now published regularly in the Weekly Weather and Crop Bulletin. It is hoped in the near future to extend this service to still other agricultural countries.

## RIVER AND FLOOD SERVICE

However disastrous in other respects, the deficiency of precipitation during the year prevented severe floods, such as are often a source of serious loss. Such minor floods as did occur were forecast with promptness and accuracy. The most damaging of these from an agricultural point of view occurred in April in the rivers of Texas. The reported and entirely unavoidable losses to crops and livestock did not exceed $60,000, while the reported value of property saved through the flood warnings of the Weather Bureau was more than $200,000.

One outstanding new feature of the year was the inauguration of a system of distribution of river and weather reports, including flood warnings, by radio. This service is now in daily operation at a number of important river centers, especially Cincinnati, Ohio, where it is maintained in cooperation with the United States Engineer Corps. Through this service farmers are now able to obtain river and weather information at 10 a. m. each day, including Sundays and holidays, whereas formerly they were compelled to wait from 12 to 24 hours.

## UPPER-AIR SERVICE

In connection with the increased interest and activity in aeronautical matters, the Weather Bureau furnished considerable assistance and advice. Among the more prominent contributions of this character were: (1) The preparation of a comprehensive program of meteorological service along airways, published as part of a report on "Civil aviation" by the American Engineering Council and the Department of Commerce; (2) assistance in drafting an "Aeronautic Safety Code" for use in regulating commercial aviation; and (3) the publication of "Aeronautical Meteorology," the first of a series of texts on all phases of aeronautics, known as the "Ronald Aeronautic Library."

Notable among the events of the year was the flight of Commander Byrd to the North Pole, a flight whose successful outcome was, as stated by Commander Byrd, in considerable measure due to the advice given by a Weather Bureau representative who accompanied the expedition and was stationed at Spitzbergen. Similar acknowledgement was received from Captain Amundsen for assistance in connection with his trans-polar flight in the *Norge*.

## HOME ECONOMICS

Probably the greatest service rendered by the Bureau of Home Economics up to the present time has been the preparation of popular bulletins bringing to the housewife the practical application of scientific facts. The popularity of these bulletins is shown by their distribution. Last year more than 2,000,000 were distributed by the department and by Members of Congress. Most of these bulletins deal with the selection, care, and preparation of food.

Housewives can make a large contribution to the family income by wise selection of materials. That this fact is appreciated is indicated by a large demand for the department's bulletin, "Floors and Floor Coverings " and also for a more recent one, " Selection of Cotton Fabrics." Bulletins on the selection of wool and silk are in preparation.

The department has for many years been interested in diet and nutrition. During the last year a summary has been prepared of all the dietary studies available up to the present time. Two conferences were called to discuss this problem, and the beginnings are being made now of a detailed dietary survey to furnish facts as to dietary habits. These facts are of importance in guiding the production and processing of food materials.

A circular entitled " Planning Your Family Expenditures " has been prepared, and a more detailed bulletin containing budgets for rural families with specific incomes is in course of preparation. This is based on material which has been collected in connection with the cost-of-living studies and actual household accounts. In cooperaton with the national meat-production committee, detailed experiments have been made on roasting meat. These show that a much lower temperature than has hitherto been employed yields a more satisfactory product on roasting. There is better preservation of flavor and less loss in weight during roasting when this method is employed.

## THE GRAIN FUTURES ADMINISTRATION

The Grain Futures Administration during the last fiscal year continued its studies relative to the volume of trading in grain futures on the various contract markets. During the 12 months ended June 30, 1926, the total volume of trading in grain for future delivery on the 11 contract markets aggregated 24,604,867,000 bushels of which 21,308,227,000 bushels, or nearly 87 per cent, represented trading on the Chicago Board of Trade, the leading grain futures market of the world. Of the total trading in all grains in all markets, 18,344,839,000 bushels, or nearly 75 per cent, represented trading in wheat futures, of which Chicago contributed 15,869,030,000 bushels or nearly 87 per cent. During the year the total volume of trading in wheat futures was only 567,000,000 bushels less than the previous year, while the total volume of trading in all grains decreased by 6,812,000,000 bushels, or nearly 22 per cent.

### Big Transactions Covered Up

An investigation in the early part of the year revealed a number of instances in which trading operations were distributed in such a manner as to keep below the limit required for the making of reports to the Grain Futures Administration, thus making it possible to cover up large transactions which at times were important market factors. To meet this situation it was necessary to amend the rules and regulations pertaining to the enforcement of the grain futures act so as to require persons making large commitments to report their holdings direct to the grain exchange supervisor.

In the belief that the wheat growers of the Pacific Northwest would benefit through a near-by futures market, the Merchants' Exchange Clearing House of Seattle, Wash., was designated as a contract market under authority contained in the grain futures act on January 29, 1926. Trading in wheat for future delivery on the Seattle Exchange was started May 1. While it is yet too early to determine the benefits to be derived from this market, the trading during the first few months indicates that it will be of value to the wheat farmers and will likewise afford the country dealers and millers of the Northwest the hedging facilities so long needed.

### Progress in Enforcement

During the past year progress was made in the enforcement of the grain futures act. Through cooperation with the exchanges designated as contract markets under the act, business-conduct committees were created by the important exchanges. These committees were given broad powers over the transactions in futures and so far have accomplished some excellent results in the keeping of prices more nearly in line with supply and demand. This was especially marked in the December and May wheat futures at Chicago when the business-conduct committee in cooperation with the Grain Futures Administration prevented the cornering of the wheat market.

A special investigation occasioned by extreme fluctuations which occurred in the price of wheat futures during the early part of 1925 was completed and the results thereof published as Senate Document No. 135. This investigation revealed a close correlation between the wide daily fluctuations and the transactions of a limited number of professional speculators who bought or sold May wheat to the extent of 2,000,000 bushels or more within a single trading day. Further investigation covering transactions in the 1926 May wheat future confirm the conclusions set forth in Senate Document No. 135 that these heavy trading operations may move prices far out of the normal line; and may temporarily destroy the hedging value of the futures market. Steps have already been taken to work out some plan, in so far as the authority contained in the grain futures act will permit, to eliminate from the market those hazards which are so unmistakably reflected whenever excessively large lines are held by a few individuals.

## LIVESTOCK-DESTROYING PESTS

Cooperative campaigns for the control of predatory wild animals during the year have resulted in a saving of livestock and game valued at more than $5,000,000. Skins or scalps of 202 wolves, 35,619 coyotes, 3,204 bobcats and lynxes, 167 mountain lions, and 176 stock-killing bears were taken, and reports indicate that a much larger number was destroyed in the poisoning operations but not recovered. These campaigns were conducted in cooperation with State departments of agriculture, State livestock commissions, game commissions, agricultural extension services, and stockmen's associations. Cooperators contributed approximately $375,000 and the department $274,220 in support of this work. Operations for the suppression of rabies among wild animals also were successfully prosecuted as a part of the work of predatory-animal control, and were participated in by State and local health and sanitary officials.

A notable achievement during the year was the work of the predatory-animal organization of the department in California in organizing and successfully carrying through a cooperative campaign for the suppression of foot-and-mouth diseases among deer in that State. Cooperating with the Biological Survey in the work were the Bureau of Animal Industry, the Forest Service, the State department of agriculture, and the California board of fish and game commissioners. The successful outcome of the cooperative undertaking has ended a serious menace to the livestock industry, and the experience gained in the campaign will be invaluable in case of future similar outbreaks.

### Controlling Destructive Rodents

Special research work in the use of thallium compounds, crude calcium cyanide, and red squill for the control of destructive rodents has developed very important results. Cooperative poisoning operations to reduce agricultural losses from rodents covered more than 15,000,000 acres and made an estimated saving in crops and forage grasses of more than $6,800,000. The department contributed $166,680 and expert leadership, while cooperators provided $614,560 and a vast amount of voluntary labor in distributing the poisoned baits on Federal, State, and privately owned lands. Arrangements made for the purchase of supplies and poisons in wholesale quantities increased the effectiveness of the control measures and resulted in a marked reduction in costs to cooperators. This service is actively supported by farmers and stockmen because of its very evident and direct value to them. It is closely coordinated with the extension work of the department, with State agricultural extension services, State departments of agriculture, county commissioners, and agricultural, horticultural, and livestock organizations. When the work was first undertaken the annual loss caused by rodents in crops and forage over hundreds of millions of acres was estimated at approximately $300,000,000. The work of suppressing these pests has now advanced to the stage where the permanent improvement of conditions represents a saving of a substantial part of the former losses, in addition to benefits resulting from the operations for the year.

It has been found that in great areas on the national forests rodents are so destructive to young trees that without their control successful reforestation becomes almost, if not quite, impossible. For several years naturalists of the department have been studying these problems, and good progress has been made in the work during the present year. Studies of the life history of the porcupine, one of the most destructive of these animal pests, have been nearly completed, and the information gained is of direct practical value in the cooperative rodent-control operations.

### Attempts to Increase Quail

Important progress was made in the investigation of the causes of depletion of both native and introduced quail in the Southeastern States. The studies are being made in cooperation with resident sportsmen to determine the best methods of keeping coverts permanently stocked with this desirable game species. Particular attention is given to the causes of failures to rear young birds, including diseases, requisite food supply, and the control of such natural enemies as tend to keep the numbers of this economically important species reduced. During the year the department issued permits for importations of 37,134 quail from northeastern Mexico, mostly for liberation in Southern States. Three of the States importing the largest numbers—Kansas, Oklahoma, and Texas—furnished 20 years ago or more most of the stock for other regions, and during this year 1,000 quail were reintroduced at a point in Oklahoma from which some of the largest shipments were formerly made.

### Surveys of Wild Life

In continuation of its special and general investigations of definite wild-life areas, the department has sent biologists to parts of Alaska and Mexico to observe conditions affecting the welfare of migratory birds. In Alaska, studies were made early in the year of the fauna in the eastern Aleutian Islands and adjacent parts of the Alaska Peninsula, the home of a variety of important species of mammals and the breeding place of many game and other birds. Later in the year an expedition was sent to northern Alaska to band migratory wild fowl on their breeding grounds, to ascertain definitely their lines of flight, through the later recovery of the bands in other parts of the continent, as an aid to the administration of the migratory-bird treaty act regulations.

A biologist sent to Mexico for the purpose studied conditions on the principal wintering grounds of migratory waterfowl to obtain information necessary for consideration in formulating a possible arrangement with Mexico for the protection of migratory birds, similar in intent to the treaty that protects birds migrating between the United States and Canada. It was ascertained that the wild fowl, especially ducks, that go south from the United States to spend the colder months in numerous lakes and marshes in Mexico, are in need of better protection, as their numbers are decreasing through slaughter for market. The sale of migratory game birds is prohibited in both the United States and Canada under the terms of the migratory-bird treaty with Great Britain.

### Surplus Game on Reservations

An outstanding achievement in connection with the administration of game and bird reservations by the Bureau of Biological Survey during the year was the disposal of 389 surplus elk and their shipment by special train from the National Bison Range in Montana to an elk-breeding association in Massachusetts. The removal of most of the elk on this range had become imperative in order to conserve forage urgently needed for buffalo, mountain sheep, and other game, including a smaller number of elk, overgrazing having reached such a point as to threaten serious injury to the range and a permanent reduction in its carrying capacity. No precedent is known for the handling of live game animals on so large a scale, and these were only a part of the elk the department is under contract to furnish the purchaser, several hundred remaining to be delivered. The receipts from the sale of surplus stocks of game from the four fenced reservations administered by the Biological Survey netted the United States Treasury $26,530.74.

## CONSERVING ALASKA'S GAME AND FUR

That the new Alaska game law, after the first year of its existence, has had the approval and support of the public is evidenced by the treatment of violators in Territorial courts. In 55 cases brought for prosecution, 43 defendants pleaded guilty, 10 were convicted, and 2 were acquitted, and the penalties imposed included both heavy fines and imprisonment. The new law is administered by a resident commission of five members, one from each of the four judicial divisions of the Territory and the fifth the chief resident representative of the Bureau of Biological Survey. Through representation on the Alaska Game Commission the bureau renders great assistance to the commission in planning and carrying out its program of wildlife conservation.

In the short period the law has been in operation excellent results have been accomplished in the conservation of game and fur animals, one of the most valuable resources of the Territory. Skins of land fur animals exported from Alaska during the year were valued at $2,500,000, an increase of $500,000 over shipments of the previous year. With proper enforcement of the new law, the stocks of wild life can be materially built up and game and fur production increased. As game is the only fresh meat to be had in large portions of Alaska, and as big-game hunters are each year visiting the Territory in greater numbers, every effort will be made to maintain the big game to the capacity of the ranges.

## FUR FARMING

Fur farming is an important industry on suitable islands in southern Alaska, and is also well established in the United States and Canada. There are about 2,500 fur farmers in the United States and Alaska and about 1,500 in Canada, the majority of whom are raising silver and blue foxes. The total investment in the industry in the United States and Alaska is about $30,000,000 and in Canada about $11,000,000. Fur farming is also being undertaken in European countries and in Japan, where it is having a quiet but steady development.

The department maintains an experimental fur farm at Saratoga Springs, N. Y., where studies of the production of fur animals in captivity include economical methods of operation and the prevention and cure of parasitic and other diseases. Publications of the department on the propagation of fur animals are in continuous demand by persons who contemplate taking up the work and by those already engaged in it.

## INSECTICIDE AND FUNGICIDE INVESTIGATIONS

An important investigation that has been brought to a conclusion during the last year has been an investigation of the effectiveness against the San Jose scale of dry substitutes for lime sulphur solution. This work has demonstrated that the commercial products on the market, recommended as substitutes for lime sulphur solution, viz, calcium sulphur ("dry lime sulphur"), sodium sulphur, and barium sulphur preparations, when used at strengths recommended by the manufacturers, in fact in strengths much greater than ordinarily recommended, do not furnish a satisfactory control of the San Jose scale. These results, which have been published and widely circulated, will be of great value in all fruit-growing sections where the San Jose scale is prevalent, and will also enable the department to bring action against the manufacturers of these products under the provisions of the insecticide act, unless the faulty claims are corrected.

Two investigations that will be of great value to manufacturers, as well as to consumers of the products involved, are the determination of the rate of loss of nicotine from nicotine dusts after packing, and the rate of deterioration of bleaching powder during storage. Both of these products, as ordinarily packed for consumption, lose their strength more or less rapidly with lapse of time, and it is impossible for the consumer to determine before use whether or not the product will be effective for the purpose for which it is used. With the information now available, manufacturers will be able to so pack and label these articles that the consumer may buy and use them with more assurance that the results desired will be obtained.

### Worthless Lice-Control Preparations

A few years ago there began to appear on the market products to be administered to chickens in the food or drinking water to control lice, mites, and other external parasites. The products were delivered to purchasers by mail for the most part, and customers were obtained by inserting advertisements in farm papers and daily and weekly newspapers. Information obtained by the department indicated that such a method of freeing chickens of insects was of very doubtful efficacy and prompt action was taken to obtain official samples of the various products for analysis and test in connection with the enforcement of the insecticide act. Most of the preparations were some form of sulphur.

An easy way to rid chickens of insect pests evidently had its appeal to thousands of people who desired some easy way to get rid of a troublesome job. Tests were completed and the products found to be ineffective. Seizure of shipments, prosecution of manufacturers, and publicity by sending broadcast over the country copies of Service and Regulatory Announcements No. 48 were the means adopted to curtail the distribution of these products and inform the public concerning them. No doubt the board's campaign against the products has been very materially aided by the editors of farm papers, which formerly carried the advertisements, now refusing to permit their papers to carry advertisements of a remedy that they are convinced is without merit.

## DISINFECTANTS

The use of disinfectants is becoming more widespread in the home, on the farm, in industrial plants and institutions, and in all places of public assemblage. Considerable numbers of the disinfectants examined under the insecticide act have been found without, or practically without, virtue or merit as germ destroyers, although the labels, circulars, and newspaper advertisements created the impression that they were unexcelled. The regulation of these materials has been one of the most difficult problems connected with the enforcement of the insecticide act. The danger that lurks in the use of inefficient or partially efficient disinfectants is evident, especially where a contagious disease is to be dealt with. The sale of a material as a disinfectant which in practice does not disinfect, is something more than a fraud on the public; it is a menace to public health. The activity of the campaign made against disinfectants and the need for regulation is shown by the fact that 260 of the 1,050 notices of court judgments issued to date were based on samples of disinfectants. Without resort to prosecution, the correction of many labels was secured through correspondence with manufacturers. A great improvement has been brought about in the labeling of disinfectants in general. The campaign against adulterated and misbranded disinfectants of various kinds has been continued throughout the year, special attention having been given to disinfectants which are recommended at too great dilution to be effective.

## CALCIUM ARSENATE FOR BOLL-WEEVIL CONTROL

The campaign inaugurated in 1919 and involving the inspection of the calcium arsenate shipped to the South for use in controlling the cotton boll-weevil, was continued during the year. It was found that the composition of this article was growing more constant and satisfactory from the viewpoint of control and lack of burning qualities. The tonnage of calcium arsenate sold on the market each year is undoubtedly far beyond the tonnage of any other single insecticide or fungicide. Less than 10 years ago only a few thousand pounds of calcium arsenate were on the market. During the year nearly 20,000,000 pounds of the product was produced, most of which was used to protect cotton from the boll-weevil. The discovery a few years ago of the effectiveness of calcium arsenate against the cotton boll weevil was the signal for its production by many manufacturers who were inexperienced in making the product. Through the enforcement of the insecticide act the department was able to keep off the market many tons of this material which was improperly made. The application of this low-grade material would have resulted in direct damage to the cotton crop and indirectly would have been a deterring influence on the willingness of planters to follow the department's advice in the use of the material.

## THE FOREST PROBLEM

One of the major economic problems of agriculture is the forest problem. Future rural prosperity and agricultural stability are closely linked with successful timber growing as a permanent form of land use. One-fourth of the land area of the United States is forest land and in the main will continue to be forest land. The cutting out of forests and the withdrawal of forest-supported industries make for local and regional economic retrogression. They decrease population, curtail the farmer's local market, deprive him of opportunities to work in the woods in off times, lessen taxable values, and increase his own taxes, and give him fewer and poorer schools, churches, roads, stores, neighbors. Contrariwise, fully sustained yields from forest land through the intelligent practice of timber growing aid agriculture and both stabilize and promote rural prosperity. Social as well as economic welfare is involved.

Merely from the standpoint of farm crops forest products rank high. As a money crop, at the time of the last census forest products gave the farmer a return of nearly $220,000,000. This was a greater total than the farmers obtained from all sugar crops and was nearly half the value of the tobacco crop. Forest products consumed on the farm in such forms as fuel, fencing, and sawed and round construction material had a further value estimated at more than $175,000,000. Yet farm woodlands are seldom skillfully handled; they should yield much more. How to make full use of the growing power of his present forest land, and of other land on the farm really best adapted to forest use, is an urgent question for the individual farmer. Until he has the answer he is at a disadvantage. But as a problem of rural economics and rural social welfare the forest problem is of much broader scope.

### Lean Acres Add to Surpluses

Agricultural instability is increased if land is cultivated on which farming does not pay. Under the urge of land hunger and the momentum of agricultural expansion across the continent, the plow has sometimes broken ground where the soil was too poor or rocky, the slopes too steep, or the climate too dry or cold to afford the tiller a fair living. The war, with its appeal to the farmer to increase production as a patriotic obligation, brought under crops still more land of relatively low productivity. Agricultural surpluses are swelled by the output of these lean acres.

Much has been heard of the " abandoned farm " in New England. There and in some other Eastern States the tide of cultivation began to ebb long ago. Between 1880 and 1920 the improved farm land in New England decreased more than 7,000,000 acres—a reduction of over 53 per cent. In the Middle Atlantic States it decreased nearly 6,700,000 acres. For the country as a whole, however, it increased each decade. Between 1910 and 1920 the increase was not quite 25,000,000 acres, or 5 per cent. What the plow surrendered in the East between 1880 and 1920 was more than made up by what it conquered elsewhere.

Yet the rate of increase, which was fairly uniform down to 1910, slackened greatly thereafter. With the approach to exhaustion of new lands to settle not only the quantity but also the quality of the acreage brought under cultivation fell off; and farm abandonment is no longer limited to the older parts of the country. By the process of trial and error the line is gradually being drawn between the lands which can and the lands which can not be successfully cultivated under present conditions. It is important to promote rather than delay the adjustment, as one of the means of promoting agricultural stability.

### Grazing Homestead Act

The pressure for more land to homestead in the decade 1910–1920 was very strong. One of the consequences of this was the grazing homestead act. Under that act relatively little land was taken up on which settlement has been maintained. The grazing homestead act is now generally recognized as a mistake. The same demand for opening land to settlement led to the listing for entry of a considerable total of acres within the national forests, which, it is now apparent, were erroneously classified as agricultural, since they either have not been taken up at all or have been abandoned after settlement or have become the means of establishing families where a fair living can not be made. We are beginning to see that a healthy and prosperous rural life must be based on sound use of land, that public policies which fly in the face of economic laws do not promote permanent welfare, and that to convert forest land and pasture land into submarginal agricultural land has broader consequences than those which fall on the individual farmer and his family, or even on the local community.

To the individual they mean an uphill struggle, poor living, and often a losing fight; to the community sooner or later a net loss; but to the country at large they mean an undue depression of the prices of the crops produced and a material waste of productive power. Abandonment of cultivation makes the backward swing of the pendulum. It constitutes a necessary though painful correction of past mistakes. It points also to the need of avoiding so far as possible future mistakes of the same kind. A sound national policy of forestry aimed to bring about timber growing on the land for which timber will be the best-paying crop is a means to this end.

The development of such a policy must be accomplished by the Federal Government and the States jointly. The fundamental task is to assist and hasten the adjustment of land use to the productive possibilities of the land itself and to public needs for what can be grown. Many of the old fields and pastures of New England whose cultivation ceased from a quarter to half a century ago have been reclothed by nature with at least a partial growth and not infrequently with a valuable growth of forest trees. In some instances the owners of the land had the discernment to hasten this process by forest planting or to apply other measures of timber culture.

### Large Earnings of Timberland

To a remarkable degree the outcome has been favorable. Enough examples of the returns obtainable from timber growing in every part of the East are at hand to leave no doubt that it is the best form of use for a great deal of land formerly regarded as agricultural. The earning power of such land under timber is often astonishingly large, and going land prices are often materially below what that earning power would justify.

In short, there is no need to wait while economic forces work their slow and painful adjustment. Continuous right use of the land can get much more out of it than mistaken use which must subsequently be rectified by taking the back track. Nor is it necessary for the farmer, part of whose land will earn him most by producing timber, to wait while nature gradually restores a haphazard forest growth on abandoned fields. There is a much better remedy for misplaced agriculture, with its waste of human effort, than abandonment of use—the remedy of guidance and assistance to right use.

**In regions where large areas of logged-off timberlands are awaiting development, or where tax-reverted lands are common, the land, tax, agricultural, and forest policies of the individual States should be so integrated that they will all work together to restore to forest use as quickly as possible the land that ought to be so used. In** particular, State policies should aim to deter settlers from establishing on this land farms that in all probability are foredoomed to failure. Economic surveys and land classification such as Michigan has inaugurated are a means to this end. Colonization schemes which seek to dispose of land through high-power salesmanship, regardless of the consequences to those who buy, should be controlled. But the most important task is the work of research and education necessary in order that the farmer may know where and how to grow tree crops.

### Forest-Minded Farmers

The most economic apportionment of our farms into the three classes of plow land, cleared pasture, and woodland requires that our rural population be not only agriculturally-minded but forest-minded. Timber culture must become interwoven into the traditions of farm practice. How to grow trees well is a question no easier to answer that how to grow potatoes or apples or sugar beets well. Crude and elementary methods of handling the forest will not produce first-class yields. Carefully organized research and demonstration must be carried on to develop an adequate scientific basis for good silviculture, and as fast as knowledge becomes available it must be passed along to the farmer. For the latter purpose, fortunately, many agencies are at hand which can and must be efficiently utilized—the agricultural colleges, high schools, the elementary rural schools, agricultural extension, the agricultural press, and other like means of affecting thought and practice. This twofold task of scientific research and rural education in forestry is in the main a public function, which the Federal Government and the States must share, as they are sharing in essentially the same task for the advancement of agriculture generally.

Amongst the obstacles to farm forestry one of large immediate importance is the lack of an adequate source of supply of forest planting stock. To reforest farm lands for which trees constitute the best crop and on which artificial reforestation should be undertaken an enormous quantity of cheap nursery-grown stock will be needed. Until private nurseries and methods of commercial nursery practice have been developed to meet this need the only way apparent to speed up the restoration to productiveness of the many millions of acres of waste farm land is through public production and supply of small trees. The Clarke-McNary law opened a way for the Federal Government and the States to join hands in building up forest nurseries, and already encouraging and significant results are in evidence. Thirty-three States have inaugurated cooperation with the Federal Government under the provisions of this section of the law; the nurseries now in existence have a present capacity of 52,000,000 trees and an output in 1927 of approximately 80,000,000 trees is expected; and the demand for stock is rising at a gratifying rate.

## PROGRESS UNDER CLARKE-McNARY LAW

The Clarke-McNary law authorizes and directs the Secretary of Agriculture to recommend for each forest region of the United States adequate systems of forest-fire prevention and suppression. The law prescribed that this should be done in cooperation with appropriate officials of the various States or other suitable agencies. It also authorized and directed the Secretary to cooperate with the individual States in the protection of timbered and forest-producing lands from fire if he finds that the system and practices of forest-fire prevention and suppression provided by the State substantially promote the protection of forest and water resources and the continuous production of timber on lands chiefly suitable therefor.

This law clearly contemplates a program based neither on the theory that the remedy for whatever ills exist should be sought through the extension of Federal power into a new field or jurisdiction nor on the theory that the remedy must be left solely to the States to discover and work out, as falling in a sphere beyond the proper concern of the Federal Government. It recognizes that the problem is a national as well as a State problem, but it has in view neither Federal encroachment nor the affirmation of a "non possumus" in the name of "States' rights." Instead it aims at the assumption and accomplishment of a joint task, under a method of common counsels and agreement.

Excellent progress is being made under this law toward nationwide forest-fire control effected through a combination of voluntary action by lumbermen and timberland owners, State legislation to abate fire hazards, State protective systems, and Federal participation in the maintenance of these systems and in the development of the general policy. An outstanding example of State legislation is furnished by Idaho in the form of a law requiring lumbermen to dispose of their slash and making it obligatory upon owners of timberlands to provide satisfactory protection both for standing timber and for cut-over lands. The whole question of the extent to which woods practices require modification in the interest of protection as an essential for continuous timber production is being studied regionally by the Forest Service and the State forestry departments in cooperation.

### Better Cooperation in Prospect

This question is by no means simple. It will have to be carefully worked out, a step at a time, and with full opportunity for the cooperation of the lumber industry in analyzing the technical and practical problems involved and in devising the right remedies. This cooperation is on the whole in prospect to an unexpected degree, and with indication of a growing sense of responsibility to the public on the part of the industry, for the voluntary elimination of practices inconsistent with permanence of the forest resource to the extent that economic conditions make feasible.

The extension and improvement of organized protection of forest lands against fire under the stimulus of the Clarke-McNary law and somewhat enlarged Federal appropriations for this form of cooperation with the States has been notable. This is particularly conspicuous in the South. As the contribution of the Federal Government more nearly approaches the amount contemplated by the act, its influence and benefits will be proportionately increased. In the States which are doing most, the present financial share of the Federal Government in protecting the forest resources, basic for the supply of national needs, is exceedingly meager.

## THE NATIONAL FORESTS

The conduct of the Federal enterprise in forest management is on the whole proceeding satisfactorily along sound lines. It has the approval of the public, is directed with vision and intelligence, and is characterized by a high degree of business competence. The cut of national forest timber is on the whole steadily rising, though with minor fluctuations due to variations in market demand corresponding with the ups and downs of general business activity; last year's cut surpassed that of any previous year both in volume and in money value, aggregating the equivalent of 1,192,000,000 board-feet, with receipts from timber totaling $3,368,685.

The timberland on the national forests productive of lumber and other high-grade forest products is around 85,000,000 acres; its eventual annual yield is the equivalent of probably 7,000,000,000 board-feet, log scale; and while its current yield is about 2 per cent of the country's total cut of these products, its estimated eventual yield is around 14 per cent. To obtain this, however, some 2,000,000 acres of burned-over forest land must be restored to productivity through planting unless the slow and uncertain process of natural reforestation is to be looked to—a process at best of many decades, during which the cost of administration and protection must run as an accumulating charge. This is neither economy nor foresight. The timber which the land might be growing will be urgently needed by the public long before it can be produced in any case.

### Permanent Production is Object

As market requirements permit, national forest timber sales are converting areas occupied by mature stands from mere storehouses of wood into growing forests; and the first consideration in all plans for selling timber is not immediate revenue but maximum permanent production. The further this process of rejuvenation is carried, the greater the investment in the public enterprise of growing timber on these lands. Fire control is essential to keep this investment from being wiped out. It is also, along with forest planting where planting is necessary, the means of establishing young growth on all the land needing it—in other words, is in itself largely an investment and not purely an expenditure to safeguard the present merchantable timber and smaller trees. Future public timber requirements make it obligatory to build up the national forests as producing properties with the least possible delay. The program essential to accomplish this now lags. This holds true both with regard to the provision for forest planting and with regard to the provision for fire control.

The expenditures for forest nurseries and tree planting last year were, in round numbers, $170,000, out of a total for all purposes in connection with national-forest administration of over $20,000,000 or exclusive of roads and trails of over $7,000,000. The area planted was 11,552 acres. The area in need of planting is approximately 2,000,000 acres. Through the acquisition of new lands by purchase and exchange and through the ravages of fire in bad seasons like last summer, when with the present provision for fire control considerable losses are certain, the area in need of planting is becoming not less but greater. Were there to be no increase in the present area needing artificial reforestation, about 165 years would be necessary at the present rate to complete the task. Obviously no such delay could be tolerated. The question is merely how long the exigencies of the general financial program of the Government will continue to preclude entering on the task in earnest. In view of its importance I believe that some enlargement of the work at the earliest possible date is imperative.

## FOREST-FIRE PREVENTION

The summer of 1926 made clear that the time has come for a radical change in the method of making funds available for protecting the national forests against fire. The need is not for larger expenditures but for greater flexibility in the use of money. Altogether too large a part of the total now goes to fighting large fires which with better preparedness need never have spread over much ground or which need never have originated at all. It is emphatically a case of saving at the spigot and wasting at the bunghole. In the last 18 years fire fighting on the national forests has cost over $15,000,000. Of this about $9,500,000 was spent on fire fighting in five bad years. There is practically no limit to the expenditures which the Forest Service is expected to make if necessary in order to stop large fires. Thousands of men hastily recruited from the neighboring country, lumber camps, and other industrial enterprises interested in getting the fires out, and the sources of labor supply in the cities may then be thrown upon the fire lines; tools, bedding, subsistence, transportation, pumps, and equipment of any kind needed and quickly obtainable can be procured; and the fight can be waged week after week in the heart of the wilderness.

A plan that is therefore deemed eminently more desirable than the present one of bolting the barn door after the horse has been stolen is to provide adequate locks and safeguards in the beginning. In other words, we should prevent rather than have to put out at great expense the large destructive fires that have devastated such vast areas of valuable forests.

## VIOLATIONS OF REGULATORY LAWS

The solicitor for the department reported to the Attorney General during the year 2,509 violations of the various regulatory laws which have been intrusted by Congress to the department for administration. Of these, 861 involved criminal prosecution and 1,648 involved civil actions. Fines, penalties, and recoveries, secured in litigated and nonlitigated cases amounted to $11,911.18; decrees of condemnation and forfeiture were entered in 912 seizure cases tried under the food and drugs and the insecticide acts; and 900 notices of judgments were prepared for publication, pursuant to the requirement of these laws.

Applications for letters patent, 31 in number, on inventions of employees of the department were prepared and filed in the Patent Office. Twenty-seven applications were allowed and four were disallowed. The inventions patented covered a wide field in the patent art. Many of them were of unusual merit, and probably will be extensively used.

Titles to lands in excess of 200,000 acres were examined, resulting in the acquisition by the Government of 180,711 acres under the Weeks forestry law. Titles to considerable acreage were also examined for acquisition by the United States under the Upper Mississippi River wild life and fish refuge act. In the latter instance, the abstracts of title have been transmitted to the Attorney General for his consideration and approval.

## THE LIBRARY

The library of the department now contains about 200,000 books, pamphlets, and bound periodicals, 14,969 of which were added during the last year. More than half of these and about two-thirds of the 3,356 periodicals currently received were obtained as gifts, or by exchange for department publications. They come from nearly every civilized country of the world and in nearly every language. A mimeographed series of " bibliographical contributions " issued from time to time by the library has proved useful. Numbers 10 and 11 of this series were issued during the year. Number 10 is entitled " Refrigeration and cold storage; a selected list of references covering the years 1915–1924 and the early part of 1925." Number 11 is a " List of manuscript bibliographies and indexes in the U. S. Department of Agriculture, including serial mimeographed lists of current literature." The library of the Bureau of Agricultural Economics issued during the year 10 additions to its mimeographed series of "Agricultural Economics Bibliographies." One of these is entitled "Alabama: An index to State official sources of agricultural statistics," and is the first of a series of indexes to State agricultural statistics which has been undertaken by the Bureau of Agricultural Economics library in cooperation with the State agricultural college libraries.

## DEPARTMENT PUBLICATIONS

A total of 30,629,006 copies of the department's various publications were issued during the year. This includes 3,942,200 copies of periodicals and 26,696,806 copies of bulletins and circulars. About 60 per cent of the publications were new while the rest were reprinted to meet the demand for information contained in the older publications.

Greater printing costs made it necessary to restrict distribution of publications and to economize in printing wherever possible. The policy of sending out announcement cards calling attention to new titles was continued, with the result that thousands of bulletins were saved and made available for those to whom they would be

**of most value. The same plan was extended to include articles reprinted from the Journal of Agricultural Research.**

The newly established radio service aided materially in the distribution of agricultural information, carrying in condensed popular form much of that contained in bulletins and circulars. Thousands of those who listened to the radio talks wrote to the department requesting further information on the subjects discussed.

There has been an increasing demand for information in the nature of progress reports of the various investigations being carried on by the department. To meet this, preliminary reports have been issued in mimeographed or multigraphed form. Such reports serve a very useful purpose in that the information is made available before it is possible to issue a printed bulletin based upon the completed investigation and final recommendations.

## PERSONNEL SITUATION

On June 30, 1926, the department had on its rolls 20,742 employees. This is an increase of 155 employees over the total force on the rolls June 30, 1925, but during the year we have effected a decrease of 103 employees in Washington, making a net increase of 258 in the field service of the department. The increase is due to the expansion of certain lines of work for which Congress provided increased appropriations and for the execution of new duties placed upon the department by legislation. The turnover in the personnel during the fiscal year 1926 was 11.41 per cent which was approximately the same as the percentage during the preceding year. Further adjustments made in accordance with the salary classification act have had a tendency to stabilize the personnel situation, and with the benefits under the new retirement act, still further improvement may be expected.

## HOUSING SITUATION

Better housing conditions for the Department of Agriculture in Washington apparently are assured by the passage of the public buildings act approved May 25, 1926. From information available at this time the department is among the first of the executive branches for which new buildings are to be provided under this act. The central building connecting the east and west wings constructed some years ago presumably will be the first unit to be constructed for the department, conforming architecturally with the wings and in general with the original plan, modified so as to provide additional floor space. The construction of this building will result primarily in a great improvement in the appearance of the Mall and the building as a whole will be representative of the place of agriculture in the Nation. While, however, the construction of the central building will permit the further consolidation of the general administrative branches of the department, it will not provide much, if any, additional floor space for the department, since the present administration building and the several smaller buildings now occupied on the Mall presumably will be razed when the east and west wings are connected. The real relief from the present unsatisfactory housing situation, therefore, will come with the completion of additional buildings for the department for which provision is made in the building program. When these additional buildings are constructed it will be possible to bring together the numerous bureaus and offices at present scattered among some 40 buildings, many of which are located at points remote from the general departmental group. This will make for greater efficiency and economy in operation and will increase generally the effectiveness of the service which the public has come to expect from the Department of Agriculture. The actual accomplishment of the entire building program, therefore, will be a matter of extreme gratification not only to all members of the department but to the agricultural industry at large.

## GENERAL ADMINISTRATION

During the year the members of the department have continued to cooperate whole-heartedly in the observance of the permanent business policy of the organization, heretofore announced, which is in all matters, whether large or small, to insure value received to the taxpayers for every dollar spent for Federal activities. Typical instances of economies effected, better business arrangements established, etc., during the year have been reported to the Budget Bureau and will be found in the annual report of the director of that bureau for 1926, pages 107 to 124.

In my last report I called attention to the consolidation of the units engaged in work relating to the general personnel and business administration of the department into one office under the supervision of a director of personnel and business administration. The new arrangement has fully justified its establishment. The reorganized plan of operation has concentrated authority and responsibility and provided better and more economical administration. New opportunities for improvement in the methods of conducting Government business and for effecting economies are constantly being encountered and taken advantage of, and in addition a gratifying reduction in personnel and in expenditures for this class of work has been effected during the year in which the plan has been in effect. The United States Bureau of Efficiency also has continued to cooperate with the department during the year and has rendered valuable assistance of the most practical sort through investigations and recommendations concerning personnel and business procedure.

W. M. Jardine,
*Secretary of Agriculture.*

# FINANCIAL STATEMENT

## Expenditures, Department of Agriculture, Fiscal Year 1926

Funds expended and obligated for work under the supervision of the Department of Agriculture for the fiscal year which ended June 30, 1926, including road building, totaled $157,485,660.84, classified as follows:

### (1) *Regular work*

| | |
|---|---|
| For regular work of department (activities for which the department is directly and independently responsible), as follows: | |
| Office of the Secretary | $948, 599. 01 |
| Division of Accounts and Disbursements | 75, 247. 71 |
| Office of Information | 1, 084, 160. 87 |
| Office of Experiment Stations | 330, 872. 36 |
| Extension Service | 1, 538, 817. 66 |
| Weather Bureau | 2, 431, 090. 47 |
| Bureau of Animal Industry | [1] 12, 625, 199. 81 |
| Bureau of Dairying | 509, 143. 83 |
| Bureau of Plant Industry | 3, 802, 405. 22 |
| Forest Service | 8, 890, 292. 23 |
| Bureau of Chemistry | 1, 456, 862. 64 |
| Bureau of Soils | 393, 876. 60 |
| Fixed Nitrogen Research Laboratory | 240, 601. 49 |
| Bureau of Entomology | 2, 482, 768. 65 |
| Bureau of Biological Survey | 968, 021. 44 |
| Library | 68, 105. 18 |
| Bureau of Public Roads | 468, 624. 03 |
| Bureau of Agricultural Economics | 4, 747, 719. 08 |
| Bureau of Home Economics | 115, 022. 49 |
| Insecticide and Fungicide Board | 187, 115. 81 |
| Federal Horticultural Board | 687, 832. 92 |
| Packers and Stockyards Administration | 401, 415. 05 |
| Grain Futures Administration | 100, 033. 10 |
| Farmers' seed grain loans | 22, 560. 39 |
| Total expenditures for regular work | 44, 576, 388. 04 |

### (2) *Other than regular work*

For work administered by department, supported by Federal funds provided as direct aid to States for special forestry and wild-life conservation work and similar objects, as follows:

| | | |
|---|---|---|
| **(a) Special conservation work:** | | |
| Cooperation with States in fire protection of forested watersheds of navigable streams | $652, 322. 88 | |
| Cooperation with States in farm forestry extension and distribution of forest planting stock | 81, 242. 04 | |
| Acquisition of lands for protection of forested watersheds of navigable streams | 1, 025, 495. 17 | |
| Acquisition of lands for upper Mississippi River wild life and fish refuge | 30, 115. 69 | |
| | | **$1, 789, 175. 78** |
| **(b) Colleges and stations:** | | |
| Payments to State agricultural experiment stations for research work under Hatch, Adams, and Purnell Acts | 2, 400, 000. 00 | |
| Payments to State agricultural colleges for extension work in agriculture and home economics under Smith-Lever Act | 5, 880, 000. 00 | |
| | | 8, 280, 000. 00 |

---

[1] Including $3,511,464.16 paid to livestock owners as indemnities for animals destroyed in connection with tuberculosis and foot-and-mouth disease eradication, and $5,033,896.63 for meat-inspection service.

| | | | |
|---|---|---|---|
| (c) **Road construction under Federal-aid roads act of July 11, 1916, as amended and supplemented:** | | | |
| Payments to State highway departments for cooperative construction of Federal-aid highways | $89, 362, 110. 64 | | |
| Forest roads and trails | 9, 353, 252. 23 | | |
| | | $98, 715, 362 .87 | |
| (d) **Forest Service receipt funds:** | | | |
| Payments to States for benefit of local roads and schools (national-forest receipts) | 1, 271, 275. 69 | | |
| Roads and trails for States (national-forest receipts) | 677, 935. 88 | | |
| Cooperative work, consisting principally of forest road and trail construction, also improvements, fire prevention and suppression, disposal of brush in timber-sale operations, and investigational work (paid from private contributions) | 2, 042, 034. 20 | | |
| Refunds to users of national-forest resources of moneys deposited by them in excess of amounts required to secure purchase price of timber, use of lands, etc | 133, 488. 38 | | |
| | | 4, 124, 734. 15 | |
| Total expenditures for work administered by department (other than regular work) | | | $112, 909, 272. 80 |
| Total expenditures for regular activities of and work administered by department | | | 157, 485, 660. 84 |

## Expenditures for Regular Work

### (*1*) *Net cost of work*

As indicated by the foregoing table, total expenditures during the fiscal year 1926 for the research, extension, service, and regulatory functions of the department, or what may be designated as its "regular work" (as distinguished from work supported by Federal funds administered by the Department of Agriculture but made available for direct use by the States or for special conservation purposes), amounted to $44,576,388.04. Partially offsetting this figure, earnings in connection with these activities during the year, amounting to $5,486,616.88, deposited in the Treasury of the United States to the credit of "miscellaneous receipts," and $137,600.91 received as fees for classifying cotton and credited to the revolving fund for that purpose, make the actual net cost to the Federal Government of the department's regular work $38,952,170.25.

### (*2*) *Distribution by types of activity*

The total expenditure of $44,500,000 for regular work was distributed by types of activity approximately as follows:

| | Amount | Per cent |
|---|---|---|
| (a) **Research** (including investigations and experiments in animal and plant production, breeding, and improvement, in methods of controlling diseases, insects, and other animal and plant pests, for soil and fertilizer studies, for the investigation of farm management, marketing, and crop utilization problems, and other scientific studies and investigations of the fundamental problems of agriculture, horticulture, forestry, etc., by means of laboratory and field experiments) | $10, 300, 000 | 23. 1 |
| (b) **Extension work** (demonstration and educational work by means of county agricultural and home demonstration agents, through exhibits, motion pictures, or otherwise, with a view to the dissemination of the information developed by the experiments and discoveries of the department and the various States) | 2, 300, 000 | 5. 2 |
| (c) **Eradication or control** (direct control or eradication of plant and animal diseases, insects, and other pests, through organized campaigns, either independently or in cooperation with State agencies) | 9, 300, 000 | 20. 9 |
| (d) **Service work** (including such activities as the administration and protection of the national forests, the weather service, crop and livestock estimating, market news services, shipping-point and terminal-market inspection service on perishable farm products, and other work of like character for the benefit of the public, not primarily involving research or the enforcement of special laws of a regulatory nature) | 12, 900, 000 | 29. 0 |
| (e) **Regulatory work** (administration of regulatory laws, such as the food and drugs act, the meat inspection law, the migratory-bird treaty act, the grain standards act, warehouse act, etc.) | 9, 700, 000 | 21. 8 |
| Total | 44, 500, 000 | 100. 0 |

## Income from Department's Activities, Fiscal Year 1926

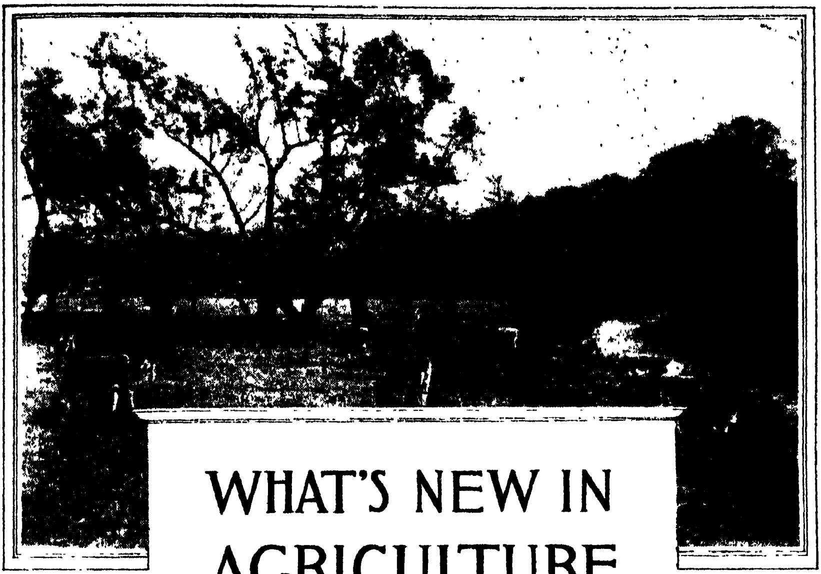
Incident to the department's work during the fiscal year 1926 direct receipts aggregating $8,829,953.15 were covered into the Treasury and fines were imposed and judgments recovered by the courts amounting to $111,911.18 in connection with the enforcement by the department of the regulatory laws which devolve upon it for administration and execution, as follows:

### (1) *Receipts*

| | | | |
|---|---|---|---|
| Deposited to credit of miscellaneous receipts fund: | | | |
| Regular work— | | | |
| From business on the national forests | $4,641,415.72 | | |
| From other sources | 845,201.16 | | |
| | | $5,486,616.88 | |
| Work administered (other than regular work)— | | | |
| 10 per cent of net receipts from business on the national forests appropriated as a special fund for forest road and trail construction in 1927 | 514,205.38 | | |
| Proceeds from sale of surplus war materials transferred to States for road-construction work | 114,817.35 | | |
| Contributions from private cooperators appropriated as a special fund for road and trail construction, fire protection and suppression, brush disposal, and investigative work on national-forest and privately owned lands | 1,925,149.98 | | |
| | | 2,554,172.71 | |
| Total deposited to credit of miscellaneous receipts fund | | | $8,040,789.59 |
| Deposited to credit of applicable funds of department: | | | |
| Fees collected for classifying cotton deposited to credit of revolving fund for conducting this work | | $137,600.91 | |
| Reimbursement to various appropriations of department for expenditures made therefrom | | 651,562.65 | |
| Total deposited to credit of funds of department | | | 789,163.56 |
| Total receipts | | | 8,829,953.15 |

### (2) *Fines*

| | |
|---|---|
| Fines imposed and judgments recovered by the courts in connection with violations of statutes entrusted to Department of Agriculture for enforcement | 111,911.18 |
| Total direct income from activities of Department of Agriculture | 8,941,864.33 |



# WHAT'S NEW IN AGRICULTURE

### ABACÁ in the Tropics of America

A collection of approximately 1,400 selected plants of six of the leading varieties of abacá, or "manila hemp," was brought from the Province of Davao, Philippine Islands, to the Canal Zone during the summer of 1925. This achievement is the successful culmination of two years' effort on the part of the department to establish abacá in the America Tropics.

Abacá fiber is the raw material from which manila rope is manufactured. The entire world supply of this fiber, with the exception of a few hundred bales produced in Netherlands India, is obtained from the Philippine Islands. The production of abacá is one of the leading industries of the Philippines, and the exports of this fiber in 1925 were nearly 350,000,000 pounds. The annual consumption of abacá in the United States is about 150,000,000 pounds.

The present production of abacá is barely sufficient to meet the world demand for this fiber. Many of the abacá growers are now planting coconuts in fields that were formerly planted to abacá, and two different plant diseases that have appeared during recent years have either damaged or entirely destroyed the abacá crop on limited areas. It has been apparent, in view of these conditions, that an effort should be made to establish the abacá industry in tropical regions other than the Philippine Islands.

#### Plants From Five Plantations

The collection of abacá plants brought to the Canal Zone was obtained from five different plantations, and included the leading varieties of abacá in Davao Province. In making this shipment of plants, an effort was made to determine the relative value of different kinds of propagating material, and also to ascertain the best methods of packing this material. The shipment included seed, buds, suckers, and rhizomes. The seed was shipped both in cold storage and packed in charcoal. Approximately 500 buds, suckers, and rhizomes were planted either in soil or sphagnum; about 100 suckers and rhizomes were packed in charcoal; and about 850 rhizomes were wrapped in paper and excelsior and shipped in crates.

Of the total collection of 1,438 plants, 1,052, or 73.2 per cent, were alive, and 769, or 53.5 per cent, were in good condition when the shipment arrived at its destination. These plants were shipped a distance of more than 10,000 miles, and a period of 129 days elapsed from the date, June 4, on which the first plants were collected in Davao, until the last were unpacked and planted, on October 10, at the plant quarantine station on Columbus Island, Panama.

After undergoing a six-months period of quarantine on Columbus Island, four different field plantings of abacá were made at widely separated places. These plantings are at Tela, in northern Honduras; at Almirante, in the northern part of the Republic of Panama; on Columbus Island; and in the Plant Introduction Gardens at Summit, Canal Zone. The climatic and soil conditions at Almirante are exceptionally favorable for abacá, and the major part of the acclimatization work will therefore be done at this place.

The abacá plants have thus far made a satisfactory growth, but it will be necessary to continue the experimental work for a period of at least two years before it can be fully determined whether or not it will be practicable to produce abacá on a commercial scale in Tropical America.

H. T. Edwards.

## AGRICULTURAL Education in United States

The progress made in agricultural education in the institutions of this country for the past few years has been very satisfactory. After a period of expansion and experimentation, the work has settled down and is now fairly well organized. A better conception of the fields occupied by the different grades of institutions prevails and a spirit of helpful cooperation is manifest. The relation of the United States Department of Agriculture with the various State educational institutions has been extremely harmonious and helpful.

Many of the colleges of agriculture have shown a decrease in attendance the past four years. Whereas in 1921 they reported an enrollment of over 15,000 students, in 1925 they reported slightly under 12,000 in attendance. During the years 1918 and 1919 the attendance dropped from 14,000 to some 10,000 students. In 1921 there was a sudden increase to over 15,000, but this number was not held as the attendance decreased about 1,500 in 1922. The decrease noted in 1918 and 1919 was undoubtedly due to war conditions and the following increase to 15,000 was a reaction naturally following earlier events. The decrease from the high point in 1921 has been due to numerous factors, such as the lessened farm income which has reduced the ability of farmers to send their children to college, and has led those who went to college to seek training in more remunerative fields. The graduates of these colleges, however, have increased in numbers from 3,024 in 1917 to 3,678 in 1925.

One of the marked developments in agricultural education during the past few years has been the establishment of teacher-training departments in the land-grant colleges. These departments are variously designated, but they, one and all, are concerned in the training of teachers of agriculture for the schools of our country. The department for the training of agricultural teachers that has had the longest continuous existence was established at the South Dakota College of Agriculture. This department antedates the passage of the Nelson amendment (1907).

### The Nelson Amendment

The Nelson amendment made provisions for further endowing the land-grant colleges and provided that these colleges "may use a portion of this money for providing courses for the special preparation of instructors for teaching the elements of agriculture and the mechanic arts." During the five years directly following the passage of this act, 7 more teaching departments were established, and during the next five years 12 were added.

Some years later, in 1917, the Federal Government passed what is known as the Smith-Hughes Act establishing vocational agriculture and mechanic arts in high schools throughout the country. This act increased the demand for college-trained teachers and opened a much wider field for instruction in agricultural teaching. At the time of the passage of the Smith-Hughes Act (1917) there were 20 departments of agricultural education in land-grant colleges existing and functioning. To-day every land-grant college has such a department that is filling a valuable place in the field of agricultural education.

Owing to a marked increase in the demand for agricultural teachers in our secondary education, due to the development of the Smith-Hughes schools, the various departments established for the training of such teachers in land-grant colleges have shown a healthy growth. Directly following the passage of this act, great difficulty was experienced in obtaining adequately prepared instructors and it was some time before satisfactory teacher-training staffs were obtained. It would have undoubtedly been better if provisions had been made to establish these training departments several years before the other sections of the act were put in operation. As it resulted, teacher-training departments were developed alongside the vocational schools and there was much to be adjusted before a smooth working program could be carried out. At this time sufficient experience has been gained to correlate the work to better advantage.

### Wide Range of Subjects Offered

A rather wide range of subjects is offered by the different colleges under the name of agricultural education. In some institutions, notably those universities wherein the agricultural work forms a department rather than a separate school, the field of agricultural instruction is limited to two or three special courses such as problems peculiar to agricultural teaching and those dealing with supervised teaching. All other subjects, though closely related to agriculture, are relegated to the academic departments of the institution. Wherever there is a separate land-grant college established in a State a much broader range is given to the courses offered. In addition to strictly agricultural topics, the subjects of educational psychology, general psychology, principles of teaching, vocational education, and educational administration are often presented. In some institutions the departments of agricultural education are not limited to agricultural subjects but include in their curricula professional training for home-economics teachers, for boys' and girls' club work, and for a certain amount of extension work that seems to be in demand in this field.

The greatest impetus given to agricultural education in general was the passage of the Smith-Hughes Act in 1917. This bill established vocational agriculture in the secondary schools of our country and made provisions for evening and part-time classes wherever they could be expediently established. This measure opened a broad field in both agricultural and mechanic arts which was immediately occupied by every State in the Union. Under the provisions of this act $500,000 was made available to the States from Federal funds for the fiscal year beginning July 1, 1917, and this amount has been increased yearly until now, in 1926, it amounts to $3,000,000; which will represent the annual contribution of the Federal Government to the cause of vocational training unless amended in some way in the future.

### Vocational Agricultural Teachers

In 1918 there were 40 institutions that were training vocational agricultural teachers under the terms of the Smith-Hughes Act. In 1925 this number was increased to 70. The number of pupils enrolled in vocational courses throughout the country has increased very materially, thereby showing that vocational agriculture is becoming more and more popular as time has gone on. In 1918 there were 164,186 students of both sexes in the vocational schools, while in 1925 this number had increased to 659,370.

While there has been a healthy growth in the patronage of these schools, there has also been a marked advance in the methods of instruction. Programs for agricultural teaching activities have been made in the various States and have been sanctioned by the Federal board that are both intensive and progressive. The entire basis of teaching the subject of agriculture has been changed from the older academic methods to the more progressive vocational types. Job analysis planned on actual farming experience has replaced the old textbook procedure. Problems, projects, managerial jobs, operative jobs, and farm enterprises are terms that are met with now when one discusses advancement made in teaching methods. A great deal of time and thought has been given to part-time instruction and the effort has been to carry the teaching idea directly to the worker in the field wherever practical. Probably no educational activity in recent years has had as marked an influence upon professional ideals as this Federal vocation act.

Besides the Smith-Hughes vocational schools there are a number of other high schools in each State that teach the subject of agriculture. These schools receive no Federal aid but depend either upon an endowment or on State funds for their support. The curricula in these institutions are generally formulated along lines that approximate

Smith-Hughes work and include as much practical field work as is possible with their equipment. Some of these high schools have developed courses in what they term prevocational agriculture while others frankly present this subject for its informational value alone, much as they present history or geography.

### Elementary Education in Agriculture

In the field of elementary education, the teaching of agriculture is required by law in 19 States. Twelve States require this subject to be taught in their high schools. Two of the States, Pennsylvania and South Dakota, require the subject in the high schools and not in elementary schools. In five States the subject is specifically permitted by law while in another five there is special State subvention of agricultural courses in the elementary schools. In some States, as Arizona, Delaware, Idaho, Indiana, Kansas. Maryland, New Mexico, Oregon, Utah, Washington, and West Virginia, State boards of education may prescribe courses of study for public schools and may include agriculture.

There has been much difference of opinion among authorities as to the place agriculture should occupy in the curriculum of the elementary schools. The recent development of junior high schools and the better development of a six-year elementary school have helped to clarify the situation somewhat. A recent survey of teachers and specialists in education has shown that 64 per cent of the teachers and 47 per cent of the specialists reporting believe that elementary agriculture should be educational rather than prevocational. None of the specialists and only 10 per cent of the teachers reported their belief that elementary agriculture should be strictly vocational. There is still a strong belief with many that this subject should be taught prevocationally in the rural schools; 19 per cent of the teachers and 26 per cent of the specialists give this as their opinion.

The work now being done in the elementary classrooms as agricultural teaching is very chaotic and needs to be standardized whatever type of teaching may finally be accepted.

In many States the laws for teaching this subject are seldom enforced and the presentation of agriculture by the rural teacher is very unsatisfactory, even under the best conditions. Definite objectives are seldom made and when made are frequently obscured by irrelevant material. The movement in elementary schools seems to be away from the vocational objective, and, under existing circumstances found in these schools, this is not to be greatly lamented. One authority in summing up the situation remarks that "students of the problem are accepting the view that instead of using instruction in agriculture in the elementary school for vocational ends or as propaganda for farm life, it should take its place as a part of the program of instruction for vocational and educational guidance, or the 'teaching for choice.'"

### Prevocational Study

A course of study that is frankly prevocational is gradually being introduced in these schools. Its major object may be enumerated as follows: (1) Problems involving the essential life relations of the farmers; (2) comparative study of occupations; (3) sampling of jobs as are met with in farming; (4) providing training in method of attacking problems; (5) motivating agriculture with other subjects in the curriculum; (6) furnishing guidance; and (7) acquainting pupils with various State and national farming agencies. This suggests a course of procedure that seems adapted to the elementary schools and at the same time furnishes an excellent background for future vocational and research work in agriculture.

F. A. MERRILL.

### AGRICULTURAL Engineering and Farm Efficiency

In America, modern productive industry as a whole, except agriculture, submits itself to engineering planning and guidance. The result has been a great increase in the rate of production by the worker. The statement has been made that engineering has been the chief factor in causing the value of the product of one hour of labor by the industrial worker to exceed so greatly that of one hour of labor in agriculture. Manifestly, therefore, the great task of the agricultural engineer is to aid in increasing the productive efficiency of the agricultural worker and to bring him to an equality with the industrial worker. An agricultural engineer is defined as a qualified engineer who, with adequate knowledge of the principles and practice of agriculture, devotes himself to the application of the art and science of engineering to agriculture.

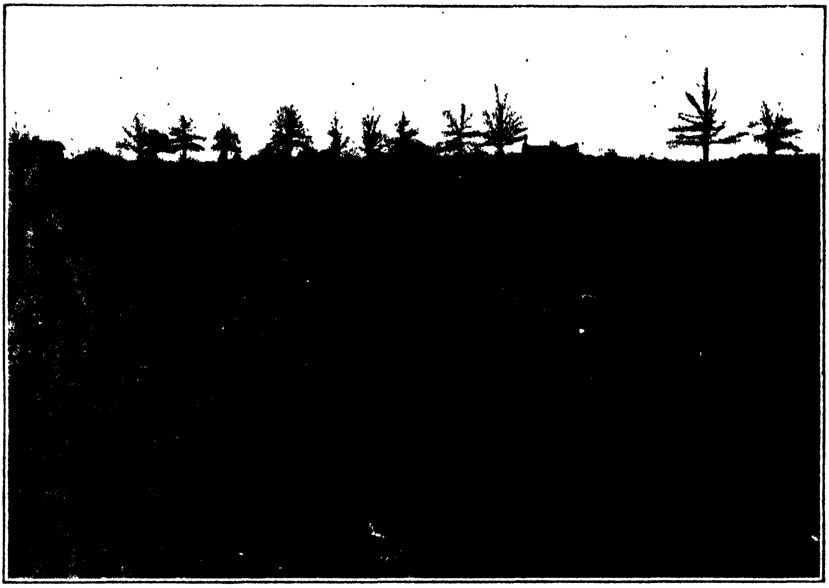


FIG. 1.—The proper laying out and construction of terraces for the prevention of erosion call for the services of the agricultural engineer

Indications are already at hand, as shown in investigations started by the Department of Agriculture in activities of agricultural engineering organizations of the colleges, and in discussions before the American Society of Agricultural Engineers and in agricultural and engineering periodicals, that a motivating realization of this opportunity and its attendant obligation has matured in agricultural engineers.

The engineers who have undertaken these investigations have given heed to the suggestion that the problems be approached with minds open to the utmost. They propose, accordingly, to accept nothing on the sole basis of tradition or established usage, and decline to assume that present methods, machines, implements, or layouts are of even proper type or are based on correct fundamental theory or principles.

### Some Practices Never Reviewed

The justification for this attitude lies in the fact that many of the methods and devices now in general use never have been subjected to review, in respect to their fundamentals, in the light of the knowledge of natural principles which has accrued since they were introduced. It permits the constant application of the old injunction laid upon us to "prove all things, hold fast to that which is good," and at the same time frees the investigator from an undue regard for precedent and sets him on the way to improvement of whatever nature or degree, ranging from the slightest modifications to the most complete and revolutionary changes.

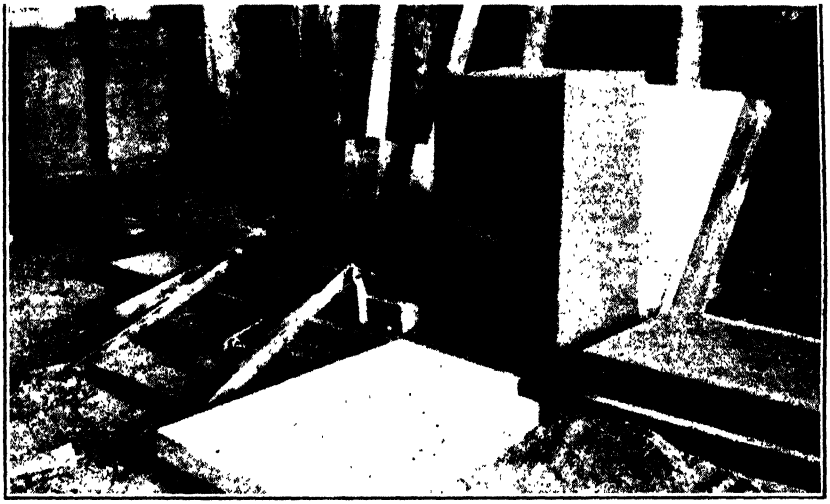

FIG. 2.—Block made of rammed earth to use in a study of the structural qualities of that material. Agricultural engineers are studying and experimenting to find more suitable materials for farm structures

If this is the correct attitude for the engineer-investigator to assume, then the farmer should acquiesce and give his moral support, to the end that undue conservatism on his part may not impede progress.

Each item of increase in efficiency of production augments the income upon which the farmer may draw to raise the standard of his living. In order that his expenditure in this direction may yield maximum returns in comfort, health, and enjoyment, engineering thought, training, and principles must be brought to bear in the adaptation to rural conditions of the material means whereby the standards of living in the cities and towns are advanced, in the invention of means to supplement or supplant these when they are found to be not adaptable, and in going beyond this to devising comforts and conveniences which rural conditions may make possible but which may not be evolved under urban conditions.

Stated in general terms, the direct objectives of engineering service to agriculture are: (1) To increase the rate of production of the worker; and (2) to improve the conditions of life on the farm. When some of the avenues of approach to these objectives are considered, it becomes manifest that the agricultural engineer should be able to progress in the desired direction.

A competent agricultural engineer should know, better than any one else, the treatment which machines receive on the farm, the proper economic balance between the cost of a machine and its life in hours of service, and other factors which determine the benefit to be derived from machine utilization—in short, the requirements of farm machines and the real problems of the farmer in relation thereto. With this knowledge and with his specialized engineering and scientific training, he can conduct investigations to the best effect and design in accordance with the proved findings of himself and others. This relates not only to machines and implements used in the growing and handling of crops, but also to those for the dairy, poultry, or other special industry on the farm, and to those calculated to expedite, simplify, and reduce the labor involved in the care and handling of livestock and in maintaining the household.

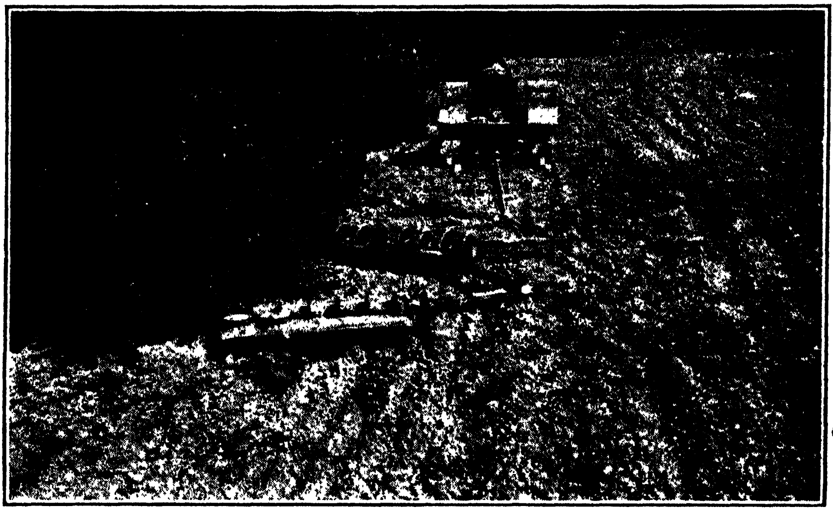

FIG. 3.—By taking advantage of the dynamic principles defined by agricultural engineers it is possible to increase the utility of the disk harrow for use in orchards and on ditch banks. Note the offset without side draft

### Generally Applicable Solutions

Many of the problems thus contemplated are of a nature such that a correct solution will be of general application. Others of them assume forms more or less special to each individual farm. The latter statement is distinctly true when the use of power on the farm is considered. Then, as a rule, it will be found that competent engineering consideration of the particular case, taking account of loads, rates, and mechanical efficiencies, will point the way to material economies. Rural architecture and farm and farmstead lay-outs also tend to assume individual form. Farm irrigation and farm drainage present individual characteristics. The best solution of all such problems demands the personal contact of the engineer and the farmer. Whether the engineer may serve as completely and efficiently in agriculture as he does in other industry, and whether a thoroughly effective relation of the agricultural engineer to the farmer can be established depends in a large degree upon the practicability of evolving some scheme of general application for bringing the two together to their mutual profit and advantage.

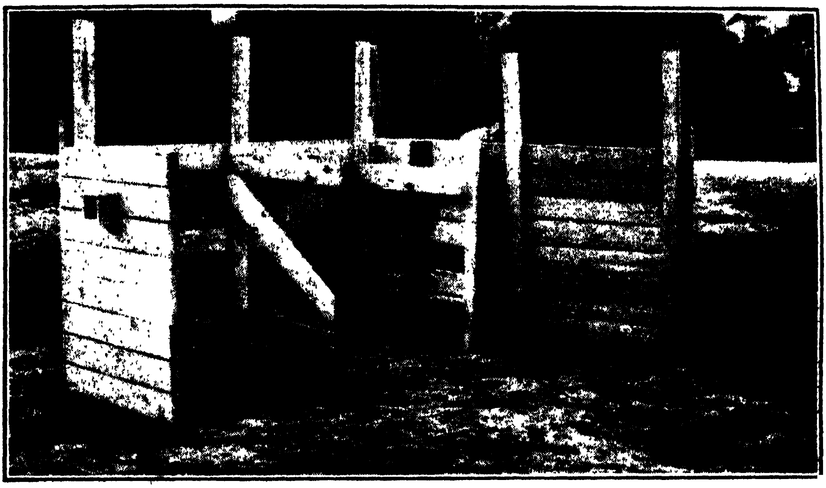

FIG. 4.—Forms for a single-chamber septic tank, designed by an agricultural engineer for repeated use. Such a set of forms has been used more than 60 times

The farmer is the direct employer of the engineer to a limited extent only. Large estates frequently retain engineers. Engineering service in some degree is quite generally a requirement for the successful installation of a farm drainage or irrigation system. Usually, however, the only engineering contact which the farmer experiences is that provided by the extension activities of the Government and the agricultural colleges, by manufacturers and dealers who have something which the farmer needs, and by those who would supply electric power for farm operations. Objection can be made to all of these on the score of the inadequacy of the service which it is possible to render. The public agencies can not engage to solve the individual problems of all of the farmers. Service direct to individuals should be rendered only as an object lesson or demonstration of somewhat general application. Service through the farm advisor as intermediary from the engineer to the farmer is helpful, but it falls short as compared with direct service on the ground. The service rendered by the engineers of commercial firms or organizations is often of the best, once it is decided to use their products, but it can scarcely be expected that the full light will be turned on for comparison with the products of competitors.

### Private Clients Few

The engineer, other than agricultural, usually has as clients or employers those who are able and who expect to pay what he must have in order to return him a net income which takes account of the time and expense involved in planning and direction of work and also of his investment in education and training. For a considerable number of agricultural engineers there is salaried employment to be had, with either public or private agencies. The one who aspires to a private practice in agricultural engineering, however, finds the assured field decidedly limited in extent. The individual farmer, operating on the ordinary scale, can afford to employ and pay for the direct service of the engineer in only small measure or under special circumstances, or under conditions not now existent.

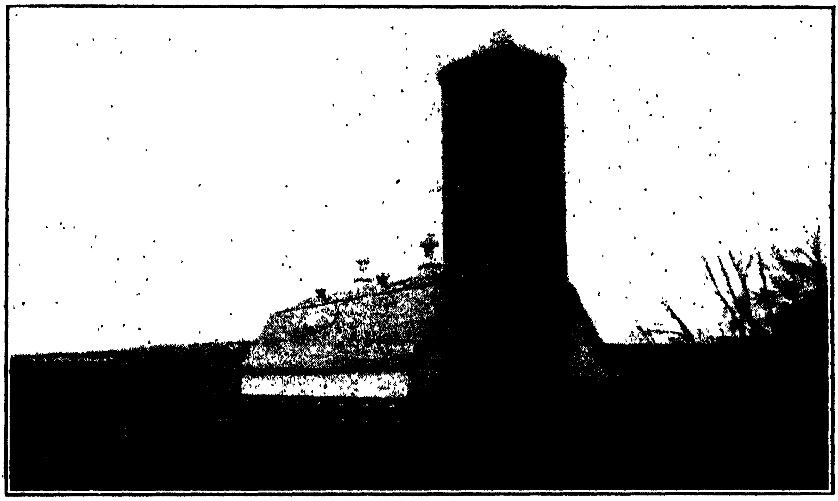

FIG. 5.—The dairy farmer finds the services of the agricultural engineer of great value in the design and construction of his barn and silo

The question as to how it is to be made practicable for the individual farmer to receive disinterested and complete engineering service has not been answered.

Civil engineers in numerous instances in the past have located in small towns or in rural communities and have been able to adapt themselves to the conditions encountered and to establish themselves in ways that are eminently satisfactory to those whose tastes and temperaments do not demand the perspective and the intensity of action that go with the large engineering undertakings. This gives rise to the suggestion that an almost unlimited number of young agricultural engineers might distribute themselves in this way over the country and become available for the direct service of the farmer. Although space does not permit the discussion of this proposition at length, a few relevant points may be noted. It has been remarked by teachers of agricultural engineering that the majority of students of that branch are "country minded." The life in the small town or rural community does not require the personal and business expenditure which an urban establishment calculated to serve larger territory demands. In the country it may be convenient, agreeable and appropriate—more so than in the city—that a somewhat inadequate income from engineering be supplemented by other means, or that practice in agricultural engineering be combined with that in some other line, such for instance as small-town engineering. Other items of this nature will suggest themselves.

It can not be expected that the farmer will ever acquire the general habit of resorting to centers of population for his direct engineering advice. The engineer must be brought within easy reach, and must, moreover, be in proper degree aggressive to demonstrate his value.

Agriculture has been the laggard amongst the industries in recognizing the degree of its dependence upon engineering. That progress has been made to remedy this condition is chiefly due to a small group of pioneer agricultural engineers who have been foremost in the emergence of that branch of the engineering profession. The continuance of this progress will depend largely upon agricultural engineers. So far as promoting between farmers and engineers the understanding and appreciation which have been lacking, it is submitted that the agricultural engineer resident in the agricultural community is exceptionally well chosen and placed for that task.

W. W. McLaughlin.

## ALFALFA Wilt Due to Bacteria

What is the trouble with my alfalfa? Is it unfavorable soil, winter injury, or disease? This question has come to the Department of Agriculture and the State experiment stations from many alfalfa growers during the past three years. The conditions in alfalfa fields that have given rise to this question are several. It is said that stands of alfalfa now die out in 3, 4, or 5 years where they once lived much longer; or that the stand has died out in spots; or that it is lacking in vigor. These complaints have come from many places, especially from the central and southern Mississippi Valley, and also from some irrigated districts.

It has not always been possible to say what cause has been operating and often it has appeared that more than one is concerned, but as a result of the attention which these complaints have focused upon the alfalfa crop, one fact has become clearly apparent. There is in the United States a bacterial wilt disease of alfalfa which was not previously recognized. This disease is responsible for a great deal, if not for the larger part, of the trouble that growers have experienced. Moreover, it appears that bacterial wilt, which now occurs in at least a few fields in practically every alfalfa-growing district of the United States, may easily become more thoroughly disseminated than at present and thus assume an importance by far the most serious disease with which alfalfa culture must contend in some districts.

Bacterial wilt has doubtless remained unrecognized for a long time because only badly diseased plants show distinctive indications of the trouble. The organism causing the disease enters the water-carrying vessels of the plant through wounds and passing downward through the taproot and upward through stems may become abundant without apparent injury to the plant. At length, the entire plant may wilt suddenly on a hot day. Later in the summer some of the roots, in which the parasite has caused a stoppage in many of the water-carrying vessels, produce short pale-colored spindling shoots with small, narrow leaves. When the taproot of such a plant is cut across, the woody portion of the root is found yellow and discolored close beneath the bark. When the bark is stripped back the wood is found yellow or brown, altogether unlike the white wood of healthy plants. This discolored wood distinguishes this disease from winter injury and other troubles.

### Investigations Under Way

This disease is now being studied both by the Department of Agriculture and by men in several State experiment stations to determine among other things where the disease is now causing damage, how it is carried from field to field, when and through what kinds of wounds it most frequently enters plants, and whether there is varietal resistance to the disease. In many districts, especially where rainfall is abundant, or excessive irrigation water is supplied, the wilt disease is undoubtedly the most serious that has threatened alfalfa culture.

## ALFALFA Seed from Abroad

The average annual importation of alfalfa seed for the years 1920 to 1925 was nearly 9,000,000 pounds. Of this quantity, about 7,000,000 pounds, or enough for sowing 350,000 acres, is regarded as undependable for our Northern States. Losses from the use of this imported seed amount to hundreds of thousands of dollars and have resulted in efforts to protect the farmers through the passage of a seed-staining bill by the Sixty-ninth Congress.

The commercial alfalfas of the world are represented by two groups, namely, the common or purple-flowered alfalfa, *Medicago sativa*, and the variegated alfalfas, which are largely the result of a natural cross between the yellow-flowered alfalfa, *M. falcata*, and the purple-flowered alfalfa, *M. sativa*. Within each of these groups are numerous strains varying widely in ability to withstand cold and drouth, and in other characteristics. With the exception of seed received through Canada, which is largely of the variegated type, practically all of our imported seed is of the common variety.

Like many of our cultivated plants, the environmental conditions under which alfalfa is grown for any considerable length of time exert a marked influence on its characteristics. Where natural selection has taken place in a cold climate, the tender, rapidly growing plants have been eliminated and this has resulted in a strain best suited for growing under conditions of severe winters and long summer days. Where alfalfa has been grown several seed generations in a warm climate, the hardier and slower growing plants are gradually eliminated by the more rapidly growing and less hardy individuals, and this has resulted in what we term "a southern strain," capable of making its best development under a relatively short day.

### Adaptability of Vital Importance

Since climatic conditions exercise such a marked influence on the characteristics of alfalfa, it is no wonder that interest should develop in the source of imported seed. This factor is of vital importance to the farmers in the northeastern section of the United States, which represents a great part of the alfalfa-seed consuming section and the part in which, due to the rather trying conditions to which the crop is subjected, the variety of alfalfa is of greatest importance.

At one time practically all the alfalfa seed imported commercially came from Turkestan, the demand for seed from that source having been stimulated by the favorable results obtained with seed produced in the cold, dry regions of that country. It soon became apparent, however, that while Turkestan alfalfa seed did fairly well in the cold, dry portions of the United States, poor results followed its use in the humid East, where it appeared so susceptible to disease that stands were destroyed in a relatively short time, usually in two or three years. This situation resulted in extensive unfavorable propaganda, which, coupled with the unsettled condition in Russia during and following the war, probably accounts for the decline in importations until in recent years the quantity received from that source has been very small.

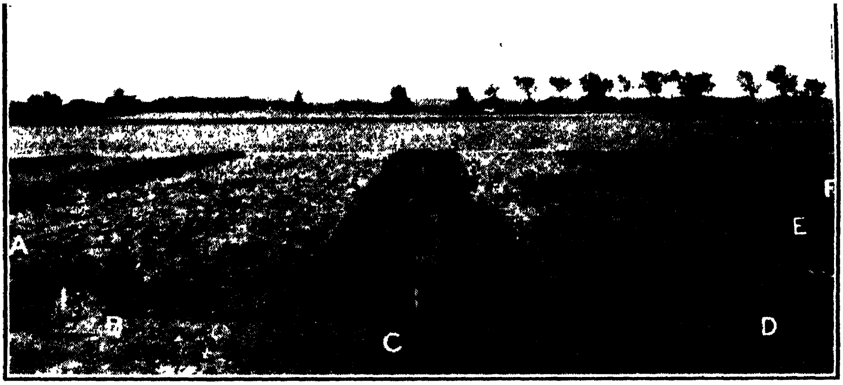

FIG. 6.—Alfalfa variety test after having passed through the first winter at Ames, Iowa. A, South African; B, Italian; C, Grimm; D, Le Beau: E, African; F, Argentine

With the decline in importations of alfalfa seed from Turkestan, Argentine seed appeared on the market in considerable quantities, importations averaging about 4,000,000 pounds annually between 1920 and 1925. The lowest temperatures recorded in the various important alfalfa-seed producing districts of Argentine range from 10° to 18° F., a condition which is not conducive to the development of a hardy variety or strain, particularly if the original seed, as seems to be probable in this instance, was of a nonhardy type.

Where Argentine seed has been grown in the northeastern section of the United States, whether by farmers or in experimental tests, the plants have sometimes killed out almost completely the first year, and where not destroyed the first year, the stand has generally suffered serious injury the second or third year, while Grimm and Canadian Variegated alfalfas, developed under more severe conditions, ordinarily survive with little or no injury. At Spooner, Wis., 85 per cent of the Argentine plants died the first winter, whereas only 57 per cent of the Kansas plants and 17 per cent of the Grimm plants were lost. At Ames, Iowa, the winter killing in three lots of Argentine alfalfa ranged all the way from 75 to 100 per cent, while the losses in the various Grimm plots were from 0 to 2 per cent, and in the Kansas plots 50 to 70 per cent. Similar results have been obtained in several other Northern States. In a few cases, however, where conditions are very favorable to alfalfa, and in mild winters Argentine alfalfa has come through with little injury even in the Northern States. In the southern half of the United States the Argentine alfalfa has given results comparable to domestic strains of common alfalfa.

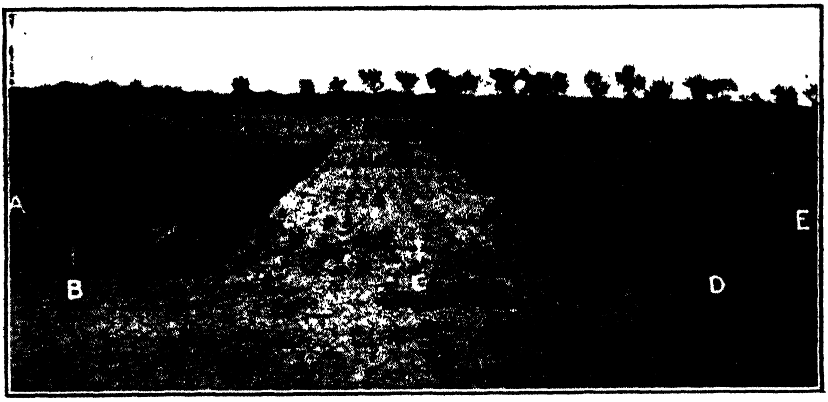

FIG. 7.—Alfalfa variety test after having passed through one winter at Ames, Iowa. A, Dakota Common; B, Turkestan; C, Spanish; D, Ontario Variegated; E, African

### South Africa Alfalfa

South African alfalfa seed has in recent years been offered on the markets of the United States and the potential possibilities for the production of seed in that country would seem to be great. Although tests conducted with South African seed are limited in number, and cover a short period, the results are rather striking. The commercial lots of seed received from that source have appeared appreciably more susceptible to winter killing than Argentine seed, plots often killing out 50 per cent the first winter where the Argentine alfalfa came through very satisfactorily. This would indicate that some of the seed at least is produced under milder climatic conditions than are found in the seed-producing districts of Argentina. While minimum temperatures of 10° F. are occasionally reported at the higher altitudes in South Africa, still much of the seed is produced where the temperature seldom falls below 20°. At Ames, Iowa, South African alfalfa killed out 100 per cent the first winter: at

North Ridgeville, Ohio, 80 per cent; at Morgantown, W. Va., 95 per cent; and at Dickinson, N. Dak., 94 per cent.

In accordance with recent legislation the Secretary of Agriculture has issued an order requiring that Turkestan and South African alfalfa seed be stained red to the extent of 10 per cent as being unadapted for general agricultural use in the United States.

### Canadian Seed Satisfactory

Canadian seed has been coming into the United States in considerable quantity for the past few years. Most of this seed is of the hardier types such as Grimm and Canadian Variegated, and as it has been produced under conditions at least as severe as the winters in our Northern States, it is highly regarded and has proved as satisfactory in the northeastern part of the United States as our domestic strains.

Other countries from which imports of alfalfa have been received from time to time are Germany, France, Italy, and Spain. Although seed from these countries has given variable results, that from Italy and Spain generally produces plants that are nonhardy in our Northern States, since the seed is produced under mild climatic conditions; whereas that from Germany and from certain parts of France where the winters are more severe withstand more cold in the United States, though in general not sufficiently hardy for our most trying conditions.

H. L. Westover.

**ALFALFA Weevil Control Methods** The alfalfa weevil attacks an important crop in such numbers, with such disastrous adroitness, and with a capriciousness so baffling to preventive treatment, that it has excited the interest of farmers, produce dealers, extension workers, quarantine officials, and entomologists wherever alfalfa is grown or consumed.

The importance of alfalfa in the great plateau region where the insect is now established depends less upon the acreage and the value of the crop than upon the vital part which it has played in the settlement of that country and which it still plays in its agriculture, industry, and commerce. This region lies nearly or quite a mile above sea level, parching for want of the rain which during most of the year is withheld from it by the western mountains; and the traveler of to-day, as its panorama of somber ranges and stark plains flits past the windows of his automobile or railway car, finds it remarkable for little besides monotony. Sometimes the glint of sun on August snow or the fragrance of distant, unseen pines on the evening breeze may arouse him to an idle question, as may the infrequent oases of green; but the question is oftenest "How does anyone manage to live in this place"?

Nevertheless, there is a story written in the sage-gray plains and slopes, with their obscure wagon tracks and their oases of alfalfa. This was once the "Great American Desert" of our fathers' school geographies; now it is the "Inland Empire" of railway folders and commercial-club booklets. Over the meandering wagon track, now overgrown with tumbleweeds and drifted full of sand, men and women plodded toward the gap between two gray hills, riding when they could and when their horses failed toiling afoot. For that dim track meant water. Where a trickle of water from a spring in the hills moistened a little of the desert they planted their precious seeds. When summer dried up the springs, the tender crops brought from the old home died, but the alfalfa lived; with the tenacity bred of a thousand rainless summers its roots followed the retreating moisture into the earth and held on. It wintered the herds when they came home from the summer range, and helped to fatten the cattle, the only product which could be marketed. It escaped from the fields and flourished in roadsides, streets, gardens, and the graveyards where the pioneers were laid.

Today the railroads and the great irrigation projects are here, and no one travels the old roads to hidden springs in the hills. Alfalfa still fights back the desert and maintains the herds, and it also produces forage for the cattle of the Corn Belt itself.

### Farmers Surprised at Damage

Alfalfa grows so luxuriantly that most insect pests make little impression upon it. It is no wonder that farmers had come to regard it as immune to attacks of that sort and were disturbed to see their crops being destroyed by the alfalfa weevil after that insect was introduced from the Old World. The green larvæ appeared in the tips of the plants in countless thousands, feeding at first in tunnels in the heart of the terminal bud and later spreading out over the leaves. Every day brought a fresh horde of newly hatched larvæ, which always first attacked the buds, where they could do the most harm. Once the buds were killed by these small larvæ, the older ones soon stripped the green tissue from the leaves, and the field, unable to produce new growth, first took on a gray tinge and then turned white as if frostbitten. The longer the crop was left standing, the worse became its condition, until, in extreme cases, even the skin covering the stems was eaten away, and of the whole plant nothing remained but a handful of woody fibers, crumbling to dust and worthless as forage.

After the wreckage of the first cutting had been removed, the larvæ, many of which were left in the field, cleaned up the scattered foliage of the stubble and then turned their attention to the sprouts which were already starting from buds near the surface of the ground, and destroyed them almost at once. As fast as other sprouts pushed up from below they were treated in the same way, and for about three weeks, or until the larvæ had finished feeding and prepared for their final transformation into the adult beetles, there was no chance for the second crop of alfalfa to begin growth.

This period of three weeks is about the term required for the production of the second cutting. Although this period ended the ravages of the pest for the year, the later cuttings being unmolested and the egg laying of the new generation of beetles deferred until late fall and the following spring, the total damage amounted to nearly half the annual yield, even in the comparatively well-watered districts near Salt Lake City, where the damage was first felt.

In the surrounding valleys, where, because of higher altitude or scarcity of late-season water, no more than one or two cuttings could ever be obtained, the alfalfa crop might be almost a total loss. In addition, in the latter localities livestock was the principal product and could not be wintered without forage.

### Control Methods

Altogether it was clear that controlling this insect was a problem beyond the reach of the individual farmer, and an appeal was made to State and Federal agencies for help. The Utah Experiment Station speedily ascertained the main facts in the life cycle of the insect and provided an emergency remedy known variously as the "brush-drag," "cultivation," or "dust-mulch" method, by which the farmer, using materials already at hand, could greatly reduce the inroads upon the second cutting.

The Federal Bureau of Entomology took up investigations into the fundamental relations of the insect to its surroundings as a basis for future control experiments, and at the same time tested the more obvious expedients, including substitution of crops, cultivation methods, irrigation, and pasturing. With the cooperation of the Office of Farm Management it selected as the most promising measure the poisoning of the alfalfa-weevil larvæ with arsenical sprays applied to the first crop, and in a series of experiments lasting six years it developed what is now the standard method of controlling the pest.

While engaged in the development of the spraying method the Bureau of Entomology, acting upon a theory that the comparative freedom of European fields from the ravages of this insect was caused by the prevalence of parasites which preyed upon it, imported for study and possible colonization many predacious and parasitic species. One of these, an ichneumon fly which destroys the larvæ, has been established in America and is being studied to determine whether it exercises any practical control of the pest. At the same time other beneficial species are being introduced.

### Spread of the Weevil

The alfalfa weevil has not waited idly while the entomologists of the State and Federal Governments proceeded with plans for its overthrow. It has spread slowly but steadily and now has colonies in seven States, as shown by the map (fig. 8) of the infested territory at the close of the season of 1926. The infested counties are as follows:

*Utah.*—Beaver, Box Elder, Cache, Carbon, Davis, Duchesne, Emery, Iron, Juab, Millard, Morgan, Piute, Rich, Salt Lake, Sanpete, Sevier, Summit, Tooele, Uintah, Utah, Wasatch, Washington, and Weber.

*Idaho.*—Ada, Bannock, Bear Lake, Bingham, Blaine, Bonneville, Butte, Camas, Canyon, Caribou, Cassia, Clark, Custer, Elmore, Franklin, Fremont, Gem, Gooding, Jefferson, Jerome, Lincoln, Madison, Minidoka, Oneida, Owyhee, Payette, Power, Twin Falls, and Washington.

*Wyoming.*—Carbon, Converse, Fremont, Goshen, Laramie, Lincoln, Natrona, Sweetwater, and Uinta.

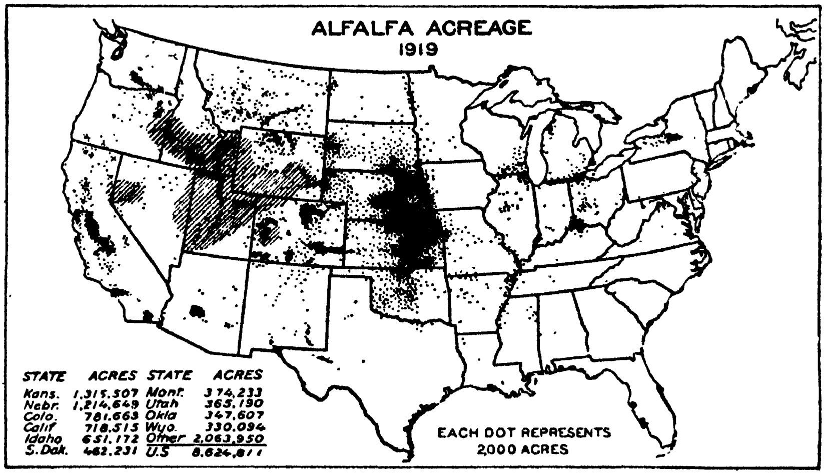
*Colorado.*—Delta, Gunnison, Moffat, Montrose, Ouray, Rio Blanco, and Routt.

*Nevada.*—Churchill, Lyon, Mineral, Pershing, Storey, Washoe, and White Pine.

*Oregon.*—Malheur, Baker, and Union.

*California.*—Lassen, Plumas, and Sierra.

In its advance into new territory the alfalfa weevil has encountered varied climatic and cultural conditions and has accordingly modified its habits. For example, in the long spring season which is usual in western Idaho the feeding period is so lengthened that two sprayings of the first crop are sometimes necessary; while in the short cold spring which is often experienced in Utah the egg laying, and consequently the number of larvæ, may be so reduced that no spraying is needed. The latter condition, although it is in itself a relief, may conceal a menace, as it has often led whole communities to neglect preparations for spraying, to their eventual loss.



| STATE | ACRES | STATE | ACRES |
|---|---|---|---|
| Kans. | 1.315.507 | Mont. | 374,233 |
| Nebr. | 1,214,649 | Utah | 365,190 |
| Colo. | 781.663 | Okla | 347,607 |
| Calif | 718.515 | Wyo. | 330,094 |
| Idaho | 651,172 | Other | 2,063,950 |
| S.Dak. | 462,231 | U.S | 8,624,811 |

FIG. 8.—Map showing the alfalfa-weevil territory in relation to the alfalfa-producing areas of the United States. The infested districts are shaded. Adapted from Piper et al.

In the absence of any known method of preventing the continued spread of the insect, it may be assumed that it will reach all the alfalfa-growing regions of this continent; and as its destructiveness is governed by natural conditions which are imperfectly understood, it would seem that improvements in the control of this pest are to be sought in improved knowledge of those conditions in order that attacks may be foretold with greater certainty and the methods already available more successfully applied.

GEORGE I. REEVES.

## ALKALI in Irrigated Districts

The occurrence of alkali salts on the surface or in the root zone of irrigated soils is an abnormal condition indicating that the irrigation water is not passing downward through the soil. These alkali salts are easily dissolved in the soil moisture, so that if there is a gradual or even an occasional movement downward of the soil solution, the dissolved salts are carried with it below the root zone. This is the only way that alkali salts can be removed from the soil.

Likewise, the only way that the accumulation of alkali salts in the soil can be prevented is to apply enough irrigation water, at least occasionally, to leach the root zone.

The reason for this is that irrigation water always contains some dissolved salts, sometimes rather large quantities. This salt that is brought into the soil by the irrigation water is left there when the water is absorbed by plants or lost by evaporation. If the water applied by irrigation never penetrates below the root zone, then the salt brought in by it continues to accumulate in the root zone, where it remains in solution in the soil moisture until the soil solution becomes such a concentrated salt solution that crop plants can not absorb from it the water they need for growth. The injurious effect of alkali salts in the soil solution is due to the fact that the salts in that solution prevent the absorption of water by plants rather than that the salts are absorbed by the plants and act as poisons in the plant system. Most crop plants can absorb water rapidly enough to supply their growth requirements from an available soil solution that contains less than 1.5 per cent of mixed salts. When the salt concentration of the soil solution gets much above that point, crop plants begin to show symptoms of injury. These symptoms of alkali injury closely resemble the symptoms of drought injury because the plant can not absorb water normally from a strong salt solution nor from the soil when the moisture content is below the wilting point.

### The Aim of Irrigation

The aim of careful irrigation should be not only to supply the water needed by the crop for its growth requirements but enough in excess to insure a cumulative downward movement of water through the root zone in order to prevent the accumulation in that zone of injurious quantities of soluble salts. It is not necessary or even desirable that this leaching of the root zone should go on continuously or that more than a small part of the water applied should pass out below. But it is essential to the sustained productivity of irrigated land that the root zone should be leached to some extent at least occasionally.

It would not be a difficult matter to apply irrigation water in sufficient quantity to leach the root zone and thus prevent the injurious accumulation of alkali salts in the soil solution if the soil and subsoil were both readily permeable to the movement of water. Where both soil and subsoil permit excess water to move freely in response to the force of gravity there is no alkali problem. It is only where a condition of impermeability exists either in the soil or in the subsoil that alkali troubles occur.

When the soil is permeable and the subsoil is impermeable to the movement of excess water, artificial drainage must be provided. In many irrigated sections subsoil impermeability occurs in the form of subsurface bars or dikes of tight or cemented material. These bars or dikes interfere with the free movement of excess subsoil water in the direction of the natural drainage outlets, such as creeks and rivers, and it becomes necessary to cut artificial channels through these barriers to afford relief. These artificial channels may be open ditches or covered lines of tile.

In planning a drainage system for a tract of irrigated land it is desirable to recognize the fact that the excess of subsoil water may originate from either of two sources. It may come chiefly from percolation through the root zone of irrigated fields or it may be due chiefly to seepage losses from irrigation canals. The importance of ascertaining the chief source of troublesome accumulations of subsoil water lies in the fact that one system of drainage is required for one of these situations and another system is required for the other. Where the excess of subsoil water comes chiefly from root-zone percolation, the indicated method of relief is to locate the impermeable subsoil barriers that hold the water back and cut these with artificial outlets. Where the water comes chiefly from canal seepage it is usually more efficient and economical to ascertain just where, in the canal system, these seepage losses occur and then either line the canal to prevent seepage or install a drain to intercept the seepage and prevent the water-logging of the irrigated land by excessive subirrigation. In many irrigated districts the water-carrying capacity of the subsoil is adequate to permit the outflow, to natural drainage channels, of all of the excess water that percolates through the root zone of the irrigated fields. In such situations, if the canal losses can be intercepted, no further drainage is necessary.

### Subsoil Permeability Important

The importance of subsoil permeability in relation to the alkali problem becomes apparent when it is realized fully that with irrigation the root zone must be leached and that with a saturated or impermeable subsoil it is not possible to leach the root zone. In fact when the subsoil is saturated, a process which is the reverse of leaching sets in. The solution that accumulates in a saturated subsoil is more salty than the irrigation water. With the progress of time it becomes still more salty as it gives up water to crop plants and loses water by evaporation. Furthermore, a saturated subsoil is an effective barrier to the downward movement of irrigation water through the soil, so that any additional salt brought in by irrigation water is added to the soil solution at any spot where the subsoil is saturated. Thus a field or a spot in a field where the subsoil is saturated soon becomes too salty to support normal crop growth and in the ordinary course of irrigation the soil of the root zone may also become saturated or water-logged.

### Impermeable Soil To Be Avoided

It is a natural assumption that where land is regarded as irrigable, the surface soil that is to constitute the root zone for crop plants will be sufficiently permeable to permit the ready penetration of irrigation water.

As a matter of fact, the attempt is often made to grow crops on land where the surface soil absorbs water very slowly and where in consequence the root zone is shallow and because of its impermeability it can not be leached. Such land may have good surface topography and be easy to prepare for irrigation. It is ultimately disappointing, however, and the experienced irrigation farmer avoids it. Spots of such impermeable soil often occur in fields where most of the soil is good.

The condition of soil impermeability here referred to constitutes a phase of the alkali problem somewhat different from that associated with an impermeable subsoil. The condition itself is due to certain physical properties of the soil, which in turn are the result of its chemical composition. The chemical composition of the soil at any time is the result of reactions of base exchange that normally take place between the soil material and the salts contained in the soil solution.

When the salts contained in the soil solution are preponderantly salts of sodium, the reaction tendency is in the direction of an exchange by which sodium from the soil solution enters into combination with the soil and an equivalent quantity of some other base, usually calcium, passes from combination with the soil into the soil solution. A soil that has thus absorbed an appreciable quantity of sodium, properly designated an alkaline soil, becomes relatively impermeable to the movement of water through it.

### Causes of Impermeability

On the other hand, a soil in which the replaceable bases are chiefly calcium and magnesium manifests those physical properties that are associated with friability and the ready penetration of water. When a soil solution becomes concentrated with sodium salts, the soil becomes alkaline as a result of reactions of base exchange. In this condition it tends to become impermeable to the movement of water whenever the concentration of its solution is reduced as a result of leaching.

An impermeable soil may occur as the result of conditions existing independently of irrigation. Many examples of such soil are found in the arid regions. On the other hand, a soil that is naturally friable and permeable to water may become impermeable as a result of irrigation if the conditions of irrigation are such that alkali salts (the salts of sodium) are allowed to accumulate in the soil solution. Such accumulation can be prevented by a system of irrigation and of drainage that insures a periodical leaching of the root zone.

CARL S. SCOFIELD.

## APPLE Trees Attacked by Cedar Rust

The three native crab apples of the eastern half of the United States have been known for many years to be attacked by one of the true rust fungi which forms orange-yellow swollen spots on the leaves. This rust was classified and named in 1859 and has been well known to students of fungi since that time and has been found widely distributed from the Great Plains eastward.

The common Virginia red cedar, *Juniperus virginiana*, occurring mainly east of the Great Plains area, but also extending from New Brunswick to British Columbia on the north and to Texas, New Mexico, and Arizona on the south, has also long been known to be attacked east of the Great Plains by a fungus which forms little brown galls mostly varying from one-fourth of an inch to an inch or more in diameter. This was also given a name by the early mycologists and classified as belonging to another group of the rusts.

About 1865 the remarkable discovery was made in Europe that the common wheat-rust fungus and the cluster-cup fungus of the barberry were alternate generations of the same organism. The barberry fungus was found not to propagate on the barberry but could only reproduce when its spores were sown on suitable wheat plants on which it produced the common wheat rust. The term "heterocism" was coined to designate this method of fungus propagation.

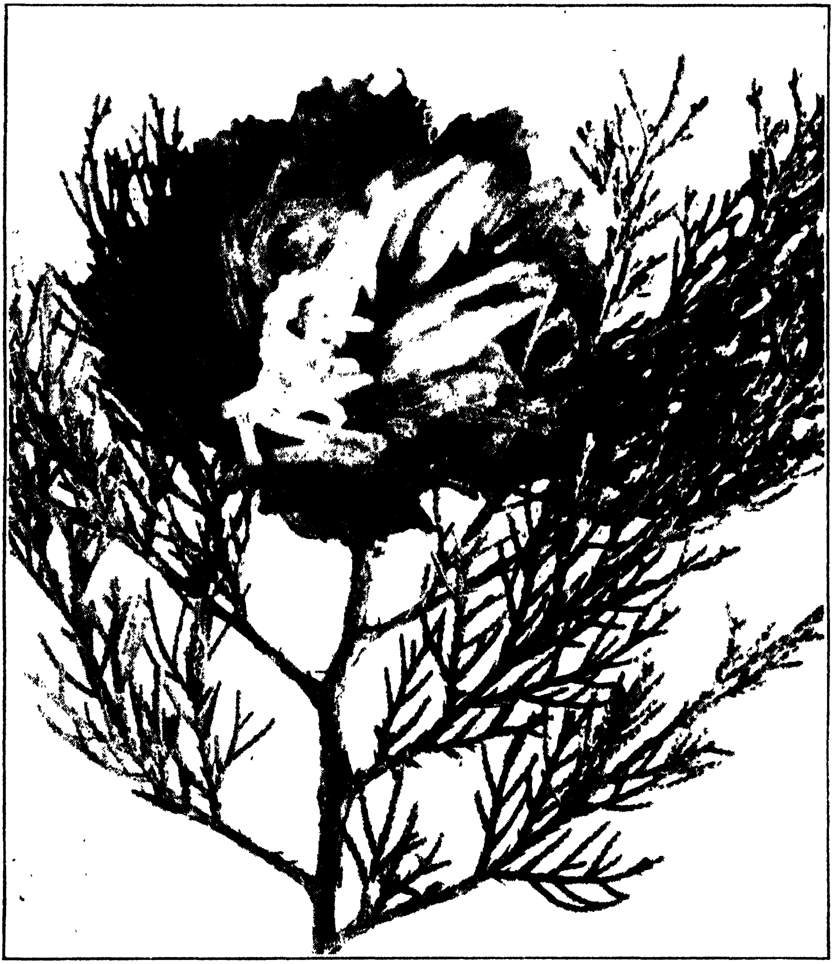


FIG. 9.—Cedar rust gall in the red cedar with gelatinous orange spore masses fully expanded by rain. Maryland, near Washington, D. C., April 27, 1926

The principle of heterocism opened up a new field in the study of the rusts and was followed by the discovery in Europe that some of the orange rusts on pomaceous fruits were alternate generations of rusts on the junipers. Between 1886 and 1888 a number of American species of orange rusts on the pome family were proved to be alternate forms of rusts on the junipers, including the common orange rust of native American crab apples and the cultivated apple and Siberian crab apple.

The cultivated apple introduced from Europe was grown in Virginia alongside the red cedars and perhaps crab apples for nearly 300 years without anything serious happening, and there was the same experience during the last hundred years in the upper Mississippi Valley. Occasionally an apple tree was found with a few spots of the orange rust on its leaves, and in Virginia the Pryor Red variety was very severely attacked. The writer saw this variety severely attacked by this rust and defoliated in the late nineties and was informed by older fruit growers that it had been so attacked for some 20 years or more. Pryor Red, however, was not an important commercial variety. Except on Pryor Red and a few localized attacks on other apples the disease was not abundant enough to be of economic importance at the beginning of this century.

### Attacked Wealthy Apple in 1905–6

In 1905 and 1906, however, this fungus attacked the Wealthy apple in Iowa and Nebraska so as to attract attention as an economic disease. In the summer of 1908 localized outbreaks began to occur in the vicinity of Winchester, Va., and the writer made a personal examination of three small colonies involving a few hundred trees of the York Imperial. That same year reports came of its increase in the Appalachian fruit belt. The York Imperial is the leading commercial variety in this entire district. Since 1908 the disease has increased east of the Alleghanies from New York to North Carolina, and attacked the cultivated apples so severely as to become a major economic disease. It has also increased in many other sections of the eastern United States. Attacks on the York Imperial were followed by its spread to other varieties—Jonathan and Rome Beauty; later Ben Davis, Yellow Newtown, and other sorts were severely attacked. The Grimes Golden and the Winesap group appeared immune at first but the Grimes Golden has been severely attacked and localized attacks on the Winesap and Mammoth Black Twig have begun.

In 1912 the disease destroyed the fruit crop in many blocks of trees in Virginia and adjacent States. That season a few enterprising orchardists in the neighborhood of Winchester, Va., had cut down the red cedars around their apple orchards, and the result was a striking demonstration of the efficiency of this method of control.

In 1914 the disease had become so severe that in the Winchester, Va., district alone it was estimated that it destroyed 100,000 barrels of apples, reducing production estimated at 500,000 to 400,000. As a result, recommendations of the Department of Agriculture and of several of the State experiment stations for eradicating the red cedars began to be carried out. Virginia passed a special cedar-rust law in 1914, West Virginia having passed a similar law the year before, and other States have followed. Whatever theory or explanation may be advanced, the facts are that this fungus gradually attacked one variety after another with increasing severity. Since localized infections have already begun on the Winesap group and other varieties previously resistant, it is doubtful whether any variety of apple can be counted on as resistant to this disease.

### The Life Cycle of the Cedar Rust

Beginning with the little brown galls on the cedar trees in early spring, these begin to exude their orange-colored gelatinous spore masses and form their secondary spores or sporidia on the first rain after the apples reach the pink-bud stage. They continue to throw off sporidia each rainy spell for about six weeks. These sporidia can not attack the red cedar but can grow only on the apple and its relatives. They can attack only young, newly formed leaves within a few days after they are expanded. They are very light and minute and are easily blown in all directions by the wind, but in general the quantity reaching any given number of apple leaves varies inversely as the square of the distance. The nearest infected cedar trees are, of course, the most dangerous. Those twice as far away are about one-fourth as dangerous but increase in the number of trees and the amount of infection may compensate for greater distance. After a fungous thread-forming spore succeeds in entering an apple leaf it produces a visible orange-colored thickened spot. This spot grows to about one-eighth or one-fourth of an inch in diameter and about the middle of July forms fringed cluster cups on the under surface, each crop filled with the summer spores of this fungus.

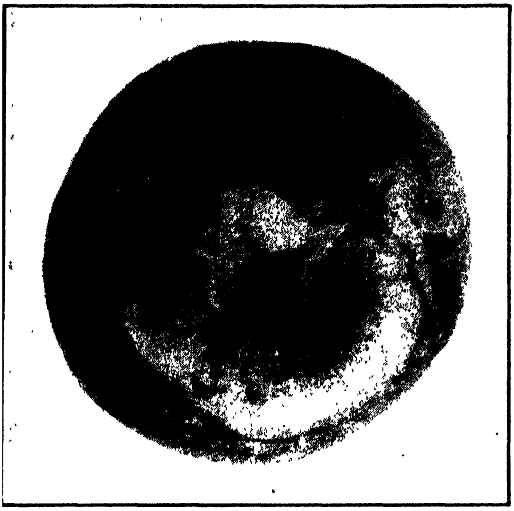

FIG. 10.—Mature Smokehouse apple from Pennsylvania carrying orange-colored diseased cedar-rust spot. The fungus as usual is only partially fruitful on this apple spot

Leaves carrying a few spots may live through the season and function, but when heavily infested they turn yellow and fall to the ground in midsummer. The fruit on heavily infested trees stops growing, is poorly colored and often less than half normal size. The fruit itself is sometimes attacked, especially near the calyx end, a similar but larger orange-colored spot being produced. Young tender twigs of some varieties are also occasionally attacked. The cluster-cup spores from the apple leaves mature in July and early August. They can not attack the apple, but can only germinate and enter the young, tender leaves and twigs of the red cedar trees. These summer infections on the red cedars remain dormant and invisible through the summer, fall, and following winter.

### Grows Through Tissues

When the infected cedars start to grow the next spring the fungus grows through the tissues and the gall forms and grows with the tree. These galls, made up of a mixture of the host and the fungus, reach practically full size by fall, and pass through the second winter in this condition. They reach full maturity and exude their spore masses the following spring and then die, thus completing the two-year cycle. The fungus, therefore, spends 2 to 4 months of late spring and summer on the leaves or perhaps the fruit of the apple, and about 21 to 22 months on the red cedar, the first winter as an invisible dormant infection, the second winter as a full-grown gall.

It should be noted that there are three living plants necessary for this cycle—the red cedar, the apple or its relatives, and the cedar-rust fungus. Without the presence of the cedar-rust fungus, red cedars and apples grow harmlessly together, neither endangering the other. However, when the cedar-rust fungus is present the red cedar becomes a pest tree to the apple orchards; and, on the other hand, the diseased apple tree serves to infect the red cedar.

Two other related species of cedar-rust fungi attack the apple in the eastern United States. Both are unimportant as apple pests as they occur only occasionally. One of these, however, also attacks the cultivated quince, producing an orange rust of economic importance.

### Control Measures

Efforts to control this disease by spraying have proved futile. Spraying has reduced the attacks of the fungus in some cases but the rapidity of the development of the new leaves and the repeated infections that occur are probably the explanation of the failure of spraying. It should be noted that cedar rust has spread in Virginia and West Virginia orchards that were annually successfully sprayed for apple scab, leaf spot, and other fungous diseases. On the other hand, efforts to control the disease by cutting down the red cedars have been uniformly successful just in proportion to the thoroughness of the cedar eradication and the distance. At first, during 1912 and 1914 good results were obtained in Virginia by cutting the cedars within half a mile of the apple orchard. Later, it was found necessary to cut the cedars within 1 or 2 miles and finally as infection increased even the 2-mile distance has been found unsatisfactory where hillsides and mountain sides were found covered with large bodies of cedars. Ordinarily a distance of 2 to 4 miles may be regarded as satisfactory, with the latter distance as probably the only safe one.

Since it is only infected cedars which transmit this disease, and since the large spored form of fungus apparently is not blown by the wind as readily from the apple onto the cedar as the sporidia from the cedar to the apple, it is probably important where a large quantity of cedars at a considerable distance can not be removed, to keep the apples away from them. In other words, a large group of cedars may receive their rust infection from a few apple trees near them and then deliver the wind-blown spores in vast quantities to distant apple orchards. Without the few near-by apple trees they would remain uninfested or little infested.

In view of the above facts the biological conditions call for the following procedures: (1) The eradication of the red cedar in the vicinity of apple orchards wherever the cedar-rust fungus is present; (2) the abandonment of the planting of red cedars in the vicinity of apple orchards in the eastern United States and perhaps elsewhere in the country; (3) the substitution of other species of conifers of somewhat similar appearance for ornamental, park, and roadside trees; and (4) the segregation of red cedar plantings for forest or other purposes into districts where apples are not grown and preferably where apples and crab apples are eradicated and with a zone of 4 or 5 miles surrounding the forest area where neither host plant is permitted to grow.

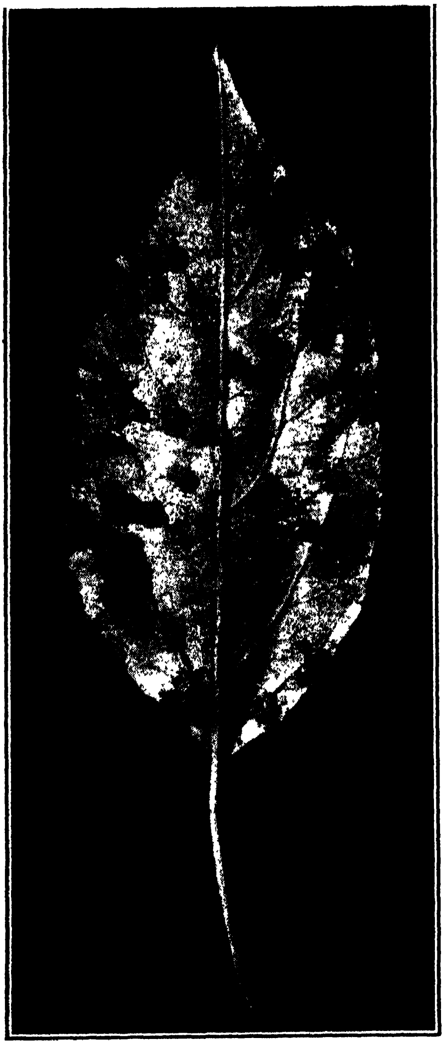

FIG. 11.—Cedar rust on underside of apple leaf (Wealthy) from Minnesota, showing the condition in September, the rust fungus fully developed and most of the spores shed

Possibly also quarantine action may be necessary in preventing the shipment and planting of red cedars. Certainly red cedars from cedar-rust infested territory should not be shipped into districts west of its natural range, that is, west of the Great Plains. Certain details in connection with the handling of these matters may be mentioned. The presence of the cedar-rust fungus on cedar trees from infested districts is not determinable when there are dormant infections. It is not easy to find moderate infection of the mature galls on account of the density of the tops. There is no likelihood of the disease ever being transmitted from dormant nursery trees of the apple, as it is only the summer form that occurs on this host. In eradicating the red cedar trees those over 3 or 4 inches in diameter may be simply cut down and the stumps will die, but trees of smaller size usually sprout and the young sprouts are more susceptible to the disease than the mature growth. All young trees, therefore, should be either pulled up or grubbed below the ground line. Many cedar trees occur in hardwood thickets. The best time to find them, therefore, is in the winter, when the leaves are off, especially when there is a light covering of snow on the ground. When the cedars are cut in the fall or winter the galls die, but when cut in March or April so that the tops remain green and the galls fresh they may exude their spore masses from the fallen trees. All tops, therefore, should be burned on trees cut after February.

M. B. WAITE.

---

**APPLE Picking at the Right Time** The time of picking apples is extremely important in determining the storage quality of the fruit. Removing the fruit while in an immature condition will give a product that is very susceptible to wilting in storage; that is, susceptible to storage scald, and which is of poor dessert quality. On the other hand, allowing the fruit to remain on the tree too long may result in the fruit becoming ripe and mealy relatively early in storage. Heavy loss from dropping may also result from delaying picking too long.

There is no one test which, taken alone, is entirely satisfactory for determining the time of picking apples. The ripening process is a combination of many changes going on in the fruit and no one change is entirely satisfactory for determining when to pick the fruit.

The tightness with which the fruit is holding on the tree is one of the most dependable tests for time of picking. Most varieties should not be picked before the fruit is in such condition that the stem separates from the spur very easily. The fruit should generally separate from the spur when lifted and given a slight twist, or when the stem is turned at right angles to the spur. Most varieties when ready to pick may be harvested with very little breaking of the spurs.

The ground color, or color of the unblushed portion of the fruit, is also an excellent index to the condition of the fruit, especially red varieties. In practically all red varieties the unblushed portion should have a distinct yellow cast when the fruit is ready to pick. The Department of Agriculture has prepared a color chart showing the change from green to yellow-green color through which apples pass prior to proper picking condition. This yellowing of the unblushed portion of the fruit is one of the most dependable tests for time of picking many varieties.

### Flesh Firmness a Good Test

A third test of much value in determining the proper picking condition is the firmness of the flesh. As the fruit ripens it softens and this softening can now be measured by a mechanical tester, somewhat similar in principle to a tire gage. This is particularly valuable as an indication of when certain varieties are becoming too ripe on the tree to be good storage fruit.

The number of days which have elapsed after the time of blooming is also a rough indication of the picking condition of the fruit. In general, different varieties have a fairly definite interval of time between the date of full bloom and the picking date. An early blooming season usually indicates an early harvest and late blooming is generally followed by a late harvest.

The color of the seeds and amount of red color on the fruit are not of much value in determining the time of picking of winter apples. No chemical test has been found that is of any real value.

The manner in which the fruit is adhering to the tree, the degree of yellowing in the ground color, and the firmness of the flesh appear to be the most dependable indexes to picking condition. A recent Department Bulletin discussed in detail the proper time of picking most of the important commercial varieties.

J. R. MAGNESS.

## ASEPSIS for Plants from Abroad

The dangers attending the introduction of plants from foreign countries have in recent years become so painfully apparent that it has led to the erection of numerous quarantine barriers and even raised the question as to whether the benefits from such introductions are commensurate with the risks involved. There are many weighty reasons, however, for continuing a guarded interchange of plant material between different parts of the world. The plant breeder, in particular, has a vital need for new introductions, especially for the wild relatives of cultivated plants. It thus becomes essential to work out an improved technique for the care of importations, and an excellent start has been made in connection with the handling of citrus plants introduced from the Old World. The occurrence of citrus canker, an insidious bacterial disease the eradication of which in the Gulf States in recent years has cost several million dollars, made necessary special precautions in handling citrus material, precautions which appear easily adaptable to other bud-propagated plants.

The first step is the construction of an insect-proof propagation house, with specially designed ventilator screens and oil moats to prevent the entrance of insects, as well as to see that no insects introduced with the plants are allowed to escape. This is vitally important, since insects are often the active spreaders of disease. The second step is the adoption of a system of " aseptic " plant propagation. This involves as a matter of routine the disinfection of clothes, tools, and person on each visit to the house; but the new feature evolved for citrus propagation is the double transfer of buds from all original plants. As received from abroad all plants are disinfected by fumigation or otherwise and placed in a metal "knock-down" screened cage (fig. 12) where they are held until new growth is made suitable to use as bud wood. If this new growth is entirely free from infection or infestation, buds are taken and inserted, by budding or grafting, on vigorous home-grown stocks held for that purpose in the " isolation ward " of the quarantine greenhouse.

### Original Plant is Destroyed

As soon as these new buds are safely established and growing, the original plant, with any adhering soil, is placed in a covered container (fig. 12), transferred to a furnace and completely destroyed. The screened cage, readily taken apart, is sterilized with live steam or dry heat before being used again. When the budded plant has made sufficient growth, butts are taken from it—a second transfer—and inserted on new, clean stocks. If these second budded plants prove to be free from infection, they are admitted to the propagation bench of the main quarantine house; but before being sent out for field trial they must still be subjected to a lengthy period of detention and rigid inspection. No plant that has not an absolutely clean bill of health is ever released from the quarantine house.

The aim of this procedure is to make certain that no portion — root, branch, bark, or bud—of the original imported plant is ever released from quarantine. Only new, clean plants, "regenerated" by bud transfers, come forth after this vigorous regimen. As a result of this special equipment and procedure, the citrus-quarantine greenhouse, instead of being a sort of plant "pest house," as it might easily become, is as nearly absolutely clean in a horticultural sense as it is humanly possible to make it. No system, of course, is proof against personal carelessness and ignorance, and success in such work presupposes intelligent management. So far as the expense of insect-proofing the house is concerned, it has been found that the added thrift of the plants, freed from insect depredation, more than offsets the cost and trouble of installing the necessary equipment. And as modern medicine has developed a system of aseptic surgery, so must modern horticulture recognize aseptic propagation, in a liberal sense, as possible and vitally necessary in dealing with imported plants.

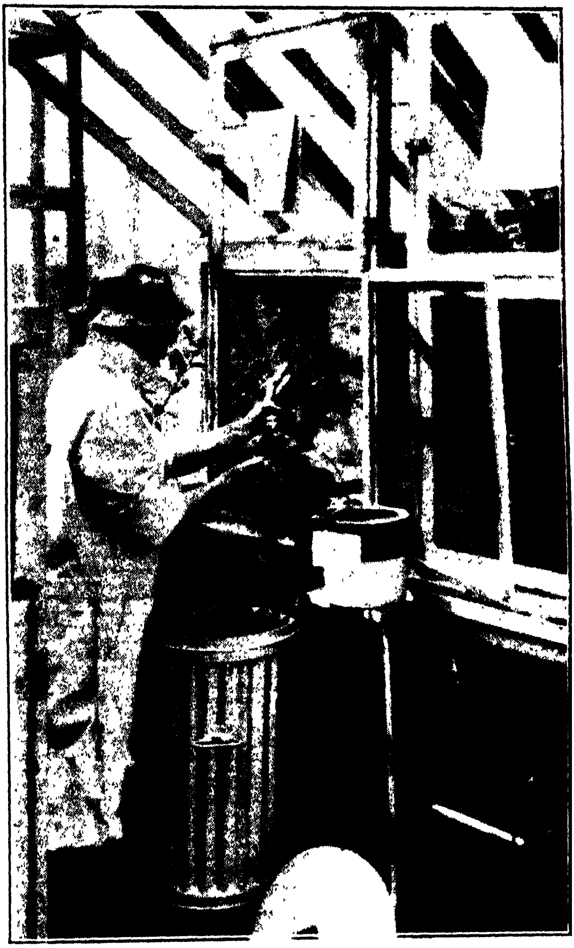

FIG. 12.—Section of "isolation ward," United States Citrus Detention Station (plant-quarantine greenhouse), Bethesda, Md., showing all-metal "knock-down" plant cages for handling separate importations, each cage surrounded by oil moat. Attendant is about to consign original plant to metal container for final destruction by fire after buds from it have been established on new stocks. Note jar of mercuric chloride solution (1 to 1,000) for sterilizing tools, hands, etc.; also attendant's one-piece suit, which may be sterilized frequently. Plants in wire-screened cages may be watered and inspected without opening doors

**BAMBOO Groves Thrive in the United States** The timber bamboo is a giant grass native of the warmer temperate regions of China and Japan. It was first introduced by the United States Department of Agriculture 25 years ago. Previous introductions in a limited way had been made earlier by private agencies, but the records in these cases are not clear.

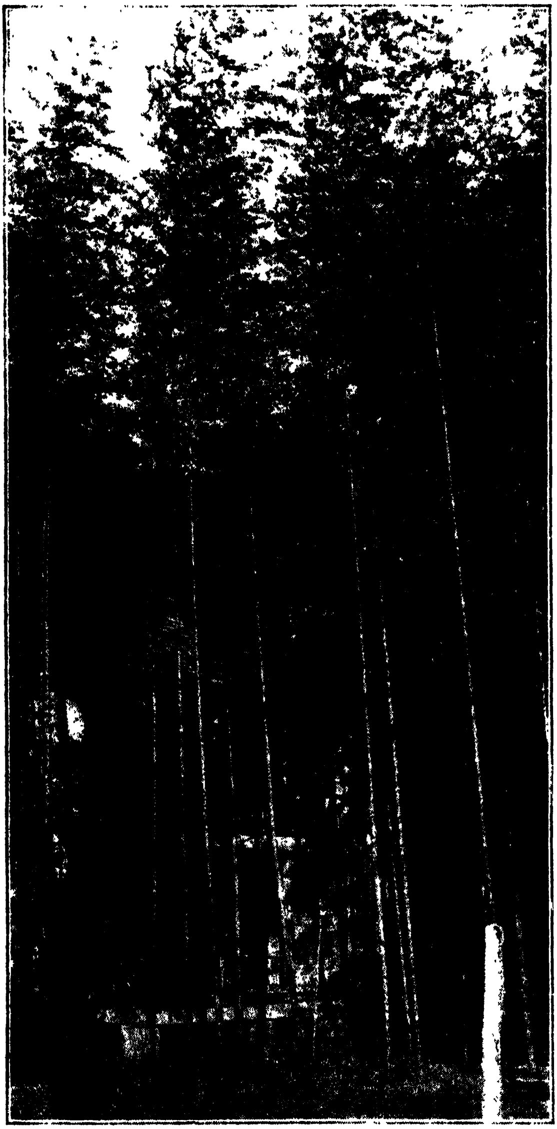

FIG. 13.—The timber bamboo as grown at the plant introduction garden, Savannah, Ga., providing a wonderful shade in summer and protection in winter

More than 400 species of bamboos have been reported throughout the world, but only 2 of these are native to the United States. They constitute the so-called canebrakes of our Southern States. There is probably no other group of plants so widely and generally used as this family of giant grasses. It is estimated that half a billion people are dependent on them in one way or another.

The timber bamboo in its young stage resembles many of our common grasses; the leaves are long and narrow and the canes or stalks are greenish, but quite hard. Like some grasses, the timber bamboo is provided with creeping underground stems or rhizomes which spread from the parent plant in all directions. New eyes or buds develop on these underground parts and these give rise to new plants. With each passing year the timber bamboo spreads and the stems and underground parts become larger and grow stronger. Age is a prerequisite for a successful timber-bamboo grove. It is not a quick crop like corn, wheat, and many other grasses. It is essentially a forestry crop. Eventually, when a grove is fully established, magnificent stems shoot up to a height of 60 to 70 feet, furnishing poles 4 to 5 inches in diameter at the base and tapering gradually to the tip, where they may be 1 to 1½ inches in diameter. The stems are hollow, but are divided by frequent cross partitions at the joints. The plants have the remarkable faculty of reaching their full size in a very short time, usually in two to four weeks, depending on the age of the parents. The new shoot suddenly bursts through the ground in the spring and then grows a foot or more a day. As the cane shoots skyward, the leaves, branches, and branchlets unfold, producing a most striking and beautiful effect. There is a majesty and grandeur to these plants that makes a strong appeal to the imagination. After attaining full size, the plants may require three to five years to fully harden and ripen.

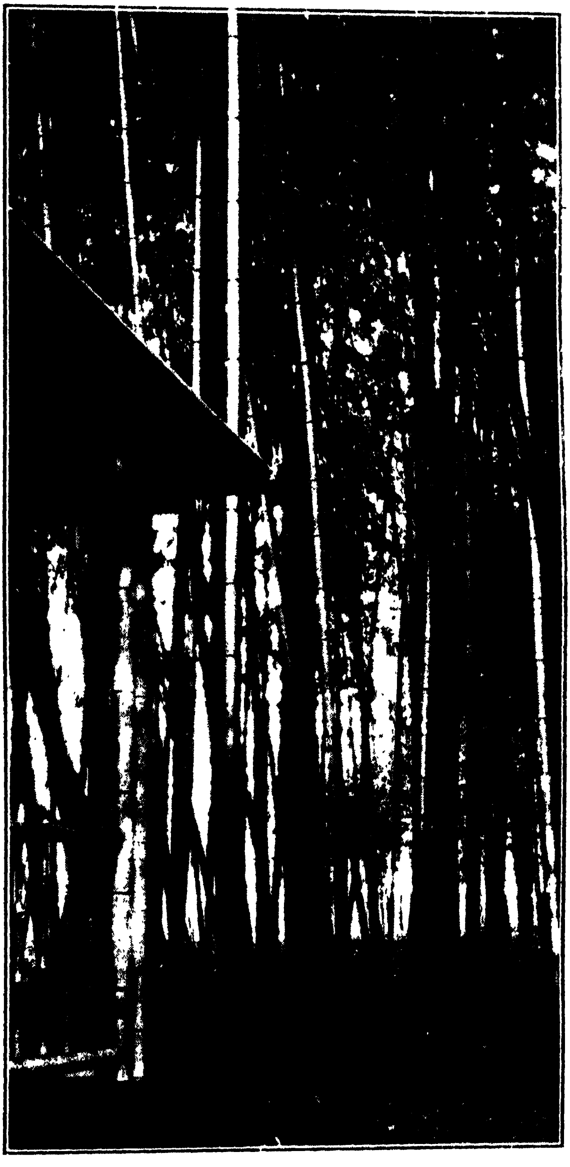

FIG. 14.—The timber bamboo. Inside the Savannah grove with the cool and quietness of a great cathedral. Note the part of porch made of bamboo stems

### Uses of the Timber Bamboo

Aside from the use of the timber bamboo as a beautiful evergreen ornamental, furnishing both grateful shade in summer and protection against cold, raw winds and storms in winter, it provides material for a multitude of uses on the farm and in the farm home; also in the marts of trade. Light fences, fence posts, trellises of many kinds, water-carrying pipes, baskets, crates, chicken coops, poultry yards and houses, and light ladders, all may easily be constructed from the mature canes. Commercial uses are also numerous, including furniture making, fish rods, phonograph needles, canes and poles for many uses in commerce, such as curtain and rug rods, flower stakes, tree props, fruit poles, and many other purposes.

The timber bamboo is adapted to a wide range in this country. It will thrive through practically all the Cotton States of the South and in the warmer moist valleys of California and the Pacific Coast States. The largest and most successful grove (figs. 13 and 14) is located near Savannah, Ga., where it has survived the winters for more than 35 years. Away from the coast country, where temperatures fall as low as 10° or 15° F. it is likely to be injured by frost.

Bamboos are of such recent introduction into this country that as yet small plants of the timber species are not available in the trade. They can not be imported on account of the risk of introducing dangerous pests of various kinds. The department, in order to encourage the planting of groves, has been furnishing plants in a limited way for several years. The plants are furnished to cooperators who are willing to put out from one-eighth to 1 acre and to care for the groves until established. The timber bamboo can not be grown from seed; hence propagation must be carried on by means of the rhizomes. These are taken from young plants in spring and set in beds. By the following year the plants from the rhizomes have usually made a good growth. It is best, however, to leave them for a second year. They may then be transplanted to a small nursery and held another year, or set directly in the field 10 by 10 or 10 by 12 feet apart.

### Careful Attention Needed

For the first two or three years the plants must be carefully tended and all weeds kept down by cultivation or hand hoeing. In good soil the plants soon begin to make runners and it is not long before the entire space is filled. The timber bamboo thrives best on well-drained deep soil. Good cotton or corn land should produce good bamboo. The crop should not be planted on wet or overflowed lands.

B. T. Galloway.

## BALANCING the Production of Agriculture

There are two important aspects to the problem of balancing the agricultural output of the Nation. One aspect of this problem deals with the matter of having the right quantities of corn, wheat, potatoes, cotton, beef, and other agricultural products so as to avoid undue shortages and surpluses of particular commodities. This is a problem of balance within the agricultural industry itself.

A second problem of balance has to do with the maintenance of the right proportion between our national agricultural output and our manufacturing and industrial output. Here the problem is one of utilizing our human and other resources in such a way that farmers will be able to maintain on their farms standards of living comparable with those maintained by people of similar training and ability in alternative occupations.

It is recognized at the outset that an accurate adjustment of our output of corn, wheat, beef, etc., can not be attained at any given time because of large fluctuations in production from year to year. Fluctuations in demand, though much less than fluctuations in production, also present an important difficulty.

The best that can be hoped for is to adjust acreage and size of producing herds and flocks in such manner that with normal yields the right quantities of the various products will be produced.

Assuming that it is possible to make these adjustments of acreage, herds, and flocks, is there danger of so restricting production as to make prices abnormally high? The answer to this question must be "No." If prices are high relative to production costs the farmer's incentive is to increase production, for thereby he can increase his income.

Intelligent discussion of the problem requires separate consideration of the major crops—cotton, corn, wheat, oats, and hay—and the minor crops. Each of these major crops occupies 35,000,000 or more acres of land in this country. No other crop occupies as much as 9,000,000 acres. The principles involved in adjusting the acreage of the major and minor crops are fundamentally different. In some localities certain of the minor crops are major crops locally. In such cases what is said of major crops below applies to them.

### The Minor Crops

Farmers are in the habit of adjusting the acreage of all their minor crops. To show why this is easily done let us consider the potato crop. Ordinarily it occupies about 3,500,000 acres of land. A 10 per cent reduction of the acreage means 350,000 acres of land available for some other crop. If corn is grown on it, this means an increase in the corn acreage of less than one-half of 1 per cent. This exchange of area might double or treble the price of potatoes and at the same time have a negligible effect on the price of corn.

The reason why the most satisfactory possible adjustment of the acreage of minor crops has not been accomplished in the past is that at planting time farmers have not known how much increase in acreage is permissible or how much decrease is desirable. They have been guided almost entirely by the price at planting time.

To bring about the adjustment all that is necessary is for every grower of a minor crop to know at planting time how much increase or decrease in the acreage of the crop is necessary to bring about the adjustment.

This information is now furnished the grower in the outlook report of the department, which is published early in February each year. Another reading on it is given in the intentions report, which is published annually the latter part of March.

There is evidence in the case of some of the minor crops that this information has in the last year or two had an important influence in governing acreage planted. It is desirable, however, to perfect better organization for the purpose of getting this information to farmers. This is being attempted by representatives of the department and of the various State agricultural institutions.

Adjustment of the acreage of the major crops is a different problem. During the war high prices and the urgency of the situation for greater production of food led to an enormous extension of all the major crops, which resulted in bringing a large area of new land into cultivation. So long as the war lasted there was a market for the products at good prices. Shortly after the war a crash in prices came, and since that time we have been producing more of all the major crops than could be sold at a reasonable profit.

### Major Crop Acreage Excession

The difficulty arises from the fact that the acreage of all of the major crops is excessive, and there are no other crops which the farmer can substitute for them profitably.

According to the census there was a reduction of 19,000,000 acres in harvested crop area between 1919 and 1924. It is not known exactly how much further reduction would be necessary to make production of the major crops fairly profitable. This can be done only by the abandonment of land now in cultivation.

The abandonment of land can hardly continue until the acreage of the major crops is sufficiently reduced to make their cultivation profitable for the reason that many million acres of land are now idle and ready to come back into cultivation as soon as it is profitable to cultivate them. It appears, therefore, that under present conditions a permanent rise in the price of the major crop products to an average level of satisfactory profit to the producer is not to be expected within the near future.

The problem of balancing the output of beef and dairy products is similar to that of the major crops; of the remaining livestock products to that of the minor crops.

W. J. SPILLMAN.

## BARBERRY Eradication in Wheat Areas

The common barberry was brought from Europe to New England by early colonists. From there pioneers carried this shrub westward to New York, Pennsylvania, and the Ohio and upper Mississippi Valleys, and finally over the Rockies. The plant was used for ornament and hedges, the berries for jelly, and the yellow roots for dyestuff.

New England farmers realized very early that grain grown near common barberries usually was blasted. As a result, laws prohibiting the growth of common barberries were passed in Connecticut in 1726, in Rhode Island in 1766, and in Massachusetts in 1775. Similar laws became effective in parts of Germany and France during the period from 1805 to 1888, and in Denmark in 1903.

### Relation to Stem Rust of Grains

Experimental proof of the connection between black stem rust of cereals and the rust of barberry was made by DeBary in 1865. He actually produced infection of small grain by placing on their leaves the rust found on the leaves of common barberry. Similar experiments have been repeated many times in both Europe and America, confirming these results.

Severe stem-rust losses have occurred frequently in various local areas. Some farmers and some localities and even whole districts have abandoned wheat growing because of repeated attacks of stem rust. As early as 1890, county-wide epidemics had come to the notice of agriculturists. More severe and more widespread epidemics occasionally were reported. In 1904 occurred an epidemic so severe and so widespread that it became of national importance.

Again, in 1916, a still more severe epidemic occurred. Because of the emergency need for wheat brought about by the World War, this one became of world-wide importance. The loss to spring wheat alone in the United States was estimated at 180,000,000 bushels. Some injury was reported to winter wheat, oats, barley, and rye. Reports from Canada estimated the loss of spring wheat in the prairie Provinces at over 100,000,000 bushels. In the years since the annual losses have varied. However, the average annual loss caused by stem rust in the 10-year period 1916 to 1925, inclusive, is estimated at more than 50,000,000 bushels of all grains.

### The Barberry Eradication Campaign

The destructive epidemic of 1916 resulted in conferences followed by legislation and action to control stem rust. In 1917 North Dakota, which had suffered such severe losses in 1916, began the eradication of her common barberries. Early in 1918 the United States Department of Agriculture, in cooperation with the 13 North Central States, including Colorado, Illinois, Indiana, Iowa, Michigan, Minnesota, Montana, Nebraska, North Dakota, Ohio, South Dakota, Wisconsin, and Wyoming, organized and began a campaign for the eradication of all common barberries from these States. This campaign has been continued from that time with excellent accomplishments. The several phases of the campaign include research, education, survey, and eradication.

The investigations include the study of (1) the time of appearance of stem rust on the barberries and on grain each spring, (2) the rate and extent of the spread of stem rust each year, (3) the severity of local and wider epidemics and the resulting loss, and (4) the characteristics and rust susceptibility of various species, varieties, and hybrids of barberries that may be distributed in the United States.

The public must be kept informed of the purpose and progress of the campaign in order that the cooperation of all present and future property owners and occupants may be obtained and maintained. Adults and children are instructed through newspaper and magazine articles, bulletins, circulars, postcards, posters, lantern slides, motion pictures, demonstrations, and direct instruction in public schools. An organization of business men and agricultural leaders, called the "Conference for the Prevention of Grain Rust," with headquarters in Minneapolis, has been most helpful in the publicity campaign.

### Surveys

The first survey was made to locate and destroy all planted and near-by escaped bushes. This survey is almost completed. It was designed to eradicate the largest number of bushes, especially fruiting bushes, in the shortest possible time and thus reduce the danger of severe epidemics.

Resurveys for seedlings and sprouts are made on all properties upon which barberries have been found. These resurveys follow the other surveys at intervals of two to four years. Seedlings have continued to appear in a few areas for eight years after all fruiting bushes were killed.

A second complete survey now is in progress to locate and destroy any bushes missed in the first survey, any that have developed since from sprouts or seedlings, and those escaped bushes grown from seeds which birds have scattered in the more remote areas of the farms and woodlands.

FIG. 15.—Escaped barberries growing in a wooded pasture. Birds often carry barberry seeds for miles before dropping them. As a result, thousands of wooded areas must be cleared of escaped bushes

The common barberry was widely planted as an ornamental and useful plant in cities and towns and on farms. Birds have scattered the seeds widely in groves and orchards, along fence rows, in brushy pastures, in thickets, along streams, and in woodlands of every type. Bushes have been found in the crevices of precipitous cliffs, in abandoned stone quarries, in the middle of great clumps of wild currants and gooseberries and visible only from above, in dense thickets of wild plums, under tangled arbors of clematis, wild grapes, and poison ivy, on the steep banks of mountain torrents, among second-growth timber of northern cut-over lands, under the forest giants of river flood plains, in wet forests of cedar and balsam fir, in tamarack swamps, and even on a floating log. There seems to be no situation except deep water where the plant will not grow.

In these 13 North Central States were a few more than 900 counties requiring survey. More than 850 have had the first survey completed. The remaining 50 counties are located on the outer edges of the area. About 200 counties have been covered again in the second complete survey. This is more than two-ninths of the total number of counties. Although more counties have been completed in the second survey than remain undone in the first survey, the job is not yet half done. The area requiring resurvey at intervals constantly increases and the second survey is covering large areas of difficult woodland not touched in the first survey. However, many more than half the bushes are out. In the eight years of the campaign, to June 30, 1926, there have been found 6,506,825 original bushes, 5,340,302 seedlings, and 291,894 sprouting bushes. The total is 12,139,021 bushes. These bushes were found on 75,000 different properties. More than 20 per cent of the properties were found on resurvey to be infested again by sprouts and seedlings. Of these bushes found, 12,075,257 have been destroyed. About 8,000,000 have been dug or pulled. More than 4,000,000 have been killed with chemicals, mostly salt. The job required 1,170 tons of salt, 20,320 gallons of kerosene, and 1,056 gallons of sodium arsenite.

### Educational Work Necessary

While survey and eradication progress there also is the job of telling the story of the common barberry and black stem rust to most of the more than 32,000,000 people in these States. In doing this the Department of Agriculture has furnished more than 2,095,000 pieces of printed matter, the Conference for the Prevention of Grain Rust has furnished over 2,785,500 pieces, and the cooperating States about 265,000 pieces, besides almost innumerable newspaper items and articles.

Tens of thousands of barberry plantings from which stem rust has spread in former years have been found and eradicated. The majority of all common barberries found since 1918 have been infected with stem rust. Hundreds of local stem-rust outbreaks have been traced directly to the infected common barberries. Many single barberry bushes have been known to spread destructive rust for more than 5 miles in all directions. Even small seedlings and sprouts infected early in the season have been proved responsible for the spread of rust to near-by fields of grain. The large number of these local rust spreads found indicates clearly that the inoculum for the more widespread epidemics comes from these numerous early local infections around infected common barberries. It is little wonder that stem-rust epidemics have occurred each year with millions of infected barberries scattered in many thousands of locations all through this grain-growing area. The wonder is that greater damage did not occur each year and that more farmers did not abandon grain production.

In the States east of the Mississippi the reduction of these local rust centers has so reduced stem rust that losses have become almost negligible, except near remaining barberries. In the group of States west of the Mississippi the number of local epidemics has been greatly reduced. The recurring general epidemics also seem to be much later in developing and much less in severity and extent. This campaign of barberry eradication must and will continue until every barberry bush, seedling, and sprout has been found and eradicated from these grain-producing States.

F. E. KEMPTON.
L. D. HUTTON.

## BARK Beetles and Timber Conservation

Bark beetles are a highly specialized group of insects that may be found in the dying trees of any coniferous forest. They are represented by numerous species, none of which exceeds the ordinary house fly in size. Their importance is due to the fact that they feed and rear their broods in the layer of tissue between the bark and the wood of forest trees. This narrow ring of tissue, generally known as the cambium, is vital to the functions of the plant, and its destruction results in the death of the tree within a short period of time.

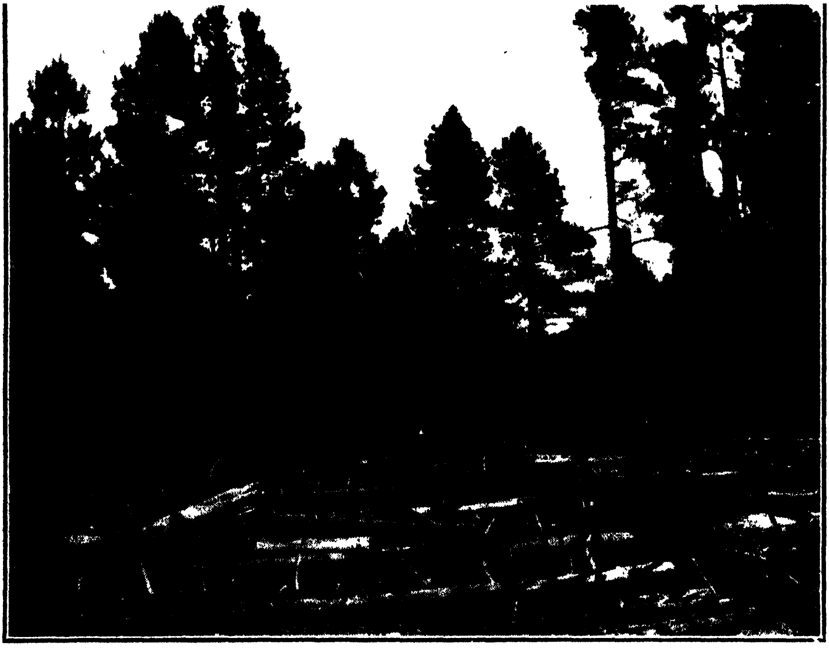

FIG. 16.—Yellow pine timber killed by the Black Hills beetle on the Kaibab National Forest

Relatively few species of bark beetles are able to attack and bring about the death of living, vigorous trees. Other species attack only the cambium of trees that are in a weakened or dying condition from other causes. Such species therefore are of small importance in the conservation of timber stands. Less than 10 of the species are known to have caused really serious losses of timber and their depredations occur mainly in the pine-growing regions of the Western and Southern States. These species belong to the genus Dendroctonus, and because of their host trees they are commonly known as "pine beetles."

All of the important pine beetles now found in the United States are native insects and therefore do not present a problem in the same sense as an introduced pest such as the gipsy moth. These bark beetles long ago became established everywhere throughout the range of their host trees. The old mature trees of our present forests have grown up under conditions in which tree-killing beetles and uncontrolled fires were important factors.

**Natural Checks Exist**

These insects do not entirely destroy the forests which compose their food supply because natural checks and balances limit their numbers. Unfavorable climatic conditions, insect enemies, diseases, birds, and the natural resistance to insect attack of vigorous trees all tend to produce a high mortality among the bark-beetle broods. Under normal conditions the quantity of timber killed by these insects does not exceed the yearly gain in volume due to tree growth. Thus the forest is maintained, as the loss is offset by increment.

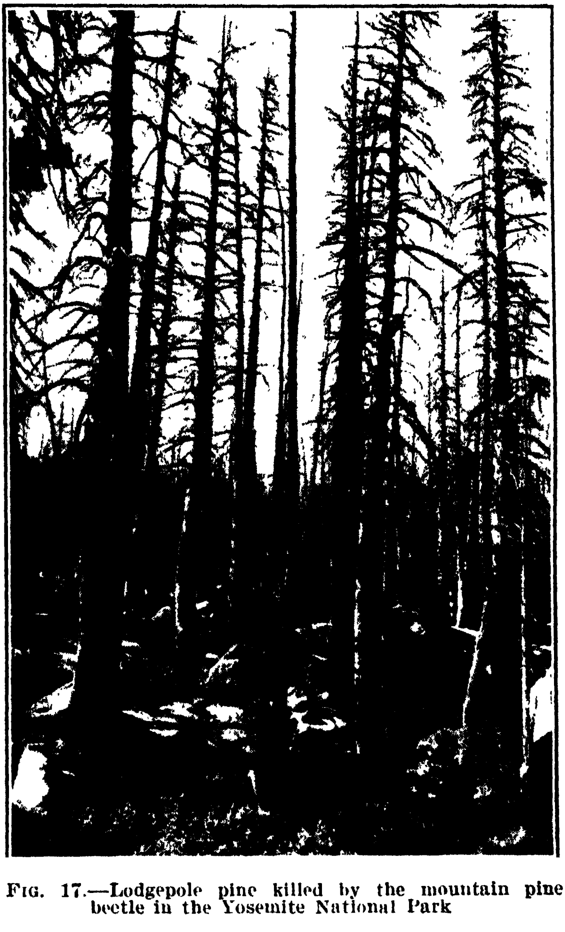

FIG. 17.—Lodgepole pine killed by the mountain pine beetle in the Yosemite National Park

At times, however, conditions arise which favor the insects. Natural checks fail to maintain the balance and bark beetles increase to the point where they kill timber much faster than it grows. Such outbreaks, usually known as "epidemics," have caused very heavy losses in valuable yellow-pine stands in California and Oregon. In Montana the lodgepole pine has been killed over vast areas by these insects to the extent that it will require a century to replace it by normal forest growth.

It is in the mature, reserve stands of pine, which for the next few decades will provide the most available supply of high-grade lumber, that the losses caused by bark beetles are now most evident. During certain seasons in some of the pine-producing regions of the Western

States the volume of timber killed by bark beetles has greatly exceeded that killed by fire. The value of pine stumpage killed by bark-beetle outbreaks has been estimated to average $15,000,000 annually.

Control methods have been devised which consist of searching out and cutting the infested trees, and then destroying the insect broods by burning or exposure to weather. When applied at the right time to epidemic conditions these methods materially reduce losses. Where timber values are high, the quantity of timber saved from destruction more than offsets the cost of the control work.

At present these control methods are the only practical means that have been found for the protection of our most valuable timber stands against bark-beetle losses. There is a real need for research work which will provide a better understanding of the natural factors that govern the increase and decrease of bark-beetle epidemics. Such studies should provide the foundation for improvement of control methods and the management of forest areas with the idea of preventing conditions that favor bark-beetle increase.

J. M. Miller.

**BARLEY Varieties New to United States** All of the many varieties of barley grown in America have been introduced from other countries. This introduction has come about in three ways and these ways correspond to three periods in our agriculture. When America was being settled immigrants brought their own seeds with them. Later State experiment stations and the United States Department of Agriculture were established for the assistance of the farmer. Although these agencies for the most part were not concerned with comprehensive efforts to obtain new things, they became a medium for testing and distributing them. Finally, within these agencies came an organized effort to procure and study plants from all parts of the world.

The varieties brought by the immigrants succeeded only where the new lands were favored with a climate similar to the section from which the farmers came. The Coast barley of the Western States and the six-rowed form grown in the Lake States 30 years ago came to us in this way. In later years Federal and State agencies have played an important part. The Manchuria and Oderbrucker barleys were distributed in the United States and Canada by State and provincial agencies. Club Mariout was sent to the Department of Agriculture from Egypt and is now an important barley in California. At one time an attempt was made to produce a higher grade of barley for malting. Svanhals and Hannchen were introduced during these activities and are now grown to some extent. Possibly the most successful of recent introductions was Trebi. This variety was selected from an importation coming from near the Black Sea. It is now almost the only barley grown on the irrigated lands of southern Idaho and is grown also in several neighboring States.

### All Varieties Sought

At present there is an intensive effort to procure all possible varieties for observation, as it is not possible to tell in advance whether or not a variety will be successful. In 1923 and 1924 selections were made in the barley fields of Algeria, Mariout, and the irrigated lands of Egypt, in northern Africa; of Kashmir, in northern India; and of Abyssinia, in eastern Africa. These selections have been grown in the United States for two years, but their value has not yet been determined. The climate of northern Africa is similar to that of the Western States, and many of the strains should give high yields in the West. Varieties not superior in themselves may possess qualities which are of great importance in crossing. The inherent vigor which causes a variety to be markedly superior under a specific condition is potentially important in a parent.

HARRY V. HARLAN.

## BEAN Wilt Traceable to Infected Seed

"The seed is blamed for everything, but weather and soil conditions are the important things," said a seedsman to the writer some years ago. Was he right? Yes, and no. It is true that conditions must be favorable to any given infectious disease if it is to flourish and become epidemic, but the

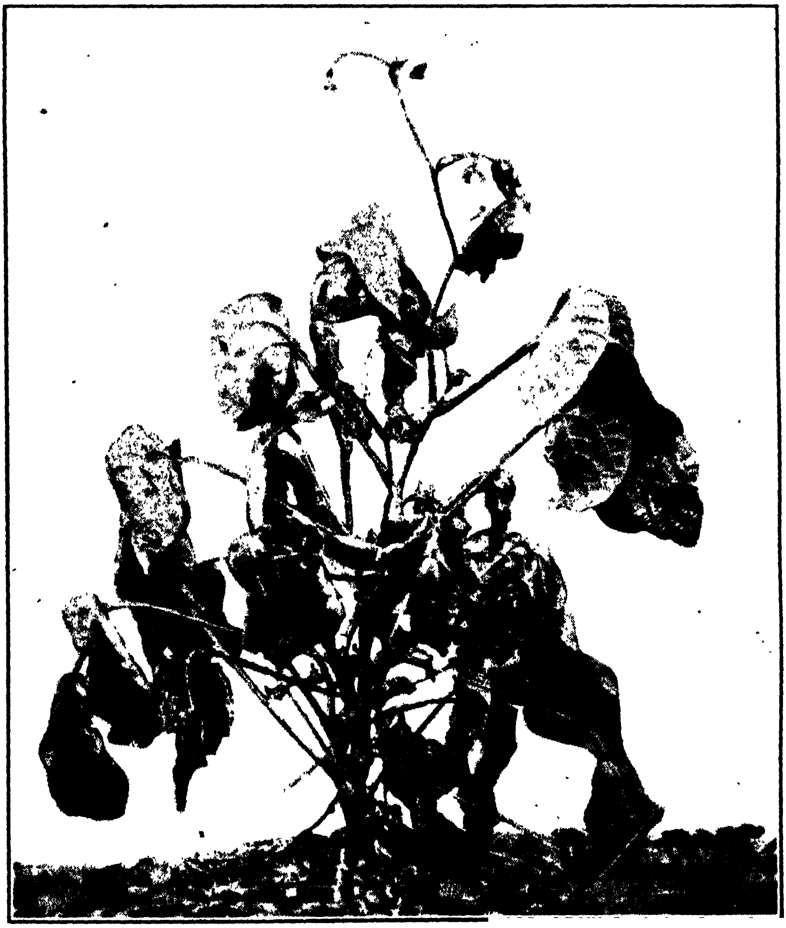

FIG. 18.—Bean wilt (*Bact. flaccumfaciens*) on navy-bean plant from badly infected field

presence of the parasite is as necessary as the yeast in the making of bread.

In the case of seed-borne diseases it is the infected seed which causes the initial outbreak in the spring. From such centers of infection the disease will spread rapidly, given the conditions of soil and weather to which the seedsman referred.

Such is the story of bean wilt. In 1923, following a year of serious outbreaks of this disease in Michigan, the writer made a tour of the bean-growing centers of that State. Wherever seedling wilt was found examination was made of the remaining seed. Invariably the yellow infected beans were found. It chanced that in every case these fields were planted with a white-seeded variety on which the infection is most easily discernible.

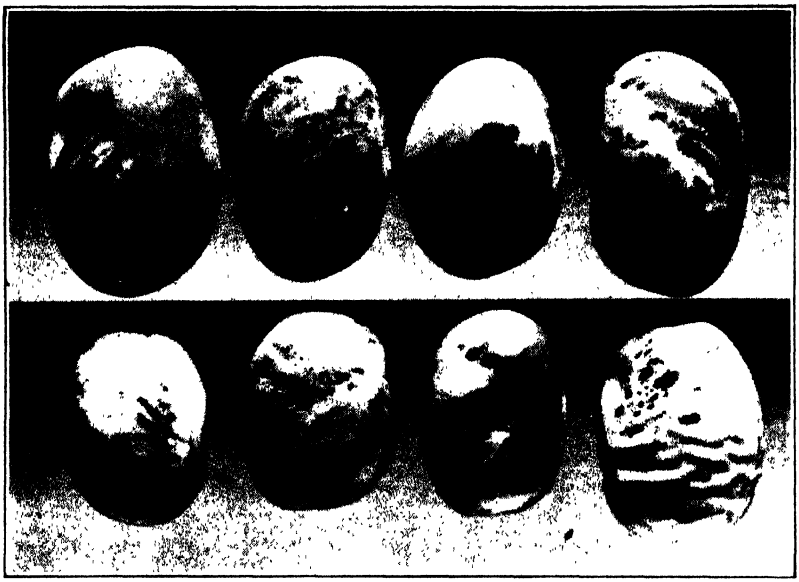

FIG. 19. —Navy-bean seeds infected with bacterial wilt. The darker areas seen in the photograph are in reality bright yellow, due to the bright-yellow bacterial mass which shows through the white seed coat. Magnified five times

A second tour of the same fields was made at harvest time, and in every case there were appreciable quantities of infected beans, although the conditions had not been favorable to the disease during the summer. Thus the cycle was complete. Wherever infected seed had been planted there was seedling wilt in June, spread of the disease through the summer, and infected beans in August.

So much vitality has this parasite that it remains alive in the seed and is still very infectious for at least five years.

Another sad part of the story is that the percentage of germination of infected seed is not very much lowered. Hence he who sows it reaps trouble.

FLORENCE HEDGES.

## BEETS of Primitive Type in Disease Control

Authorities are in agreement that the cultivated forms of beet originated from the wild beets of the Mediterranean or western Asiatic region. The cultivated forms as we know them have been in use by man for centuries and no record exists as to how or when they came under cultivation. The intensive work of sugar-beet breeding of the last hundred years has consisted largely of selection work upon beets which trace back to a very few high sugar-producing lines.

Contrasted with the uniformity presented by the sugar beet as it exists to-day is the multitude of forms shown by the wild beet, commonly called *Beta maritima* L., but which most botanists now concede is properly included in the same species as the sugar beet, *B. vulgaris* L. These wild beets, while conforming in botanical characters to the species, exhibit great variation in leaf form, growth habit, coloration, and root character.

With the failure to find in cultivated lines of beets the characters desired it is logical to turn to the primitive types in search of these characters. The severe conditions imposed by the habitats occupied by this plant and the severity of parasitic disease attack have led, by natural selection, to the elimination of the less hardy forms and the predominance of adapted types. The hybridizations and the resultant recombinations of characters have produced an enormous variety of types among the wild beets.

### Wild Beets Attacked by Rust

In nature, the wild beets were found by the writer to be attacked by the rust disease (*Uromyces betae* (Pers.) Tul.), root rot (*Phoma betae* (Oud.) Fr.), mosaic and leaf spot (*Cercospora beticola* Sacc.). The last named existed in epidemic form in many localities, and wild beets were found of all degrees of resistance, from apparent immunity to extreme susceptibility. Seed was selected from the most outstanding of these plants and the plants grown from this seed when subjected to further tests under severe disease conditions have shown the same relations to the leaf-spot fungus.

Similarly, certain of these wild forms have been exposed to the attacks of viruliferous leaf hoppers (*Eutettix tenella* Baker) to inoculate them with the curly-top disease of beets. In the case of curly top, no field selection was possible since this disease, so far as is known, does not exist in Europe and no natural selection has been going on. With most of the plants inoculated the effect of the curly-top virus was extremely severe. With certain wild forms, however, it was very evident that the disease produced only mild symptoms.

It has been demonstrated that, among wild beets, forms exist which are strikingly resistant to Cercospora leaf spot and which are tolerant of curly top. There is some promise that utilization of these forms may lead to development of resistant types with commercial possibilities. Introduction of these characters from the wild source seems necessary if we are to develop disease-resistant sugar beets, since commercial forms as now existing do not possess this characteristic. In a test of 500 strains of sugar beets at Rocky Ford, Colo., in 1925, under epidemic conditions for Cercospora leaf spot, no commercial variety of beets possessed any marked resistance to the leaf-spot disease. Tests in 1926 with 638 strains of sugar-beet seed at Las Cruces, N. Mex., under epidemic conditions for curly top showed that the same situation exists with this disease.

### Hybrids Show Resistance

The tests with sugar-beet strains which have arisen as a result of definite crosses of wild beets with sugar beets of high quality confirm the viewpoint expressed in this article. Certain selections of such hybrid origin show extremely high resistance to curly top when grown in field tests where curly-top infestation was practically 100 per cent.

Development work with a biennial plant such as the beet, which is subject to cross pollination, is of necessity slow. The commercial demands as to tonnage and sugar production are exacting. The introduction of the additional characters for disease resistance to leaf spot and curly top while maintaining present standards of quality presents to the plant breeder and plant pathologist formidable problems. The work carried on to date indicates that in certain wild forms we may have desirable breeding material.

## BEVERAGE Juices from Apples and Grapes

Unfermented fruit juices are once more becoming popular as beverages in spite of the strong competition offered by a multitude of synthetic soft drinks. The kind of cider made from apples which are valueless for any other purpose is not gaining in popularity; the product which is finding wider consumption is one which is made by methods of manufacture which are carefully controlled and from materials which are selected with all the care that long training and experience can bring to bear on the task. In consequence present-day fruit beverages have attractive appearance and standardized quality, and are finding favor among consumers to whom the kind of cider which was "just apple juice" made no appeal. The Department of Agriculture has contributed materially to this improvement in beverage juices by work on several phases of the technology of juice manufacture as well as by studies of the raw material.

Very few of the cultivated varieties of grapes, still fewer of the varieties of apples ordinarily grown, make satisfactory beverage juices when a single variety alone is employed. This is for the reason that our dessert apples and grapes have been selected and propagated because of the agreeable flavor when eaten out of hand. The possession of such quality indicates that the juice of the fruit will be somewhat lacking in the tartness and sprightliness which is regarded as desirable in a beverage juice. In consequence, in order to make juices which appeal to most palates, it is necessary to modify the rather insipid juice which will be obtained from most dessert varieties of apples by the blending of the more acid and astringent culinary apples or crab apples.

Studies carried on in the department over a series of years have included analyses of more than 500 varieties of apples, including a large number of crab apples and other astringent apples, as well as practically all the important varieties to be found in commercial and home orchards. The possession of these data permits the manufacturer, by inspection of the analyses which he has available, to determine what mixture of varieties should be made in order to produce a blended cider of palatable character.

### Improved Appearance of Cider

Other studies have had as their purpose the improvement of the appearance of bottled Pasteurized cider. Many people object to the cloudy, muddy appearance of the ordinarily Pasteurized cider and to the presence of the more or less abundant precipitate usually present after pasteurization. Detailed studies in which a great number of clarifying agents and aids to filtration were employed led to the development of a method of filtration, with the aid of purified infusorial earth, which gives a beautiful, permanently clear liquid with no modification in flavor and which does not become cloudy on being Pasteurized. This method of filtration can be applied to juice immediately after pressing from the fruit so that the whole process of preparation and Pasteurization in the final containers can be carried out in a few hours. It is thus much less laborious and costly than the older method of pressing, Pasteurizing and storing for settling, filtering, bottling, and Pasteurizing a second time.

### Filtering Improves Taste

The studies of methods of Pasteurization carried on in the department have brought out very important facts in regard to the cooked or boiled taste so often complained of in ordinarily Pasteurized cider. It has been found that when juices immediately after pressing are filtered by the use of diatomaceous earth they may subsequently be heated to Pasteurizing temperature without the development of the modified or cooked apple taste. This is for the reason that the substances which undergo changes on heating resulting in the modification of flavor, are removed by filtration with diatomaceous earth so that the juice can be heated after filtration to ordinary Pasteurization temperature, or even much higher, without any injurious change.

As a result of the information acquired through these and other studies bearing upon the problems of fruit-juice manufacture the department is in position to advise fruit-juice makers as to the selection and blending of fruits and the processes of extraction, clarification, bottling, and filtration of their products.

## BLACKBIRD Control in Grain Areas

Damage to grain by blackbirds is most frequent along the border line of agriculture or where cultivated fields lie close to the marshes in which these naturally gregarious birds breed or roost. In recent years most of the complaints against blackbirds have come from the rice areas of the Gulf coast, Arkansas, and the Sacramento Valley, Calif., and the milo and barley fields of the Imperial Valley, Calif. Red-winged blackbirds have been the principal offenders, but grackles, jackdaws, and the yellow-headed Brewer, and rusty blackbirds also have been destructive, especially when their numbers have been increased and concentrated during migration.

Ripening and mature crops, as well as the sprouting kernels, of rice, milo, corn, and oats are the chief grains attacked. In some localities entire fields of milo and rice have been so severely damaged by the birds that harvesting was unprofitable; and losses varying from 10 to 25 per cent over larger areas are not infrequent.

From those sections where for years farmers have had to combat blackbirds with firearms and less effective frightening devices, appeals for aid in a wholesale destruction of the birds have been increasing. To determine the practicability of such an undertaking has required much experimental field work and laboratory research.

Outstanding among the results obtained is the fact that during the ripening period or the harvest no extensive control measures can be successfully and economically carried out. The abundance of highly acceptable food, together with the quickness of blackbirds to detect danger and to shun areas where some of their numbers have met misfortune, makes poisoning operations unreliable in summer and fall. No bait can be devised more attractive than the abundantly available crops upon which the birds have become accustomed to feed.

FIG. 20.—A rising cloud. Mixed flock of red-winged and yellow-headed blackbirds over milo field in Imperial Valley, Calif.

Poisoning operations are more successful in periods of comparative food scarcity, in winter and early in spring. Blackbirds can then be destroyed in considerable numbers, though not at a reasonable expenditure of money and effort. Moreover, careful analysis discloses that extensive poisoning at that time may not accomplish the desired purpose. In the rice fields of Louisiana and Texas, for example, the winter blackbird hosts are multiplied manyfold by the presence of northern breeding birds in those congenial climes. Wholesale destruction at this season would involve killing many northern migrants that do not seriously affect the local problem and that may even be useful to agriculture in their summer homes.

Even the resident birds that are to blame for most of the damage wander throughout the entire Gulf coast region, though the narrow strip in which a reduction of their numbers is desirable is limited to the southern border of the rice belt.

The wisest and most economical measures of relief involve local control for the region of principal blackbird damage through poisoning at sprouting time, to prevent excessive damage at that season; and the continued use of firearms during the ripening period and the harvest. In large fields the small-bore rifle fired from a shooting tower has proved to be more effective and economical than the shotgun.

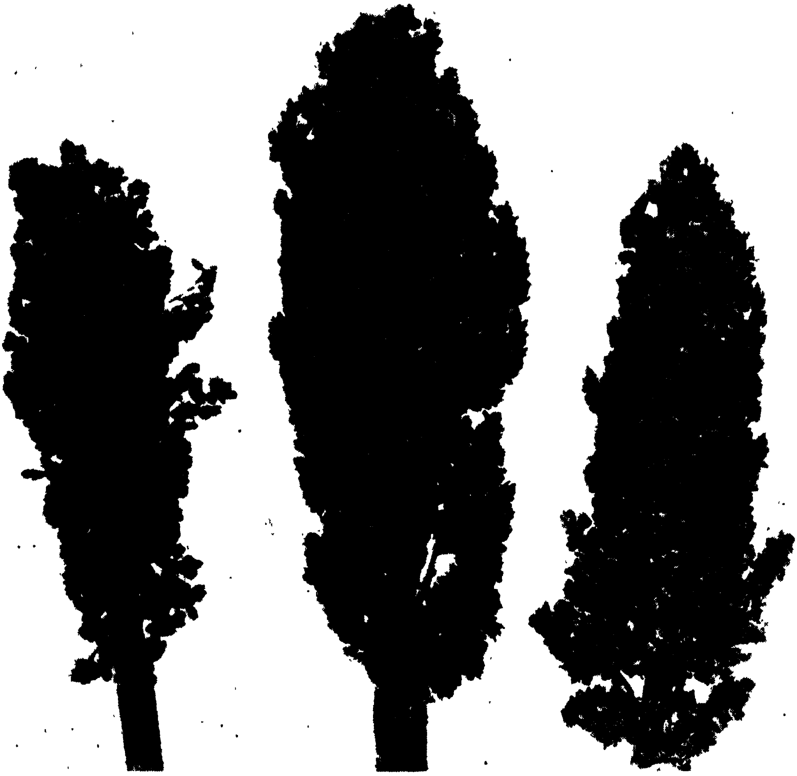

FIG. 21.—What the blackbirds left. Heads of milo stripped of grain by redwings, Imperial Valley, Calif.

E. R. KALMBACH.

**BLACK Currant is Nurse of Blister Rust** The European black currant is not extensively grown in the United States but is found to some extent in most sections where currants are cultivated. As its name indicates, it is of European origin. It is commonly called cultivated black currant. Under the conditions existing when it was first brought into the United States, this plant did no harm, but the introduction of white-pine blister rust has changed the situation.

White-pine blister rust is a fungous disease destructive to white (five-needled) pine trees. It can attack these trees only after it has undergone a period of development on the leaves of currant or gooseberry plants. This disease is comparatively new to North America. It was introduced from Europe on white-pine planting stock at various times between 1898 and 1910, and has become established in both the eastern and western portions of the United States.[1]

European black currant is a nurse plant for white-pine blister rust. So extremely susceptible is this species to the white-pine blister-rust disease, thereby favoring its rapid spread and establishment, that the United States Department of Agriculture recognizes the cultivated black currant as a distinct menace to the white-pine timber supply of the country. It is so serious a danger to the production of white-pine timber as to make this kind of currant a public nuisance in all States where white (five-needled) pines grow.

The department advises against the growing of this species of currant (*Ribes nigrum* L.) anywhere in the United States and recommends that State authorities, nurserymen, and growers take active steps to accomplish its prompt elimination from the Pacific, Rocky Mountain, Atlantic, Appalachian, Ohio Valley, upper Mississippi Valley, and Lake States. The growing of cultivated black currants, in home gardens as well as in nurseries and commercial plantings, should be entirely abandoned throughout these States, because of the great importance of the white pines and the relatively small value of the black currants.

The department, in cooperation with the infected States, has developed means for preventing blister-rust damage to white pines in a given tract or area. Such local control of the blister rust is feasible only in localities where pine values are sufficiently large to warrant the expense and labor of ridding the area of wild and cultivated currant and gooseberry bushes. This work must be done before the white-pine forests are severely attacked, hence it is important to apply general control measures to retard the spread of the blister rust into uninfected regions. The principal means of delaying its spread are through enforcing quarantines which regulate or entirely prevent the movement of the host plants of the blister rust, eradication of European black currants, regulated planting of other kinds of currants and of gooseberries, and sanitation of nurseries against the disease in order that only healthy pines shall be planted.

### Blister Rust a Fungus

The blister rust is caused by a parasitic fungus which grows within the tissues of its host plants (five-needled pines, currants, and gooseberries). It saps the life of these plants. Currant and gooseberry bushes are defoliated by the rust when infection is severe, resulting in reduction of the yield of fruit. On white pines the disease first causes the death of twigs and finally kills the trees. It kills white pines of all ages and, unless controlled, prevents the growing of these trees in areas where currants and gooseberries are abundant.

The disease does not pass directly from pine to pine, but only from pine to currants or gooseberries. However, the rust spreads from one currant or gooseberry bush to another, causing the under side of the leaves to appear as if spotted with iron rust. The spores (reproductive bodies) of this currant-rust stage may retain their germinating power for several weeks. The spores from a diseased pine are also long-lived and may retain their power to infect currants or gooseberries for months.

---

[1] The infected States on Sept. 1, 1926, include the New England States, New York, New Jersey, Pennsylvania, Michigan, Wisconsin, Minnesota, Washington, and Oregon.

There is still another and vitally important stage in blister-rust infection—the pine-infecting stage. A close knowledge of the life history of any plant pest usually discloses some point on which human intelligence can base control measures to reduce the damage caused by the pest and limit its spread. Thus our knowledge of the extreme susceptibility of European black currant to blister-rust infection is helpful in checking the rapid advance of the disease into uninfected regions. After the blister rust reaches the white-pine forests, local control of the disease rests upon the peculiarity of the pine-infecting stage of the rust.

Shortly after the rust has appeared on the leaves of currant and gooseberry bushes there is developed on the under surface of the infected leaves a feltlike mass of tiny hairs. These hairs produce blister-rust sporidia, or spores of exceedingly small size, which are so delicately formed that they retain their vitality for a comparatively brief period, and can infect a pine tree only under special conditions of humidity and temperature. Owing to the short life of the sporidia, white pines are infected only within a short radius of the diseased bushes. Even the extremely susceptible European black currants seldom spread infection to pines growing more than a mile from them.

### Remedy is Demonstrated

It has been conclusively demonstrated during the past 10 years that under ordinary forest conditions in the eastern United States white-pine forests suffer no further appreciable damage from blister rust after all currant and gooseberry bushes are removed from the pine area and from a surrounding zone 900 feet in width. In addition, European black currants must be removed within at least 1 mile radius of the pines, and occasionally it is necessary to remove plantations containing large numbers of plants of the yellow and red flowering currants within the same radius. More facts are required before the exact width of the protective zone under western forest conditions can be definitely specified. However, there is no indication that it will vary greatly from the distance found effective for local control of the blister rust in the Eastern States.

White-pine blister rust attacks trees of any species belonging to the white-pine group. The white pines commonly have five needles within the sheath which envelops the base of a leaf cluster; hence are also known as five-leafed pines. Some of our most valuable American timber trees are menaced by the blister rust. Among these are the well-known white pine (*Pinus strobus*), widely distributed in the eastern and northern United States; sugar pine, (*P. lambertiana*) found in California and Oregon; and western white pine (*P. monticola*), which occurs in Montana, Idaho, Washington, Oregon, and California.

The future timber supply of the United States depends upon systematic forestry. No trees have more desirable qualities for forestry purposes than the white pines. These species are readily reproduced, grow rapidly, and yield more in merchantable timber and in money value per acre than is common with other kinds of forest trees. The result is that forestry development in many States centers prominently around white pine, western white pine, and sugar pine as major species in forest management. All white-pine species have high ornamental value also and are planted as lawn trees and, to some extent, for windbreak and shelter-belt purposes.

The common history of white-pine blister rust since its introduction into the United States is that European black currants "catch" blister-rust infection in localities far from any infection center, causing the disease to advance by leaps and bounds. Many examples of such long-distance spread are recorded. In one instance cultivated black currant plants 110 miles from any white pines were infected. A careful investigation was made and all facts indicated clearly that the blister-rust spores causing this infection had been carried at least 110 miles by the wind. When it has thus reached a new point the rust soon completely covers the under surface of the foliage of all European black currants in the vicinity of the plant first infected. Other kinds of currants or gooseberries which grow close to the infected black currants may also show a small amount of the disease. Usually the disease is confined entirely to European black currants until near-by white pines become infected, after which all kinds of currant and gooseberry plants in the vicinity develop more or less rust.

### Cultivated Black Currants Responsible

Cultivated black currants have been largely responsible for failure of the efforts to eradicate the blister rust, because the disease had spread long distances to black currants before the infected pine plantations were destroyed. They have been responsible for firmly establishing the blister rust in hundreds of square miles of white-pine forest which would have remained free from rust for many years if there had been no black currants present. Thousands of square miles of white-pine forests are still free from the rust, and if possible must be kept free.

Nurseries producing white pines or currants and gooseberries should distribute plants guaranteed to be free from white-pine blister rust. This can be done, but not while European black currants are growing in the locality. At least nine-tenths of all rust-infected white pines in nurseries have been due to the proximity of these pernicious plants. So long as such black currants are permitted to exist in the pine-growing States shipment of white pine, currant, and gooseberry nursery stock from infected States must be closely restricted. If the black-currant plants have been generally eradicated, healthy white-pine stock can be produced from seed sown in an area entirely free from all other kinds of currant and gooseberry plants for a distance of 1,500 feet around the nursery beds. Certain wild currants, such as *Ribes bracteosum* and *R. petiolare* (found in the West), may have to be removed within a greater distance than 1,500 feet of the nursery, and also any large aggregation of *R. aureum*, *R. odoratum*, and *R. sanguinium*.

The total value of all European black currants in the United States is estimated to be $898,000, if each bush is worth $1.25 (an excessive value). The value of the merchantable five-needled pine timber of the United States is $548,250,000, or six hundred times as great as the total value of the black-currant plants. The future value of the young pine already growing must be estimated in terms of national necessity rather than money.

Blister rust threatens the future of the white-pine forests. Cultivated black currants accelerate the advance of this disease. The United States can do without them better than it can suffer the blister-rust losses, due directly and indirectly to their cultivation. Federal plant quarantine No. 63 prohibits the interstate shipment of European black currants from any State into the 36 States having native white-pine forests and in which the planting of white pine is of great economic importance. Oregon has eradicated them from the State. Idaho, Montana, Washington, and California will soon be free from these plants. New York has declared them a public nuisance. Public welfare will best be served if the growing of these plants is discontinued in every State.

Samuel B. Detwiler.

## BOOKS on Farming Increase

A distinguished feature of recent farm literature is its realism. As contrasted with the prejudiced or the sentimental attitude toward agriculture, characteristic of past times, it seeks to view conditions as they actually are. This realistic attitude is found in both of the classes into which agricultural literature may be divided—the works written for the farmer or the student of agriculture, and the works intended to interpret farming and the farmer to city people.

The average number of books on agriculture published in the United States annually, exclusive of bulletins and other official publications, is slightly under 100. This number, many times that of a few years ago, indicates a broadening interest in agriculture, although the average sale of each book, which is under 5,000 copies, suggests that the interest is as yet far from ideal. One must, however, consider in this connection the number of excellent bulletins published by the United States Department of Agriculture and by the various State experiment stations, the circulation of some of which is as high as 2,000,000.

Production manifestly is the basis of agriculture, and a large proportion of the books in the field deal with this subject. These books, for the most part, are specific and accurate, based on experiment and investigation, tested by actual farm practice. The general book on agricultural production has disappeared, except as a text for elementary courses.

### Financial Status of Farming

In recent years, however, the financial status of farming has directed attention to marketing and other economic problems. This is reflected in the titles of books in the agricultural field. A few years ago there were not even any general works on agricultural economic or farm management. Now, however, each year sees the publication of a number of specific books on the economic problems of farming. More of these deal with farm marketing than with any other topic, and there are not a few significant discussions of the cooperative movement. Among books of the last year or two are American Cooperation, consisting of papers and discussions presented at the annual session of the American Institute of Cooperation, Mears and Tobriner's Principles and Practices of Cooperative Marketing, Nourse's American Agriculture and the European Market, Moorhouse's Management of the Farm, Boyle's Marketing of Agricultural Products, Benjamin's Marketing Poultry Products, Horner's Agricultural Marketing, Mackintosh's Agricultural Cooperation in Western Canada, and McMurry and McNall's Farm Accounting; Principles and Problems. Manifestly the business side of farming is receiving appropriate emphasis.

Nor is the interest confined to the strictly economic side of rural life. The Federal Council of Churches, for example, has published Social Aspects of Farmers' Cooperative Marketing, by B. Y. Landis. Indeed, the emphasis on economics has brought to light numerous social problems of the rural community. It has come to be recognized that the value of economic advancement is in promoting a more satisfying family and community life. As yet the social aspects of the country have not received the study which has been given to the economic side of farming, though progress has been made by the American Country Life Association and by various students. The two most notable recent books in the field are James Mickel Williams's Our Rural Heritage and The Expansion of Rural Life, which contain the results of a 20-year study of a single rural community in all its social aspects, with, of course, frequent references to other communities. For these works Doctor Williams was awarded the Grant Squires prize by Columbia University. Israel and Landis's Handbook of Rural Social Resources, published in 1926, both presents discussions of various types of rural social work and contains a directory of national agencies engaged in rural social work, with the program of each. The 10-volume encyclopedia entitled "The Book of Rural Life" is notable for the emphasis which it lays on both economic and social problems.

### Few Works on Agricultural History

Only very recently has the history of agriculture received serious study. The number of works on the subject remains extremely small. Gras's History of Agriculture in Europe and America, published two years ago, is the only comprehensive study of this rather wide field. Agriculture in the northern part of the United States up to 1860 has been covered effectively in a volume by Percy Wells Bidwell and John I. Falconer. A volume dealing with the agriculture of the South is in process of preparation by L. C. Gray.

No little progress has been made in the last two or three years in interpreting agriculture and rural problems as a whole. Most of this has been done through newspapers and magazines, though such works as Bizzell's The Green Rising, Dies's Solving the Farm Riddle, Wallace's Our Debt and Duty to the Farmer, and Warren and Pearson's The Agricultural Situation, are significant contributions.

Perhaps a more vivid interpretation of the farmer as a person is obtainable from well-grounded fiction than from books which discuss problems as such. The increase in the number of novels dealing with farm life is a remarkable development of the last two or three years. For the most part these books are sound, sincere interpretations by writers familiar with the life with which they deal.

Three recent rural novels enter upon new ground. They present farmers in their effort to unite for the betterment of agriculture, chiefly on its marketing side. These works are Lorna Doone Beer's Prairie Fires, Lynn Montross's East of Eden, and E. R. Eastman's The Trouble Maker.

### The Farmer as Individualist

The other recent farm novels treat of the farmer in his traditional individualism. It is noteworthy that all of these novels give due emphasis to the place of women in farm life, a subject that receives insufficient attention in most discussions of rural problems. Among contemporary farm novels are G. D. Eaton's Backfurrow, Ben Ames Williams's The Rational Hind, Ellen Glasgow's Barren Ground, Walter J. Muilenburg's Prairie, Thomas Boyd's Samuel Drummond, and John T. Frederick's Green Bush. The last of these works makes as vivid an interpretation as has ever been made in America of the deepest aspects of farm life. The author of this book, himself a farmer as well as a novelist, has been able to create a credible character who finds final peace on a northern farm. He says:

> Of this alone I can be certain: That love and knowledge of the earth, which means daily observations and acceptance of the facts of birth and death, of the puniness of man's efforts and the little meaning of his life, has brought me happiness, compounded of joy in simple things—pleasure in food, in wife and children, in beauty of flower and tree, of sky and water and the forms of earth, in the dependence and faithfulness of beasts, in freedom that comes from knowledge and acceptance of my weakness and of death.
>
> The earth has maimed and broken me, perhaps, as ultimately it will defeat every effort of my life. But also it has given me strength to bear disaster and defeat, and death.
>
> To me death is not a strange or fearful thing. I see it all about me daily, hourly—myself the agent of a million deaths as I reap or mow or plough my fields. All day long I slaughter little trees—slender gray-trunked maples, green-barked poplars, silvery birches—that my cattle may have a place to graze, or that my plough may turn the soil to raise food for beasts and men. I know death as common and simple—a part of life.

NELSON ANTRIM CRAWFORD.

**BOYS' and Girls' Club Leadership** The value of local volunteer leadership in boys' and girls' club work has been recognized from the outset. Owing to the cost, it has been possible to extend the paid leadership in club work only to the county units. Consequently, to obtain a broad expansion of the work, it has been necessary to utilize local volunteer leadership extensively. As a result, a large number of people with ability for unselfish leadership, have become active partners with their paid leaders in helping young people through club work to develop themselves and become constructive community builders.

To-day there are in the United States over 50,000 such leaders carefully guiding the half million and more boys and girls, 10 to 20 years of age, enrolled as club members. These leaders meet with club members in their local groups at regular intervals in the field or barn, or in the comfortable living room of a farm home. Topics of discussion relate to poultry, gardening, canning, bread baking, dairying, or some other line of work of particular interest to young people and of definite concern in a local extension program centered in the upbuilding of community life.

### Developing Local Leadership

There are two ways along which local leadership in boys' and girls' club work is being developed. When we think of the vast number of farm boys and girls which should be reached, the problem is that of selecting and developing adult leadership for them. When we think of the farm boys and girls with whom club work is being conducted, the problem is that of developing in boys and girls those qualities which will fit them to become leaders in their turn. The good local leader continually calls into play the qualities of leadership in the members of his group. He aims to enable each boy and girl to make maximum contribution to the work under way.

FIG. 22.—Boys and girls as club members become familiar with the extension programs of their community and county and take part in carrying it out. Thus they are prepared when older to take active and constructive leadership in community and county affairs

Of the 50,000 local adult leaders who led clubs of boys and girls in 1925, those who proved most successful were interested in making the community the best possible place for young people to live in. They were endowed with those personal traits which attract young people. They were able to place as well as to assume responsibility. They were recognized and respected by their associates. They were either skilled or willing to be trained in the farm and home practices which were to be demonstrated by club members.

More attention is being given to the amount of work to be done by each leader. Instead of expecting all to perform the full task, the amount to be reasonably expected from each is being increasingly determined by the agent in the county. Interest, capability, and available time of the leader are important factors to be considered. Invariably, however, they attend meetings of the club, encourage and assist the members in solving their individual problems, and keep the community informed concerning the work.

FIG. 23.—The efficient local leader constantly studies the abilities of his club members and gets each one to take as active a part as possible

Conferences for local leaders are being held in every State. In some instances, they are state-wide but more often they are confined to county units. State leaders, subject-matter specialists, and county agents assist at these conferences as well as through personal conferences, correspondence, and literature in order to render as efficient as possible the work of the volunteer leader. In some States, the local leaders are organized into State and county associations, assuming responsibilities for various club activities such as exhibits, encampments, and tours. An increasing number of older boys and girls known as captains of smaller groups are now sharing such responsibilities. Successful adult leaders continually study the members of their groups and encourage them to assume responsibility for club activities.

Through the initiative, confidence, and broadened viewpoint developed through such leadership, many former club members themselves are now taking an active part as leaders in their home communities. They are acting as officers in rural organizations, directors of fair associations, trustees of school boards, and county commissioners. They are thus wielding considerable influence in developing among their neighbors a feeling of responsibility which in turn insures a happier and more self-sustaining rural people.

In realizing such results, local volunteer leaders find their reward. They gain too that personal satisfaction which comes from unselfishly serving the community and watching conditions grow better. They win the approval of parents and neighbors as well as that of college-trained specialists who realize the good being done. Perhaps greatest of all, they win the confidence of those young people who, in turn, will ultimately become constructive community leaders.

**BOVINE Tuberculosis Being Suppressed** Nine years have elapsed since animal tuberculosis-eradication work was begun by the department in cooperation with the various States. It was believed at the time that, in order to make progress in keeping with the expenditure of funds provided by Congress and the respective State legislatures, the work would require the indorsement and hearty practical cooperation of the individual herd owner as well as other agencies interested in our livestock industry.

Tuberculin, as a diagnostic agent for detecting tuberculosis in livestock, had been used in the United States since 1892. Livestock owners had had an opportunity to become familiar with this product, and its efficiency, through their local veterinarians. However, they did not avail themselves of the opportunity to free their herds of tuberculosis in a way that would insure the development of the industry on a safe and sound basis. Tuberculin testing in various localities throughout the country had been of a sporadic nature, and it is doubtful whether much good would have been accomplished by the system then in vogue.

The department took the position that each cattle owner should be responsible for maintaining his herd on a tuberculosis-free basis, and that he should so maintain it when he became sufficiently familiar with the economic importance of the work. In the development of the cooperative plan in the States where it was inaugurated, the first steps taken were the dissemination of knowledge of the existence of the disease, the ravages wrought by it in cattle and swine, the economy that could be effected by its control and eradication, and the necessity for maintaining herds in a tuberculosis-free status. An educational campaign, consisting of the distribution of pamphlets, posters, bulletins, and the exhibition of motion pictures, was carried on in every community.

As a concrete method of controlling the disease in individual herds, the accredited-herd plan was adopted by the livestock sanitary officials of the various States at the annual meeting of the United States Livestock Sanitary Association in December, 1917. This plan was approved by the Federal Government and then presented to the livestock owners. Under the plan each owner agreed to submit his herd to the tuberculin test whenever it was deemed advisable by the cooperating authorities. He further agreed to dispose of tuberculous animals, clean and disinfect his premises, and to procure replacements of cattle from herds which were considered free from the disease. In this way cooperation was established among the livestock sanitary officials in all the States, the livestock owners, and the Federal Government.

### Press Gives Active Support

In the campaign of education the most potent influence outside of the regular authorities was exercised through the press and the agricultural papers. The editors, both of the daily press and of the periodical farm papers, commended the work to the livestock owners, and watching its progress, pointed out from time to time ways by which the method might be improved upon. They encouraged the officials and livestock owners to work together in the great enterprise contemplated—the suppression of the great white plague among the livestock of America. Cooperative assistance, however, was not limited to the organization heretofore set forth.

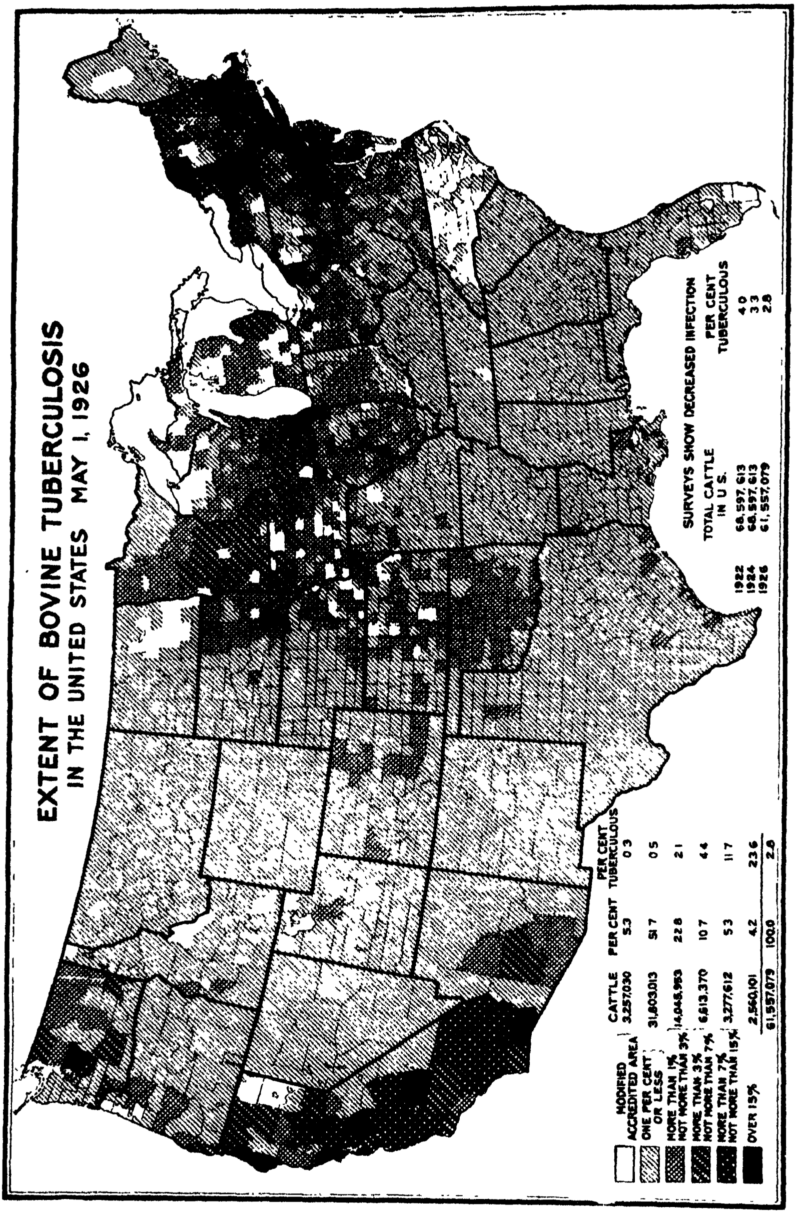
The livestock exchanges throughout the country, recognizing the importance of checking the spread of tuberculosis, and realizing the future benefits to be derived through its suppression, lent their assistance by actively cooperating in the employment of commissioners who carried on educational work and encouraged legislative bodies to provide adequate funds for the campaign.

These agencies were maintained through funds of the various bodies affiliated with the marketing and slaughtering of livestock at the various market points. Active cooperation was received from so many sources that it is difficult to enumerate those that have participated in the work and have done so much for its successful conduct.

The agricultural colleges, through their extension services and veterinary departments, have rendered valuable support and other organizations have been prominent in advancing the work throughout the country. The practicing veterinarians throughout the country have rendered most excellent service, both by making private tuberculin tests for herd owners and by assisting county, State, and Federal forces in area work. More than 6,000 veterinarians have qualified by written examinations to do tuberculin testing under the uniform accredited-herd plan.

### Cooperation Produces Results

In 1917 there were no tuberculosis-free accredited herds in the United States, with the exception of a comparatively small number in Minnesota and Illinois. On July 1, 1926, there were 96,392 accredited herds, comprising 1,577,087 cattle, and in addition to these there were 1,304,432 once-tested herds with a total of 10,358,259 cattle. Both groups of herds are being added to each month. From 1917 to June 30, 1926, 29,359,407 cattle received either their initial tuberculin test or a retest, of which 1,008,741 cattle reacted and were condemned and killed. At the end of the last fiscal year, 756 counties were engaged in area tuberculosis work, and 198 counties, one part of county, and 4 townships were recognized as "modified areas," indicating that tuberculosis was known to exist among the cattle to less than one-half of 1 per cent. Such areas are modified for a period of three years, during which cattle may be moved interstate without the tuberculin test. At the expiration of three years the



EXTENT OF BOVINE TUBERCULOSIS
IN THE UNITED STATES MAY 1, 1926

TOTAL CATTLE IN U S.
PER CENT TUBERCULOUS
1922 68,597,613 4.0
1924 68,597,613 3.3
1926 61,557,079 2.8

county must show that the infection still is less than one-half of 1 per cent. This is accomplished by the tuberculin testing of at least 20 per cent of the cattle in the modified area. In most of the States practically all the purebred herds of cattle are under State and Federal supervision for accreditation.

Owners of accredited herds, determined to protect their cattle from reinfection by neighboring tuberculous herds, insisted that the area plan of eradicating tuberculosis be put in operation. This plan was adopted as one of the main projects of tuberculosis work since its inauguration in 1917. The area plan has almost supplanted the individual accredited-herd work in many States. It is well adapted to any program for suppressing the disease, and it can be applied in such a way as to fit the condition which exists in any State. A number of States have adopted a program of work which contemplates the tuberculin testing of all the cattle within a given number of townships and counties each year.

### Cooperation is Required

The progress of the work under the area plan depends largely upon the amount of cooperation obtained, not only from the livestock owners but from the local officials and prominent citizens, from civic organizations, women's clubs, business organizations, and the public at large. In the larger towns and cities, as well as in small communities, the determination of health officials, supported by the public, to obtain milk from tuberculosis-free cattle has been a great stimulus to the work. It is doubtful whether so much progress could have been made in the work without the aid of those who realize the importance of the control and eradication of tuberculosis of livestock to public health. The part played by bovine tuberculosis in affecting the human family with the great white plague is being recognized more and more each year.

Summarizing cooperation and its influence on tuberculosis-eradication work, it is apparent that there is no other project of animal-disease-control work that is associated so closely with human health and welfare, and which is more entitled to the hearty support of the public at large, not only in the rural districts, but in the cities as well.

## BREEDING Improved Livestock

"That's good hay," an extension worker remarked to a busy farmer, who was putting a load of alfalfa into his barn. "But," he added, "a good many other farmers near here are getting better prices for their hay than you are likely to get for this."

"How's that?" the surprised farmer demanded.

"Because they are feeding it to better livestock. Improved animals pay better returns for the feed they get," was the extension worker's reply.

This brief conversation resulted in serious thinking on the farmer's part and some months later influenced him to obtain a purebred bull to grade up his herd.

The fascination of livestock breeding as an art and the challenge of competition in the show ring continue to appeal to many breeders, but there is even greater interest, perhaps, in breeding to improve the utility value of farm livestock. During the last year department officials sponsoring better-livestock studies have come into the possession of several singular facts.

An extensive demonstration, privately financed but now conducted by trustees of three universities, at a large stock farm near Kansas City, Mo., has shown conclusively the value of purebred beef bulls in grading up a herd of common cows. The enterprise, commonly know as the Sni-a-Bar Farms demonstration, has already produced many carloads of fat steers of the first, second, and third crosses.

Market returns show clearly that breeding is a dominant factor in the production of high-quality beeves, and that good feeding and management will not bring best results unless the element of good breeding is present also. The use of a good purebred bull, according to the results, means approximately $2 a hundredweight increased value of his calves at marketing time compared with average calves sired by scrub or grade bulls. During a 10-year period, steers sired by purebred bulls at Sni-a-Bar Farms topped the market 16 out of 20 times. Similar results are being obtained in other localities also where the sires are of high quality.

FIG. 25.—The quality and market value of stock produced determine the real worth of purebred sires. These fine Hereford calves were raised by a stockman cooperating with the department in livestock improvement work

## Purebred Bulls in Union County, Ky.

As a result of local efforts to improve the bulls in Union County, Ky., cattlemen of that county attained in April, 1926, the enviable goal of having 100 per cent of its bulls purebred. All scrub and grade bulls had been shipped out for slaughter, and 140 purebreds of good quality—chiefly of the beef breeds—were in service. The accomplishment was the result of excellent teamwork among cattle owners with assistance from county, State, and Federal livestock specialists. For the last two years the majority of bulls in the county had been purebred, and, as in the case of the Sni-a-Bar Farms demonstration, the quality of stock sold to market was evident in the returns received. At the three principal packing centers to which beef cattle are sent—namely, Evansville, Ind., Louisville, Ky., and St. Louis, Mo.—stock from Union County usually top the market.

With the accumulation of evidence that improved livestock are more efficient producers than common animals, there has been an increasing interest in stock breeding among banks, railroads, and the meat-packing industry. In one of its newspaper advertisements, a bank in Union County, Ky., recently stated: "This bank sponsors every move for the betterment of livestock conditions in Union County. The best asset on the farm is the purebred sire."

There is similar interest in dairy localities. In Campbell County, Ky., the most productive herd in 1920 averaged only 24 pounds of milk daily per cow. At that time only 30 purebred dairy cattle could be found in the entire county, and these were owned by four farmers. Following local efforts to improve the quality and efficiency of the stock, conditions have improved in a most striking manner in the short space of six years. Now a heifer to be kept in a good herd, must give not less than 35 pounds of milk a day, and, in contrast to the former low number of purebreds in the county, there are now 500 purebred cattle owned by 75 dairymen.

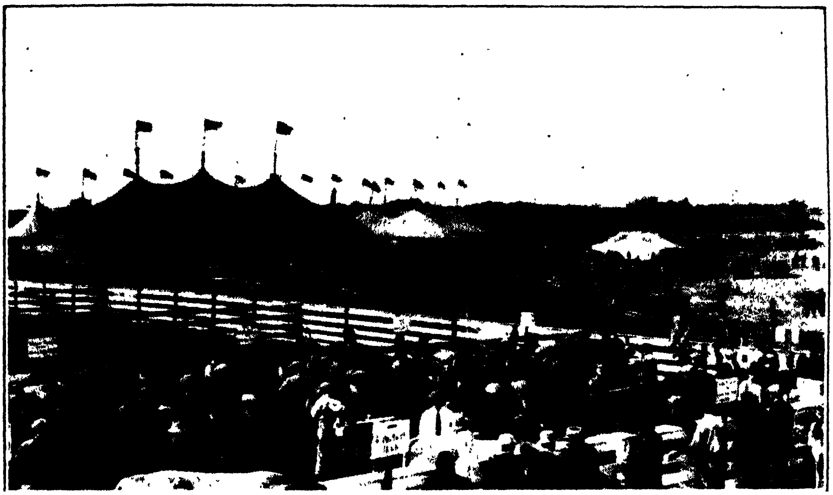

FIG. 26.—A "bull circus," as the public demonstrations of purebred sires and their offspring at Sni-a-Bar Farms might aptly be called. The picture illustrates the great public interest in improved breeding as a means of making stock raising more profitable

The cashier of a bank in that county reports an increase of bank deposits from $475,000 to more than $800,000 in that time, notwithstanding that a competing bank opened its doors in the meantime. The cashier reported that he had observed deposits of individual customers to pick up noticeably after the purchase of purebred bulls. "We find the same thing true," he stated, "in payments on notes. Owners of purebred sires make better payments on mortgages and are better risks. Eighty-five per cent of the depositors of this bank keep cattle."

### Public Trials Show Sentiment

One of the most entertaining as well as effective means for bringing about a public discussion of livestock improvement is through mock trials, at which an inferior sire is the prisoner at the bar. His friends have the opportunity to defend him; others, who have concluded that inferior breeding stock are a distinct liability, have the opportunity to prove, by their experience, that such animals are out of line with high-priced land, labor, feed, and other costs of production. Attendance at some of the trials has exceeded 1,000 persons.

There has been a tendency for communities to look at county agricultural agents or other local officials for leadership in livestock improvement work. But even the most energetic and capable leaders assert that, for such work to be successful, committees of enthusiastic stock owners must work with them. To bring about extensive livestock improvement among stock owners of varying temperaments, nationalities, and financial means is far too great a task for a small corps of specialists, however capable. The influence of progressive local breeders, when appointed on active committees, on the other hand, has been highly successful in making the merits of purebred sires better known.

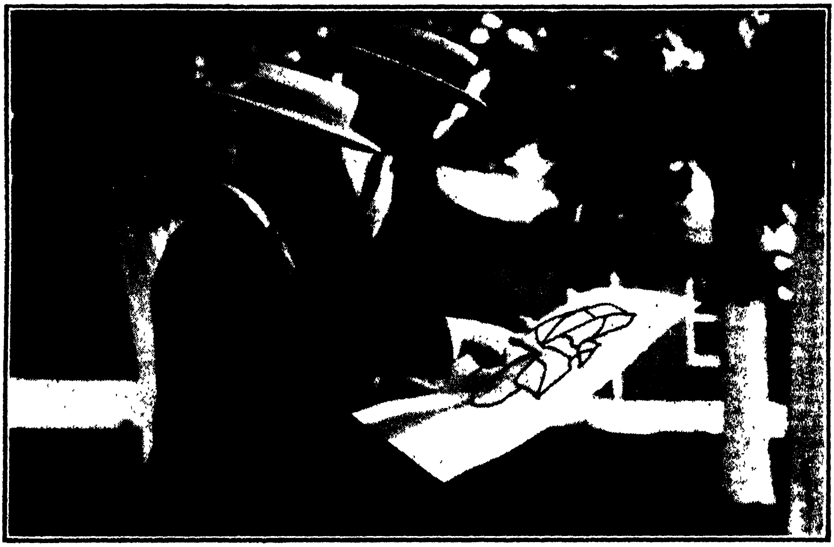

FIG. 27.—Planning a county-wide drive to eradicate inferior sires. A map showing the location of farms and the kind of sires used is an important aid in the work

## Evolution Toward Better Stock is in Progress

Evidence from many sources shows that livestock evolution toward improved types is going forward gradually. More than 17,000 stock owners cooperating with the department have signified their intention of improving their herds and flocks by the use of purebred sires. In 43 counties this work is specially intensive, there being 100 or more of such progressive stockmen in each of these counties.

With the use of purebred sires, there is also a large increase in the number of purebred females. Production of purebred livestock has now reached the point where, according to a recent survey, purebred animals are now being sold extensively for slaughter. This is specially true of hogs and, to a somewhat less extent, of cattle and sheep. Thus, the breeder of improved livestock has two outlets, the sale of purebreds for breeding stock, and disposal of purebreds and high grades for slaughter, both of which methods are satisfactory and evidently profitable.

The average experience of about 500 stock owners as reported to the department indicates that the earning power of well-bred livestock is fully a third greater than that of common animals resulting from random breeding. Such an advantage is certain to become an important influence in returns from stock raising, both from an individual point of view and in international competition.

D. S. BURCH.

## BUILDING Decay and Ways of Preventing It

Wood will wear out in the course of time under hard usage. When it is left exposed to the action of air, sun, and rain it slowly goes to pieces. It has its natural enemies, wood-rotting fungi and insects, which destroy it, but in spite of them all it will last a long time if given proper care. Clapboards which are not protected by paint are more than likely to warp and twist out of shape. The exposed surfaces check and crack, and the nails are sure to work loose. This form of deterioration is called weathering. It was formerly believed that wood rotted simply because it was exposed to air and water. It is now known that this is only partially true. Rot is caused by fungi which grow in wood and destroy it as they grow.

Weathering and rot often work together to cause a great deal of damage to farm buildings, implements, and machinery. It is sometimes difficult to prevent wear. It is a fact, however, that wood which has begun to rot will break or wear out sooner than sound wood, because rot reduces strength. Of course, some kinds of wood stand up much better than others under constant exposure. Weathering can be stopped by paint, properly applied to seasoned wood. It is much better to leave green lumber, or green fence posts, unpainted, because paint retards the evaporation of moisture, and the wood is therefore likely to rot sooner than if it were left exposed.

### Fungi Can Not Grow Without Water

The toadstools and shelf fungi of the fields and trees are representative members of the great family of wood-destroying fungi. They are all plants. The key to the whole problem of controlling decay is the fact that they can not grow without water. Toadstools spring up overnight after a rain, but they are rarely seen during a spell of hot dry weather. Excess water, however, prevents decay. If wood is completely submerged fungi can not grow, because their air supply is cut off. Air and water must be available in proper proportions. Stagnant, saturated air favors fungous growth. Temperature also plays an important part in decay, for, other things being equal, wood will rot more rapidly in warm climates than in cold climates.

Wood that is in contact with the ground is certain to be wet a good part of the time. Poles and posts decay at the ground line because the moisture which the wood absorbs from the soil makes it possible for fungi to grow. The same would be true of foundation posts or of any wood resting on damp foundations. Floors laid directly on concrete will rot out very quickly if the concrete becomes moistened by seepage water. The ends of beams which are embedded in mortar or brickwork will absorb moisture from the wall and decay. Rot is almost sure to develop at the base of porch pillars, or around steps, where water can seep into joints or cracks. Leaky roofs, gutters, rain spouts, and water pipes will sometimes provide just enough water to keep wood-destroying fungi growing. Occasionally, in muggy weather, the drip from sweating cold-water pipes is sufficient.

### Dry Wood Will Not Rot

In considering the prevention of decay in buildings the most important principle to bear in mind is that the wood must be kept dry. As a general rule buildings should be set on concrete, or on well-made brick or stone foundations. The rest is comparatively easy. Drain surface water away from the foundations, and make provision for draining seepage water out of the cellar. Provide enough gutters and spouts to take care of rain water, and make sure that there are no leaks in roofs, or around sinks, pumps, water pipes, water tanks, refrigerators, washbowls, bathtubs, and toilets. See to it that there are proper means for ventilating all cellars and basements, and all unexcavated spaces under sheds and porches. If these precautions are taken there will be no decay.

In case rot has already gone so far that repairs are necessary, the first step will be the removal of every bit of the wood which shows signs of rot, and, in addition, some of the apparently sound wood around the rotten place. There is no way to tell the early stages of rot with the naked eye. The only safe procedure is to take out more wood than appears to be necessary. All of the material removed should be burned. Fix all leaks in water pipes, spouts, and drains, and improve the chances for ventilation if necessary. Then repair the damage with well seasoned heartwood, or with wood which has been properly treated with a wood preservative.[2]

The wooden parts of farm machinery depreciate very rapidly when equipment is left in the open. Everyone knows that iron and steel will rust under such circumstances, but few people seem to realize that hickory and ash, for example, are not durable woods. To be sure they are hard and strong, but only so long as they are protected from weathering and decay. One of the first principles of farm economy is to store farm machinery and tools in dry sheds.

### Nondurable Fence Posts Should be Treated

Aside from the depreciation in buildings and farm equipment probably the most troublesome constant problem on the farm is the maintenance of fencing. Millions of fence posts are cut in the forests and woodlands of the United States annually. Each individual owner of farm land knows that most of the posts which have to be replaced are rotten and that if he could stop the rot he could save himself a lot of work. It is, of course, impossible to keep a fence post dry. The fence can not be protected from the weather. Unless durable woods in a class with cedar, redwood, catalpa, black locust, or white oak are available the only businesslike way to handle the problem is to protect the fence post from decay by treating it with a wood preservative.

---

[2] See The Preservative Treatment of Farm Timbers, Farmers' Bulletin 744, United States Department of Agriculture.

Prevention of excessive weathering and avoidable decay not only saves immense quantities of raw material, but also untold numbers of hours of replacement labor, which could be used much more pleasantly or productively.

Reginald H. Colley.

**Bulb Culture Makes Progress** Rather remarkable progress has been made during the past 10 years in the acquirement of information on bulb culture by the rank and file of our plantsmen. Still more remarkable has been the change in the general attitude toward the production of bulbous stocks in America. Instead of questioning whether these various items can be grown here, the only doubt now is whether it can be done at a profit, and even that doubt is fast disappearing.

The gladiolus, the freesia, the caladium, the tuberose, and the calla lily, have long become characteristically American. No one has thought of going abroad for commercial stocks of them for a long time. Ere long the Regal and other lilies will be with us in such abundant supply as to satisfy our demands.

Impatience is sometimes expressed at the slowness with which such an easily-produced bulb as the Regal lily has become available commercially, but no surprise should be occasioned by a delay of 8 or 10 years in the production of a new crop. It should be remembered that stocks must be worked up, costly mistakes corrected, and experience acquired. These matters take years to accomplish.

### Daffodils

The country has had experiences, both commercial and experimental, with daffodil stocks extending over a period of 15 years or more, and with some of the older varieties a great deal longer than that. In southern Illinois and the cape region of Virginia experiences have been had extending over a period of 30 years or more. In the latter region it has been with stocks imported in colonial days. All of these experiences have been an asset in the establishment of the industry of American production of these stocks.

Experiences and experiments have demonstrated the possibility of producing stocks of daffodils in various sections of the country equal to those grown anywhere. One of the most astonishing things in connection with recent experiences with the commercial varieties of daffodils is that the crop is about as adaptable as oats. It is being produced satisfactorily on sands, peats, and clays in the Northwest;

on various types of soils on the Atlantic coastal plain; and even on the northernmost of the southern sands.

Handling in storage has been a rather difficult problem in the warmer sections but it is gradually being learned that protection from undue exposure, with abundant aeration, accomplishes the desired result.

The Polyanthus group of daffodils, adapted to the warmer sections of the country, seem to present the least difficulty. Even the oriental type of the "Chinese sacred lily" can be duplicated on our muck and peat soils, and Paperwhites of perfect form, firmness, and performance are now grown on both heavy clay and sandy loams.

### Tulips

Tulips have also proved to be even more adaptable to soil conditions than daffodils. They demand fresh, clean soil each year, but will succeed on clays and sands when proper fertility is supplied and moisture is controlled. Successes are recorded for the Pacific Northwest, Michigan, and the Northern Atlantic coastal plain.

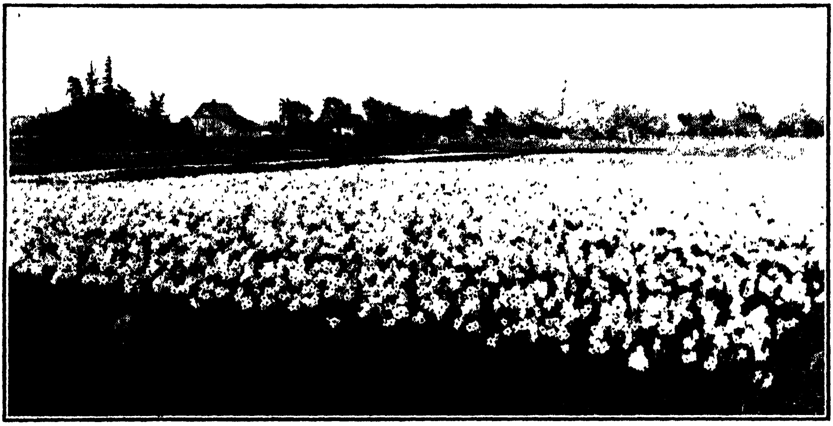

FIG. 28.—Elvira narcissus the second year after setting. When dug, this area yielded at the rate of more than 1,000 bushel lug boxes of bulbs per acre. Plant introduction garden, Bellingham, Wash.

In the warmer sections the great difficulty again has been with storage during the dormant season, but it has been learned that if provision is made to reduce ventilation after the bulbs are dry, the coats can be saved, excessive desiccation prevented, and the bulbs preserved in good condition.

### Hyacinths

Hyacinths have always been looked upon as a proverbially difficult item to produce and one, above all others, that America could not grow. After 10 years of experience the writer has no hesitancy in saying that they present no insurmountable difficulties.

There is practiced with the hyacinth an artificial propagation. This process must be learned, but it is simple and the same in principle as propagation from cuttings generally. Details of procedure vary a little, but they are not complicated nor are the conditions of success any more exacting than those required to grow many of our common plants from cuttings.

Experimental stocks of hyacinths are now in their third propagation from imported bulbs and seem to hold up well both in Virginia and the State of Washington. One commercial success is chronicled on Puget Sound, where it is considered that the hyacinth has succeeded even better than tulips or daffodils on the same farm.

### Lilies

It is considered that at the present time as much real progress is being made in the production of lily stocks in this country as in any other group of bulbs. The ready propagation from seed, from scales, and from layered and heeled-in stems is giving a great impetus to the culture in several sections of the country and under very diverse conditions.

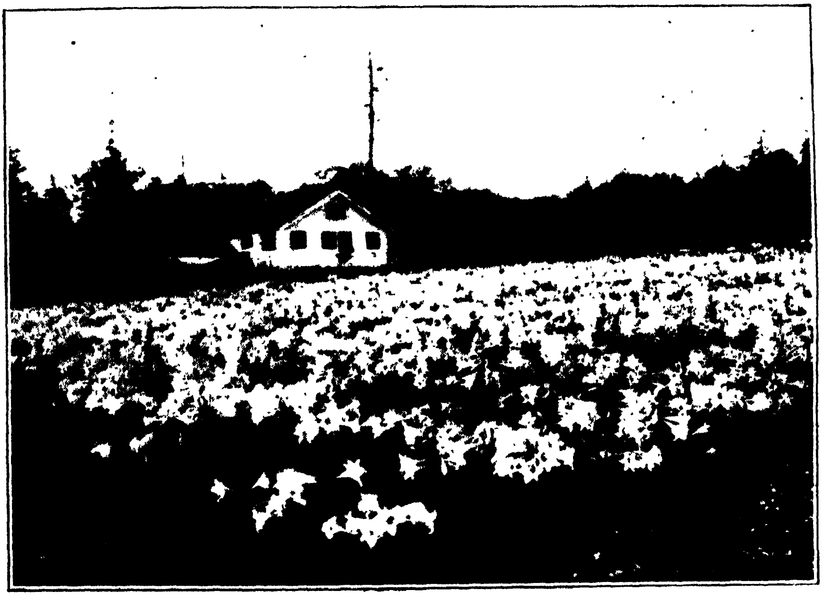

FIG. 29.—The Easter lily (*Lilium longiflorum*) in a commercial planting near Seattle, Wash.

Material for propagation is scarce and high priced, but when once a little is secured it works up in numbers very rapidly, often as high as a hundredfold at a vegetative propagation, and many hundredfold from seed.

Culture of lilies must be looked upon generally as a three-year task, i. e., it takes about that time to produce merchantable stock in most cases. This, coupled with the necessity of gaining experience with each item and starting with a limited quantity of stock, are the deterrent factors to rapid progress. Stocking the market may, therefore, be some distance away, but good healthy progress is being made in that direction. There are a dozen or more growers in the country to-day that marvel at their own success, which eclipses even their fondest expectations of five or six years ago.

All of this, however, is not supplying the market—far from it. There are some years of struggle ahead with little or no income, and there are discouragements, due to unforeseen causes, but the start has been made. Enough experience has already been gained to prove that a baker's dozen of good commercial lilies can be produced in quantity in our northern tier of States on both coasts, at many inland points, and some of them are on our Gulf coast.

### Iris

The iris, although a single genus, is an exceedingly diverse group, most easily divided into sections by the characteristics of the underground parts. The rhizomatous sections especially have always been grown in sufficient numbers and have received a great impetus from the organization of the American Iris Society. It has been quite different with the cormous and bulbous groups.

The Spanish and Dutch irises, which form one of the groups of the bulbous-rooted section of the genus, were entirely imported until about 10 years ago. Now, after 10 years of experience and a great deal of adverse criticism, a number of growers have sensed the requirements and accomplished the production of first-class stocks. This, again, has been done under very diverse conditions. Success is scored on both the northern and median sections of the Atlantic coastal plain, in southern California, and northwestern Washington.

Here again the greatest difficulty has been with storage during the dormant season. The growing has not been so difficult when good stock was planted, but, with overexposure causing excessive desiccation, the planting stock has so often been devitalized. The neglect of the inroads of the tulip or iris aphid, easily controlled by the application of tobacco products, has also contributed largely to failures, especially in California.

One potent influence inhibiting the accumulation of stocks of these groups of iris has been the commercial situation. There is little use to expect the grower to produce bulbs of Spanish and Dutch iris to sell for $35 per 1,000 when the cut flowers command a price which will net him 50 to 100 per cent more. The cutting of the flowers, of course, reduces the vitality of the bulbs which, when finding their way onto the forcing benches, perform poorly.

Both growers and dealers realize that the round bulb in Spanish or Dutch iris is the most desirable for the forcing benches; however, little effort has yet been made to put this character of bulb, and this only, on the market. We are just beginning, after 10 years of experience, to put the right kind of material on the market.

The beautiful English iris, another bulbous group, has always been conspicuously absent from American gardens. We have learned that they too can be perfectly grown on Puget Sound, and one instance has recently been called to the writer's attention wherein one variety has thrived in a private garden in Massachusetts for a dozen years. Seedlings have already been produced in this country which seem to be vastly superior to the imported stocks.

The Palestine group of cormous-rooted iris and their hybrids are becoming so well understood that it is possible to grow them now not only on the Pacific coast but in our eastern humid regions as well, by simply digging them at the close of the growing season and carrying them dry on the shelves until planting time comes around again in late fall.

### Miscellaneous Bulbs

Experimental experience, and in several cases commercial as well, is accumulating rapidly on many of the so-called lesser bulb stocks. Leucojum, ixia, sparaxis, babiana, watsonia, montbretia, nerine, amaryllis varieties, ranunculus, anemone, fritillaria, etc., are in some cases in sufficient quantity to supply a large portion of the demand.

FIG. 30.—Representatives of the Red Cross selling daffodil flowers at the Bellingham (Wash.) plant introduction garden during the war

Muscari, scilla, eranthis, ornithogalum, chionodoxa, galanthus, puschkinia, crocus, etc., have received less attention commercially. Experimental cultures show conclusively that there are no insurmountable difficulties in the production of any of these, while some are even weedy in their nature.

### Forcing Quality

There is no mystery about the production of bulbous stocks that will force in contradistinction from good stocks with other qualities. A daffodil, a tulip, a hyacinth or a lily grown to proper size and firmness has a flower in it. If placed under suitable conditions of fertility, temperature, and moisture, it will produce that flower. That there is some mysterious secret process through which bulbs must be put after being properly matured is one of the fallacies which have grown up in some quarters around a foreign article concerning the production of which little information was available.

Daffodils, tulips, or hyacinths, after being dug, need to be dried out so that they will not mold. In the case of the tulip there is danger that the drying may be carried too far and wilt the bulb and crack the skin. With the daffodil of any variety, or the hyacinth, there is less danger of too much drying. This, coupled with storage in the shade and not in stuffy, superheated situations, is all there is to the matter.

Of course, there are certain accelerating processes that may be employed to induce early flowering. The bulbs may be grown the last year in a region which has an early season. If the bulbs mature early they will force early the next season. A similar result may be accomplished by digging the bulbs before they are thoroughly mature with or without subjection to 10 to 20 per cent above the ordinary atmospheric temperature for a week or 10 days.

With our varied climate, from the short season of our northern tier of States to the early-maturing conditions from Virginia and Oregon south, these stocks will mature so as to force early enough without resort to any such artificial measures.

Experience over a period of 10 years in the production of these stocks and their subsequent forcing under glass has uniformly shown that properly grown stocks of any of these bulbs run true to form. When produced in America they force just the same as they do when grown elsewhere.

David Griffiths.

## BUTTER and Egg Marketing Methods

Efficiency in marketing and merchandising dairy and poultry products is not obtained by "hit-and-miss" methods. Neither is it a "rule-of-thumb" proposition. Rather it is obtained by employment of methods which meet present-day conditions. Then why do "hit-and-miss" and "rule-of-thumb" methods continue? Why are not the more modern and scientific methods employed?

In many country communities the housewife or the farmer takes the eggs and farm-made butter to the country store where a price is paid or merchandise needed in the farm household is offered in trade for the butter and eggs. No grading for quality of the eggs or butter takes place. No premiums for higher quality eggs or butter are offered. No incentive is offered the producer to produce the best. One flat price is paid to all patrons. This is a "hit-and-miss" method. If the product sold is of ordinary or poor quality the producer "hits" a good price for it, but if it is of extra fine quality he usually "misses" the premium price that he should receive.

The situation is similar if it be cream or poultry that the farmer markets, although he may take the poultry to a local produce buyer and the cream to a local cream buyer. Here standardization or grading for quality is usually not employed and flat prices are paid for all qualities so long as they are of fair marketable quality.

These local buyers, including the country grocery store, ordinarily do not attempt to practice any standardization or grading of the products before they leave their hands. Consequently, by a sort of "rule-of-thumb" method they aim to dispose of the products at a price slightly above that which they have paid, or, if they operate on a commission, they pay the price authorized by their employer.

In this way more than half of the products of the poultry industry and more than one-third of those of the dairy industry, or nearly $1,000,000,000 worth of farm products, are sold by farmers annually. These methods continue in many country communities and towns because the producers do not realize the increased value that better methods would bring to them. Moreover, they have not set up marketing machinery which could employ the better methods. nor have they demanded of those to whom they sell that such methods be used.

### Cooperatives Are Pioneering

In contrast to these methods, other communities are served by local buyers of eggs, farm butter, poultry, and cream or they have set up their own machinery in the form of cooperative marketing associations which standardize and grade the products according to their quality and pay a graduated series of prices for each product according to the market value of each standardized quality or grade. In turn, these buyers, and the cooperative marketing associations generally, seek to sell each quality or grade in that channel of trade where it is in greatest demand and brings the highest market price.

These buyers and associations often have their established brands and employ modern merchandising methods and advertising in creating and developing an increased demand for their particular products. If the local buyer is a cooperative organization and is a local unit of a large-scale organization or is affiliated by federation or otherwise with a large-scale marketing organization, it is able to bring directly to the community the benefits that accrue from such connection or affiliation.

Since such organizations often are capable of employing the most modern and scientific methods of marketing and merchandising, many benefits are obtained by the communities they serve. They not only have the incentive that results from standardization and a system of buying which recognizes quality, but they obtain the benefits which come through a system of distribution that seeks to widen the market for standardized and branded products. They sometimes obtain the maximum price because of these wider outlets and new demands.

Inefficiency is not due to incompetency of existing agencies, but to their lack of development of the more efficient methods which might be employed. Moreover, the volume of product handled by the local agencies is often too small to permit the setting up of a machinery that could economically employ the more modern and efficient methods. Some communities undoubtedly would not now appreciate the better methods even though they were made available. That may account for lack of modern methods in such communities.

There is no doubt that this inefficiency in marketing will tend to disappear with the growth of a better understanding and appreciation of the value of standardization among producers of dairy and poultry products. Concerted community effort will gradually be put forth to obtain the results which come from marketing farm products on a graded or quality basis.

**CALF Crop in Beef Industry** In the production of beef, calves are the basis of the final marketable product; thus the calf crop is a factor of great economic importance in the beef industry. The greater the percentage of calves raised the greater will be the returns from the enterprise, other conditions being equal. There is a close correlation between the net cost of raising the calf, the pounds of beef produced per cow, and the calf-crop percentage. The expense of maintaining the cows and bulls must be borne by the proceeds from the calves marketed. As the number of calves in a given herd increases, the net cost of raising each calf decreases proportionately.

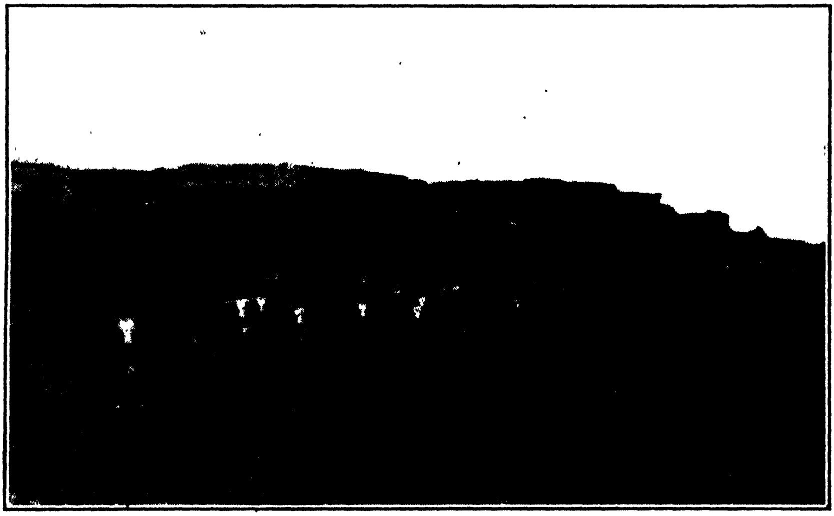

FIG. 31.—Two-year-old heifers on the range. Note their uniformity, which was brought about largely by good breeding

Variation in the calf crop is influenced by many factors. Among the more important are the range conditions, the number of cows allotted to each bull, and the ability of the manager. Other factors having a direct bearing on the calf-crop percentage are the maintenance of the herd in a thrifty condition, high breeding efficiency in the herd, and, on the range, proper distribution of bulls.

Investigations show that the calf crop in range areas is affected more by range conditions than by any other factor. The rainfall and control of grazing are responsible for the condition of the range. The ranchman has no control over climatic conditions, but by careful management of the range, especially in normal seasons, he can put his grazing areas in a better condition to withstand droughts.

When grass and beef prices are good there is a tendency to overstock the range. Such a practice depletes the range and brings on ruin if followed by a drought.

### Rotation Grazing Useful

A system of deferred and rotation grazing is of great value. Deferred grazing, allowing a [illegible] growth of grass, or even allowing the grasses to seed occasionally before turning the cattle on the range is a very desirable practice. In some grazing areas there are numerous grasses, but usually one or two species predominate in a specific area. The various types of range should be grazed when at their best. This can be done by a system of rotation, moving the cattle from one area to another when conditions for grazing are most satisfactory.

FIG. 32.—Feeder calves with quality and uniformity are always in demand

Experiments have shown that under range conditions the calf crop is not affected by the number of cows allotted per bull unless the bull is allowed more than 25 cows. If the cattle are handled in small pastures, under controlled conditions, twice that number of cows can be bred to a proved sire with satisfactory results.

It is not only important to have a sufficient number of bulls in the herd, but they must be distributed properly over the range as well. The practice of weaning calves at 6 to 9 months of age, allowing the cows to regain normal vigor before bearing another calf, and the maintenance of the breeding herd in a thrifty condition are important factors in the successful management of a producing herd.

In addition to the importance of numbers, it is necessary that the calf crop possess quality, good weight for age, and early maturity. Too much emphasis can not be given to uniformity in the calf crop.

This can be obtained only by having all breeding animals conform to a certain type or standard, and by controlling breeding, so as to have all calves born at approximately the same time. A uniform drove of good-quality cattle nearly always tops the market.

W. H. BLACK.

**CAMERA in Livestock Research** Photographs when properly taken can be used for many purposes. Pictures are especially desirable for giving accurate descriptive information quickly. Several persons may read any amount of unillustrated text and no two will form the same mental picture of the subject. In the purchase of animals for breeding purposes, when it is not practicable to see the stock, a written description may be entirely misinterpreted. The purchaser wants to see, as nearly as possible, an exact likeness of what he is going to get. If the animal has long or short legs, shallow or deep body, he wants to know it. In other words he wants to see as much as he can with no part exaggerated at the expense of another.

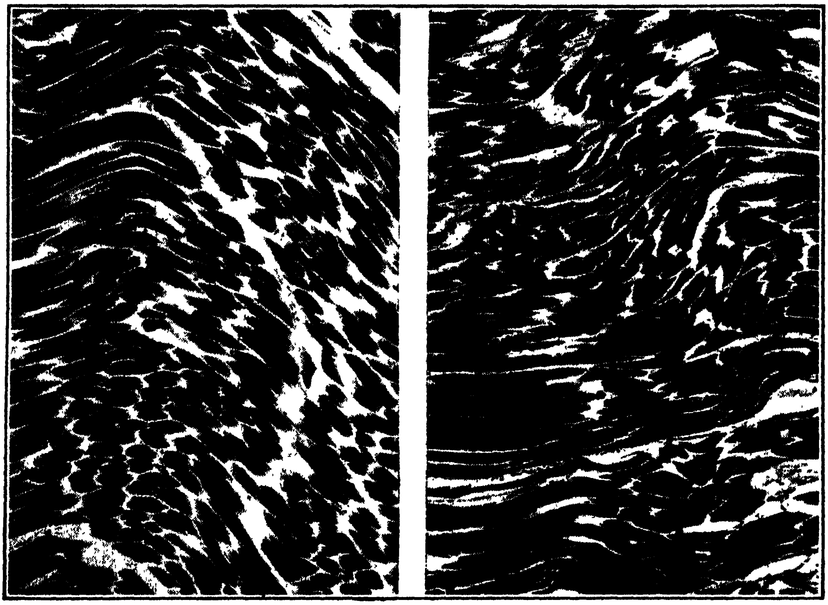

FIG. 33.—(Left) Photomicrograph of beef (enlarged 55 times) from common animal. Note the rather dense, stringy appearance. (Right) Photomicrograph of beef (enlarged 55 times) from choice animal; the meat has the appearance of having made more rapid growth

Animals in feeding experiments are constantly undergoing changes and it is not possible to remember the appearance of each at the beginning or at different intervals. In this work there are many points of value in which the camera is an excellent means of obtaining and preserving a record.

Other photographs of value are those taken through a microscope. They permit examination of the finest details whereby many important discoveries are made.

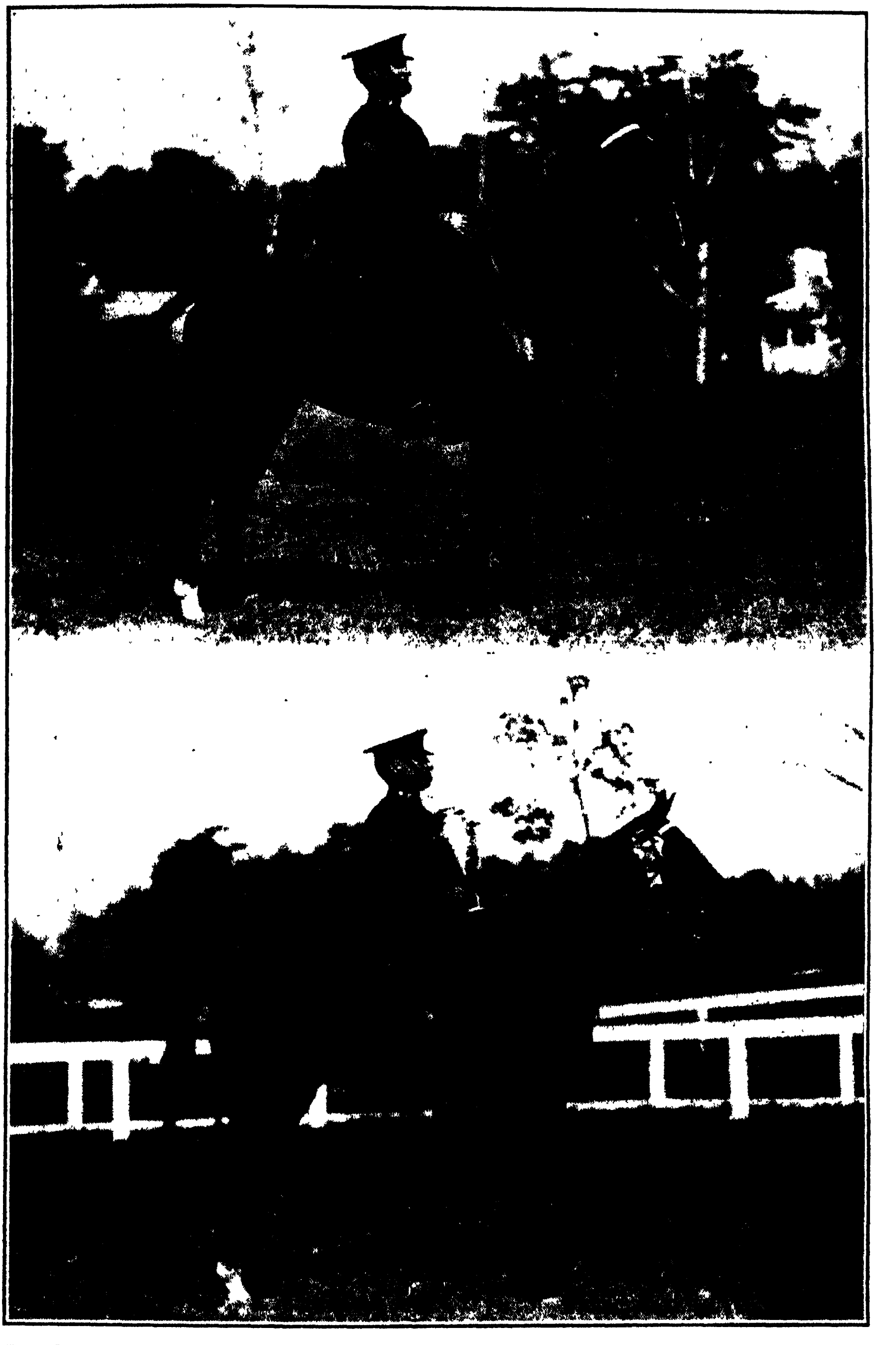

FIG. 34.—Winner of the 1924 horse-endurance ride at Warrenton, Va., photographed, A, before and, B, after the ride. The horse appears to be in as good condition at the finish as at the start, an almost incredible statement, but supported by photographic proof. Further evidence of the horse's vigor was the winning of the same ride the following year

FIG. 35.—Side-view pictures of hogs do not show some of the important points in conformation for comparing different breeds or types to best advantage. In this picture, taken directly from above, note the width across the shoulders of the Tamworth, on the left. This would cause a front view to make the Tamworth appear as broad as the Poland China, at right. Views out of the ordinary often show surprising results and draw attention to points otherwise overlooked

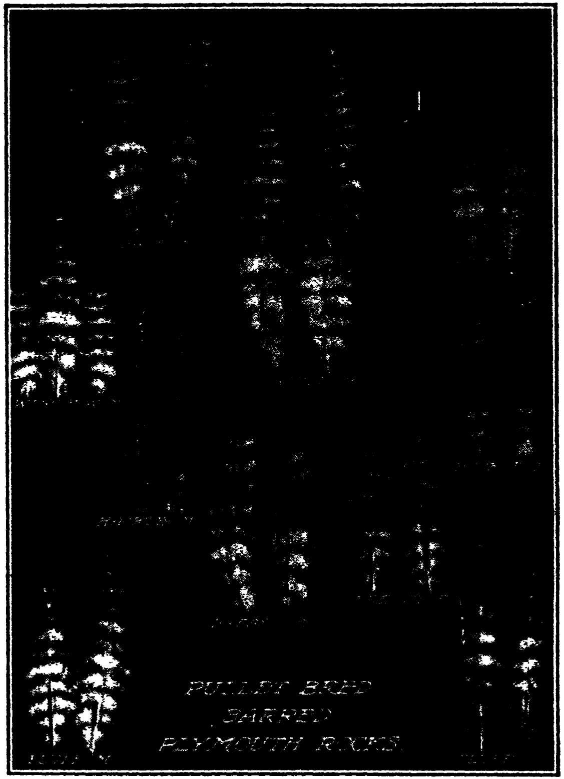

FIG. 36.—A photographic study showing distinctiveness of pattern in surface and undercolor of chicken feathers. It is impracticable to record shades or tones in any other way. The letters M and F refer to male and female

For several years horse associations in various parts of the country have held endurance rides which are considered very severe tests. Under present requirements the horse must carry a weight of 225 pounds, including the rider, 60 miles in 9 hours of each day for 5 consecutive days. For various reasons many horses do not finish the ride, but when animals are in good condition the test is not so exhausting as is sometimes asserted. As the photographs in Figure 34 show, the horse illustrated finished in excellent condition. It won in the same test the following year, demonstrating that the ride had no serious effects. Figure 35, which compares two types of hogs, shows another of the many ways of getting results with the camera. Besides its value in studies of breeding and feeding and in other ways that have been discussed, the camera is highly useful also in pointing out effects of diseases and parasites. Accordingly, it can be made an important adjunct to veterinary medicine and similar scientific work.

## CATTLE Feeding for Profit

The net return from fattening cattle is determined by the width of the margin or spread between the purchase and sales price per pound and by the cost at which gains are made. It is necessary to have a margin to fatten cattle profitably because the cost of gain is usually higher than the sales price per pound. The problem of the feeder is to get the widest possible margin consistent with a low cost of gain.

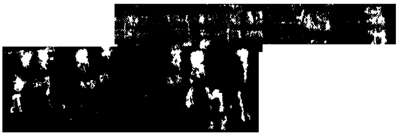

FIG. 37.—Typical cattle-feeding scene in the Corn Belt

The margin received depends on the quality and degree of finish obtained and on the judgment used in purchasing feeder cattle, as well as on general market conditions when the cattle are sold. The feeder must be a good judge of values not only to recognize individuals that will do well in the feed lot but to estimate the probable price at which cattle of different weights, quality, and degree of finish will sell several months later when his steers will be marketed. The price received depends upon several seasonal influences which should be kept in mind and also upon many other factors of supply and demand, such as the number of cattle fed, general business conditions, and other things that can not be so readily foreseen.

The cost of gain depends largely on the price of feed, the length of feeding period, and the size and quality of cattle. Eighty-five per cent of the cost of gain is usually for feed. Hence, the margin required increases with the price of feed, particularly corn. Calves require about 65 per cent as much feed to put on 100 pounds of gain as heavy cattle of over 1,000 pounds initial weight. Cattle usually gain less rapidly as the feeding period is lengthened. This increases the cost of gain and the margin necessary to meet costs except in cases where the cost of gain is less than the sales price per pound, as is often true in feeding calves. It is possible to feed heavy cattle for short periods of 60 to 90 days with less margin than medium-weight cattle require because of their greater original weight. After this length of time, however, their greater cost of gain overbalances their advantage of greater original weight and the margin necessary to cover costs widens faster than for any other weight of cattle.

### Ordinary Feeding Period

Ordinarily it requires a feeding period from seven to eight months to bring calves to a desirable weight and finish. A six-months' feeding period is sufficient for medium-weight cattle, and heavy feeders may be finished in four months' time. On account of their longer feeding period, calves consume practically as much grain per head as the heavy cattle. As shown in Table 1, the calves ate 44 bushels of corn per head as compared with 48 bushels for the heavy cattle. The calves gained 330 pounds, the yearlings 300 pounds, medium-weight steers 285 pounds, and the heavy cattle 260 pounds.

TABLE 1.—*Typical performance of steers fed in dry lot* [1]

| Size of cattle | Initial weight | Gain per head | Time on feed | Daily ration | | Corn per head | Margin required [2] with corn at 50 cents per bushel |
|---|---|---|---|---|---|---|---|
| | | | | Corn | Hay | | |
| | *Pounds* | *Pounds* | *Days* | *Pounds* | *Pounds* | *Bushels* | *Dollars* |
| Heavy | 1,060 | 260 | 133 | 22 | 10 | 48 | 1.00 to 1.50 |
| Medium | 870 | 285 | 186 | 19 | 9 | 49 | 1.00 to 1.50 |
| Yearlings | 650 | 300 | 205 | 18 | 8 | 47 | 1.00 to 1.25 |
| Calves | 420 | 330 | 219 | 13 | 6 | 44 | .50 to 1.25 |

[1] Figures taken from a five-year study of cattle feeding in the Corn Belt.

[2] This margin does not include shipping and marketing expense.

Heavy cattle are able to better utilize stalk pasture, corn fodder, and other coarse feeds than are calves and yearlings, and because they already have their growth they fatten more readily in a short time, whereas calves must be full-fed on grain for a much longer period or they will merely grow instead of fatten properly. The demand for cuts of beef from heavy cattle is much more limited than for beef from handy-weight steers and hence their price is more sensitive to changes in the market supply. This fact makes the feeding of heavy cattle more hazardous than the feeding of calves and yearlings.

The grade of cattle to fatten is a problem that must be considered by every feeder. There are a number of seasonal factors to be kept in mind in this connection. Common cattle are generally lowest in price in October and November during the time of large runs of cattle from the range. Choice finished cattle are usually higher in price than at any other time of the year because there are ordinarily very few grain-fed steers marketed at this time. Because most of the corn-fed cattle are fattened during the winter and sold in the spring, the price of choice steers is lowest in April and May. Common steers, on the other hand, bring the highest price of the year during May.

### Requirements in Fall Marketing

This seasonal variation in the price of different grades of beef cattle would suggest that fed cattle to be marketed during the late summer and fall should be of good quality and well finished so that they will not need to compete with the large number of range cattle being marketed at that time. Whether good or common cattle should be fattened during the winter to be sold in the spring depends on the price at which they may be bought. In the feed lot a good grade of steers will make more rapid and cheaper gains and will require a narrower margin to meet feeding costs than is necessary for common steers. Common steers, however, may often be purchased in the fall cheaply enough to overcome their disadvantage in feed-lot performance and sale price, especially if marketed not later than May of the following year.

George W. Collier.

## CHANGES in Type of Farming, 1919-1924

Farming in the United States has undergone more radical changes during the five years from 1919 to 1924 than in any similar recent period. These changes have been due mainly to continued low prices for a number of the major farm products.

In the United States as a whole 3.25 per cent of the land included in farms in 1919 had been abandoned for farming purposes by the end of 1924.

The decrease in farm acreage was very general, being over 30 per cent in one State and nearly 20 per cent in another. The details are given in Figure 38. The only section of the country in which farm area increased was in the far West, in Oregon, Wyoming, Nevada, Utah, Arizona, and New Mexico. There was a decrease in every other State in the Union.

Changes in the percentages of farm land in harvested crops behaved somewhat differently, as is shown in Figure 39. In the United States as a whole there was a decrease of 2.3 per cent.

There are three groups of States in which there was an increase in the percentage of farm land in harvested crops. The largest group consists of Minnesota, Iowa, the tier of States from North Dakota to Kansas, and Montana and Colorado. There is a slight increase in New York and the New England States, and an increase in Tennessee, Arkansas, and Texas. In all the other States the percentage of farm land devoted to harvested crops decreased.

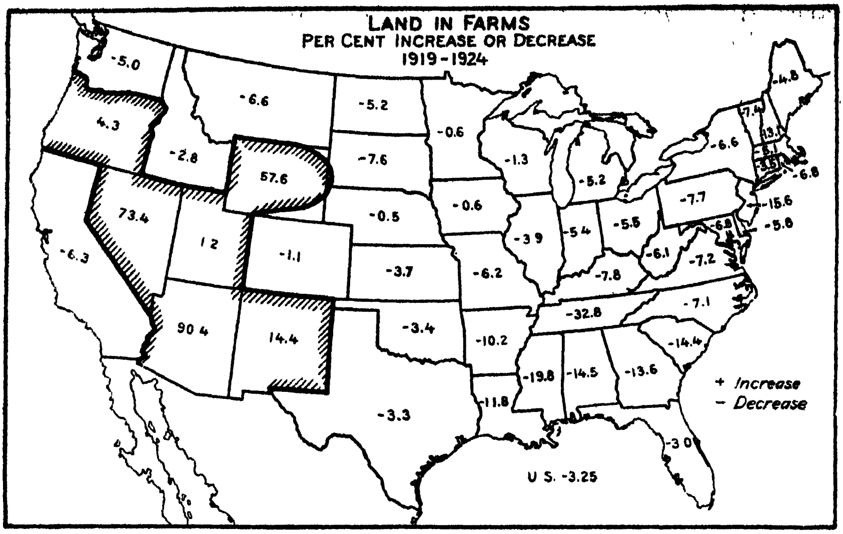

FIG. 38.—Acreage of land in farms decreased in most States. Actual abandonment, encroachment of cities and towns, and reversion to forest contributed to the decreases

### Where Farm Land Decreased

The area of land in farms decreased in all the States east of Wyoming. In the Middle Atlantic and east North Central States, where the decrease in farm land was considerable, there was a still further decrease in the percentage of farm land in harvested crops. This means that in these groups of States there was not only a considerable abandonment of farm land, but that on land remaining in

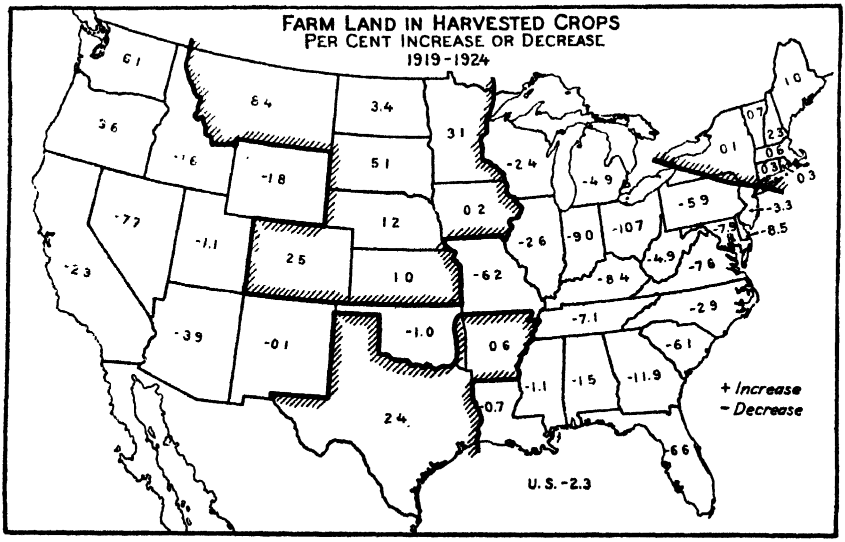

FIG. 39.—Three groups of States increased the percentage of farm land in harvested crops, though the percentage for the country as a whole declined. In some of the Western States the decrease is due to considerable increases in pasture areas

farms there was a reduction in the intensity of farming, much land formerly devoted to harvested crops reverting to grass or even to forest. In the two groups of States, the Northeastern and the Southern, in which there was a decrease in farm acreage as shown in Figure 38, but an increase in the percentage of farm land in harvested crops as shown in Figure 39, the interpretation is that the abandonment of farm land affected the less intensively used areas, such as grassland and timberland, more than it did crop land. In some of the Western States the decrease in the percentage of farm land in harvested crops is due to a considerable increase in pasture areas.

Figure 40 shows the increases and decreases in the area of harvested crops. Except for a few very small areas the only part of the country in which there was an increase in crop area was in the Plains region, extending from Texas to Montana, and eastward into southwestern Minnesota and northwestern Iowa. In most of this region land is still being brought into cultivation, while in the eastward extension into Minnesota and Iowa the increase is to be interpreted as a conversion of pasture land into crop land.

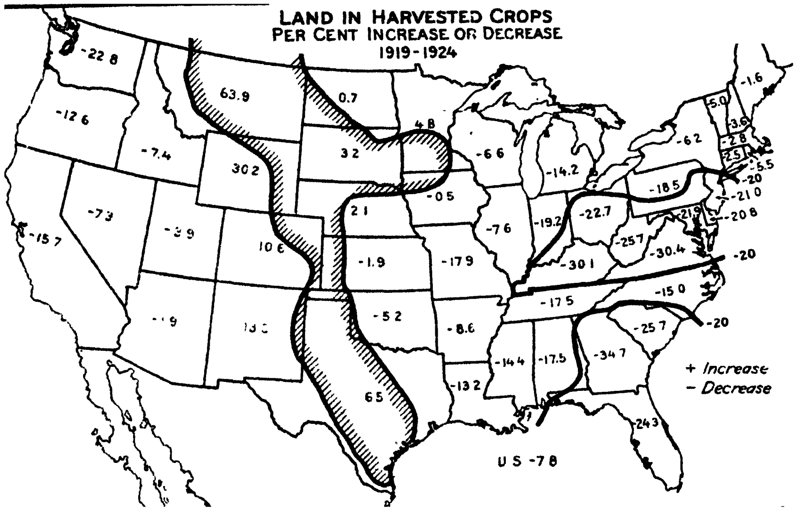

FIG. 40.—The acreage of crops harvested in 1924 was 29,089,832 acres less than in 1919. The decrease was general throughout the country except in the Plains region and a few very small areas within States which as a whole showed decreases

In all the rest of the country except in a few small areas the acreage of harvested crops decreased. In two groups of States, as shown in Figure 38, the decrease was in excess of 20 per cent. In the extreme southeastern group these decreases are due largely to the effect of the boll weevil. In the central-eastern group the effect is in part due to near-by industrial development which gives farmers a better opportunity to obtain employment in the industries. This is also a region in which wheat and corn are important crops. During a part of the period in question the prices of these two major-crop products were very low.

The decrease in crop area for the entire country was 7.8 per cent and is to be attributed in the main to the unprofitableness of farming during most of this period.

The various major crops were affected differently by the agricultural depression. The effect on each of them is described briefly in the following paragraphs:

The acreage of corn increased in the Northwestern States, the central and northern Great Plains, and in the northern Mountain States. In some of these States the increase was striking, particularly in North Dakota and Montana. The swine industry is following corn into this region. The northern Plains States are becoming an important factor in the hog industry.

### Decrease of Corn Acreage

Outside of this group of States there was a decrease of corn acreage in every State in the Union, the decrease being very large in the Central Eastern States. Thus in Kentucky, which in 1919 had the largest proportion of its total crop area in corn of any State, the acreage decreased during the five-year period 32 per cent. In Ohio, which is an important corn State, the decrease was 39 per cent.

The relative importance of corn as a crop increased slightly for the country as a whole.

A marked increase in acreage of crops for silage, mostly corn, took place in the States from Wisconsin to Montana, including Wyoming, with a small increase in Iowa and South Dakota. There was also an increase in the acreage of silage in Ohio and in the Atlantic seaboard States except South Carolina and Delaware. Outside of these two areas only Mississippi and Nevada showed an increase in the acreage of silage crops.

### Wheat Acreage Declines

Changes in wheat acreage were more marked than in the case of any other crop. For the country as a whole there was a decrease of more than 30 per cent in the area devoted to wheat, and the proportion of crop land devoted to wheat fell from 19.5 per cent in 1919 to 14.7 per cent in 1924. There was an actual increase in wheat acreage in only two States—New Mexico and Montana. The increase in Montana is due in part to the fact that in 1919 a very large acreage of wheat was not harvested, and hence was not included in the area of harvested crops.

The decrease in wheat acreage was very marked in many sections, amounting to 68.5 per cent in Missouri, 57 per cent in Minnesota, 45 per cent in Illinois, 43 per cent in Indiana, and 78 per cent in Kentucky.

This readjustment of wheat acreage represents a return to normal conditions following the remarkable extension of wheat acreage during the war. In several States the 1919 acreage had been increased to such an extent as to unbalance the farming.

### Acreage in Oats and Hay

There was an increase in oat acreage in nearly all the States where corn acreage increased; that is, in the Northwest and the northern Plains region. In the States adjacent to this group there was a slight decrease in the acreage of oats. Elsewhere, except in Ohio and Arkansas, where the acreage increased, there was a very marked reduction, particularly in the extreme Southern States and in some of the New England States. For the country as a whole the acreage of oats decreased less than 1 per cent. Oats made up 10.2 per cent of the harvested crop acreage in 1919, the percentage increasing slightly during the five years.

The acreage of hay was affected in a peculiar way by the radical changes that occurred during this census period. In the eastern and central portions of the country, where there was considerable abandonment of farm land, and for the most part a decrease in the proportion of farm land in harvested crops, the acreage of hay actually increased. This is to be accounted for largely by the fact that when farm land is abandoned so far as cultivated crops are concerned, there is already considerable acreage of hay and in most cases some new seeding which next year is added to the hay acreage. The increase in the acreage of this crop is therefore to be interpreted mainly as a result of a change toward less intensive utilization of the land. In some of the Western States the increase is due in part to the increasing importance of livestock in the local farming.

### Changes in Cotton Acreage

Cotton acreage decreased in all the States from South Carolina to Louisiana except Alabama. The increase in Alabama is interpreted as a revival of agriculture after the panic caused by the advent of the boll weevil. The decrease in Georgia, South Carolina, and Florida was very large. Only in Georgia, however, did the relative importance of cotton decline during the period.

Along the northern border of the Cotton Belt, and particularly in the West, there was a phenomenal increase in cotton acreage. Texas, which in 1919 had the lion's share of the crop, increased the acreage during the period 44.5 per cent. For the country as a whole there was an increase of 16.2 per cent.

These increases were the result of the high prices for cotton that prevailed during most of the war years and for some years afterwards. The increase appears to have gone too far, for at the present time the situation of the cotton grower is critical because of low prices.

Further changes in type of farming are required to balance the agriculture of many sections. We now have a surplus of all the major crops. Cotton, hay, and oats are in the worst position.

W. J. SPILLMAN.

---

## CHESTNUT Blight is Unchecked

Of the numerous foreign plant diseases which have gained entrance into this country, none has been more destructive than the chestnut blight, a fungous disease from Asia. In the last 25 years millions of acres of chestnut growth have been killed by the blight and the remaining American chestnuts in the East face certain destruction.

The chestnut-orchard industry of the New England and the Middle Atlantic States has been practically destroyed by the blight and there remain only rare trees of the American and European chestnuts or their hybrids and a small percentage of the more resistant Japanese chestnuts. Unfortunately the killing of the chestnut forest growth and orchards does not result in the self-extermination of the disease, as many of the roots of the killed chestnuts remain alive and send up sprouts which continue to spread the disease for many years. Consequently chestnut orchardists in the eastern half of this country can expect the blight to be an important factor, though losses from this diseases may be insignificant in localities where chestnut and chinquapin are not native.

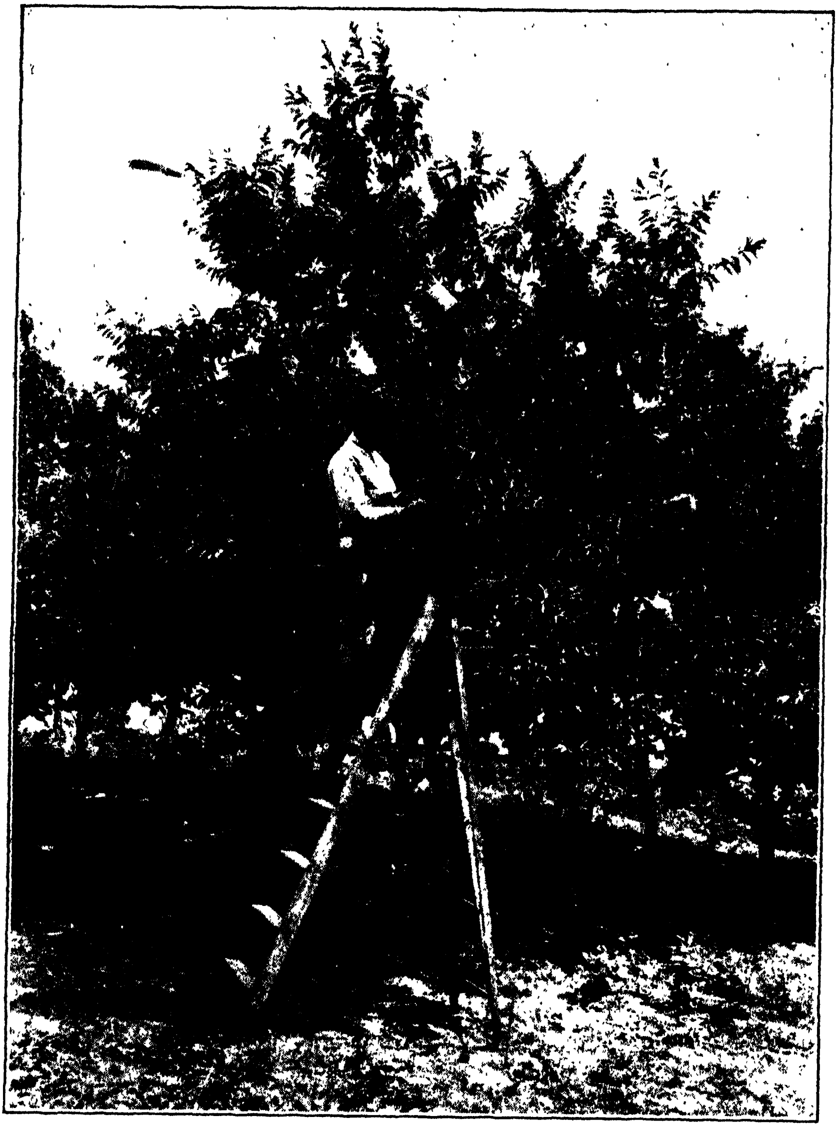

FIG. 41.—A view of an orchard of hairy Chinese chestnuts planted by Doctor Van Fleet at Bell, Md. This species is being crossed with other species of chestnut. Many of the trees in this orchard have never had deep cankers which justified treatment, although the blight has been present in the orchard for the last 12 years

Experience in the department chestnut orchard at Bell, Md., indicates that in orchard practice the blight can be controlled on various strains of the hairy Chinese chestnut, *Castanea mollissima*, (fig. 41) at a reasonable cost. A simple treatment which has given satisfactory results with this species consists of cutting out every spring the trunk infections which reach into the cambium region and painting the cuts. The majority of the trees do not require the removal of infections every year, while some few trees frequently have deep cankers. In orchards where the blight is being eradicated, much more frequent, careful, and drastic treatment is required. It is important in both the control and the eradication of the blight to keep the trees in vigorous condition. Although the blight can be controlled on the hairy Chinese chestnut, other factors such as the sale price of the nuts and the chestnut weevils, for which there is no satisfactory control at present, must be considered by the prospective orchardist.

Successful inoculations on varieties and species of chinquapins from different parts of the Gulf States and Arkansas show that the blight will eventually spread over the chinquapin area of the South. These shrubs will be a source of infection for orchards considerably outside the range of native American chestnut. As the chestnut blight is carried for long distances in various ways, there is no assurance that even the chestnut orchards of the Pacific coast will remain free from the disease. Orchardists and inspectors in that region should be on the watch for the blight, as young infections can be easily and completely eradicated, whereas older ones can be eradicated only with much greater difficulty.

### Ornamental Chestnut Trees

The planted American chestnuts of the Northeast have largely disappeared, and those of the southern Appalachians and the Ohio Valley are doomed. Owners who are dependent upon these trees for shade should take immediate steps to plant resistant chestnuts or other kinds of shade trees to replace the native chestnuts when they die. Many strains of the Japanese and hairy Chinese chestnuts are sufficiently resistant to the blight to be grown as shade trees with very little treatment, whereas others are rather susceptible and require considerable treatment. The natural beauty of these trees, together with their production of edible nuts, makes them very desirable for planting in many situations. A few trees of the hairy Chinese chestnut will supply the farmer's family with sweet nuts.

Most of the chestnut forest growth north of Virginia and east of the Allegheny River has been killed by the blight, and that of the southern Appalachians and Ohio Valley will be destroyed in the near future. As shown by Figure 42, the blight is now present throughout most of the range of the commercial chestnut. It is spreading more rapidly in the South than it did in the North, and already over one-fifth of the chestnut stands of the southern Appalachians are 80 per cent or more infected. Forecasts based upon the present distribution of the disease and its past rate of spread indicate that the major part of the remaining chestnut trees will be infected or killed by 1930. As the distribution and spread of the blight are somewhat irregular, each owner must watch his stand in order to determine the amount of infection in it.

Owners should make plans to utilize their chestnut poles before they are killed by blight, because killed poles will usually not be accepted by purchasers. Very severe financial losses have been suffered by many owners of standing poles, who failed to cut them before they were killed. Chestnut trees suitable for lumber should preferably be cut before they are killed, although such trees are not so much reduced in value as dead poles. To a limited extent chestnut which has been dead for many years has been utilized for making tannin extract, but the yield of extract from a given area is much reduced by the loss of sapwood and partial decay of the heartwood.

In the eastern part of the heavily infected zone nearly all of the trees are dead, while on the western edge of this zone most of the trees though infected are alive. In the zone shown as less than 80 per cent infected, the percentage of infected trees ranges from less than 1 to 80

### Future for Tanning Unpromising

The future of the American chestnut as a source of tanning supplies is not promising. In regions where the blight has been present for many years some trees, which are much more resistant to the disease than the general average, have been located, but still more resistant trees must be found before it will be possible to recommend their planting.

The hairy Chinese chestnut, however, has possibilities as a source of tannin because of its resistance to blight and its high tannin content. Analyses of this species made by the Bureau of Chemistry and chestnut-extract companies show that its tannin content is higher than that of the American chestnut. However, the growth of this tree in China and in a few plantations in this country indicates that it is not so good a forest tree as the American chestnut.

Although America produces an excess of many farm products, it at present imports annually approximately 25,000,000 pounds of chestnuts as the domestic production from chestnut orchards is very small. This country also imports about one-half of the vegetable tannin supplies used in making leather, and with the passing of the American chestnut, whose wood yields approximately one-half of our domestic production of tanning materials, the United States will probably be dependent upon foreign countries for 75 per cent of its vegetable tanning supplies. In France the growers of chestnut not only receive a material income from the nuts, but also sell the mature trees and the trees removed in thinning to the tanning-extract companies. Such a combination may in the future prove profitable in this country since the hairy Chinese chestnut, which is not so prolific in nut production as the European chestnut, has a higher tannin content.

G. F. GRAVATT.

### CHESTNUT Blighted Wood Good for All Timber Uses

The chestnut blight has robbed northeastern forests and wood lots of one of our best all-around timber trees, and is sweeping relentlessly southward through all the Atlantic States. In a comparatively few years chestnut will be gone entirely from our eastern woodlands. What can the woods owner with chestnut trees a part of his timber crop do about it?

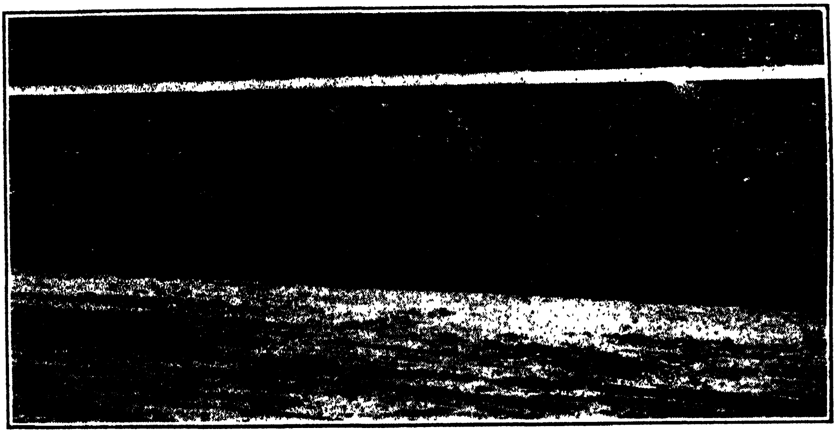

FIG. 43.—Getting the good of a doomed species. This fence, constructed in part of blight-killed chestnut, has for 14 years given testimony to the soundness of this wood

The living tree can not be saved, but the valuable wood can. The blight itself does not affect in any way the strength of chestnut wood. If the wood is harvested before fungi and worms attack the dead tree, the timber is as good for all purposes as any ever cut from a thrifty, unblighted chestnut. However, if this timber, living or dead, is to be saved, it must all be cut and used in the next 15 years.

Even where the blight has not yet entered, the chestnut in farm woods and larger tracts should be disposed of at the first opportunity, regardless of whether the trees are at full maturity. Where the blight has entered, some knowledge is needed of the uses to which the wood may be put, according to the degree that the wood has been attacked by wood-destroying organisms. These uses may be summarized as follows:

Sound wood, trees two years dead or less.—Use for round products, as poles, piling, construction timbers, mine timbers, highway and railway round fence posts, hewed ties, and all the uses that follow where sapwood is not objectionable.

Sapwood decayed but heartwood sound, trees dead two to four years.—Use for sawed products, as box and yard lumber, mill products, coffins and caskets, furniture, core stock (veneer), cabinet work, woodenware novelties, and slack cooperage. Where lumber is to be kiln dried, there is no fear that decay will spread, for this process sterilizes the lumber effectually.

Sapwood decayed and heartwood checked but fairly sound, trees four to six years dead. Tannin wood, pulp wood, farm fence posts. lumber or timbers for temporary construction. Wood less sound can be used for fuel. This class of material should never be supplied for the purposes listed in the preceding paragraphs. Where this has been done it has in some regions brought about an embargo on all chestnut.

Chestnut constitutes about 25 per cent of the woods and forests on 33,000,000 acres in the Appalachian region, and represents in merchantable timber fifteen to twenty billion board feet. To utilize this timber before it is destroyed is a national obligation. To delay doing so will in many instances result in a considerable loss to the owner.

R. D. Garver.

## CHINESE Jujube in Southwestern United States

The Chinese jujube (*Ziziphus jujuba*) has been grown in northern China since ancient times. It is one of the five principal fruits of that country, and many excellent varieties have been developed by the Chinese. The tree is deciduous, rather small, and somewhat spiny, with firm, shining-green, oval or oblong leaves 1 to 3 inches long. (Fig. 44.) The fruit is a drupe, elliptic or oblong, up to about 2 inches long, with a thin dark-brown skin, and crisp, whitish flesh of sweet, agreeable flavor, inclosing a hard two-celled point stone. (Fig. 45.)

Although a few seedling trees were grown in the United States as early as about 1837, it was not until Frank N. Meyer, agricultural explorer, visited China in 1908 that scions of large-fruited varieties were introduced. As a result of Meyer's work there are now established in California and the Southwest a number of the best and largest-fruited forms of the jujube.

The fruiting of these varieties in this country has stimulated interest among fruit growers and others, especially in Texas and California, and there is an ever-increasing demand not only for propagating material, but also for information concerning culture and utilization of the fruits.

The tree has withstood successfully temperatures as low as —22° F., and as high as 120°. It reaches its best development where the weather is dry, the sunshine brilliant, the nights warm, and the summers long and hot. Large areas of the southwestern United States, therefore, are well adapted to jujube culture. Because of its habit of late flowering, the jujube is free from injury by spring frosts and bears regularly and abundantly. In respect to soil requirements, the jujube has shown that it thrives in sandy alkaline soil and also in heavy nonalkaline soils, but the best results are obtained on sandy loams and lighter soils.

### Varieties of the Jujube

Of the many different varieties introduced by Meyer from China, four have been selected as being distinctly superior to all the others.

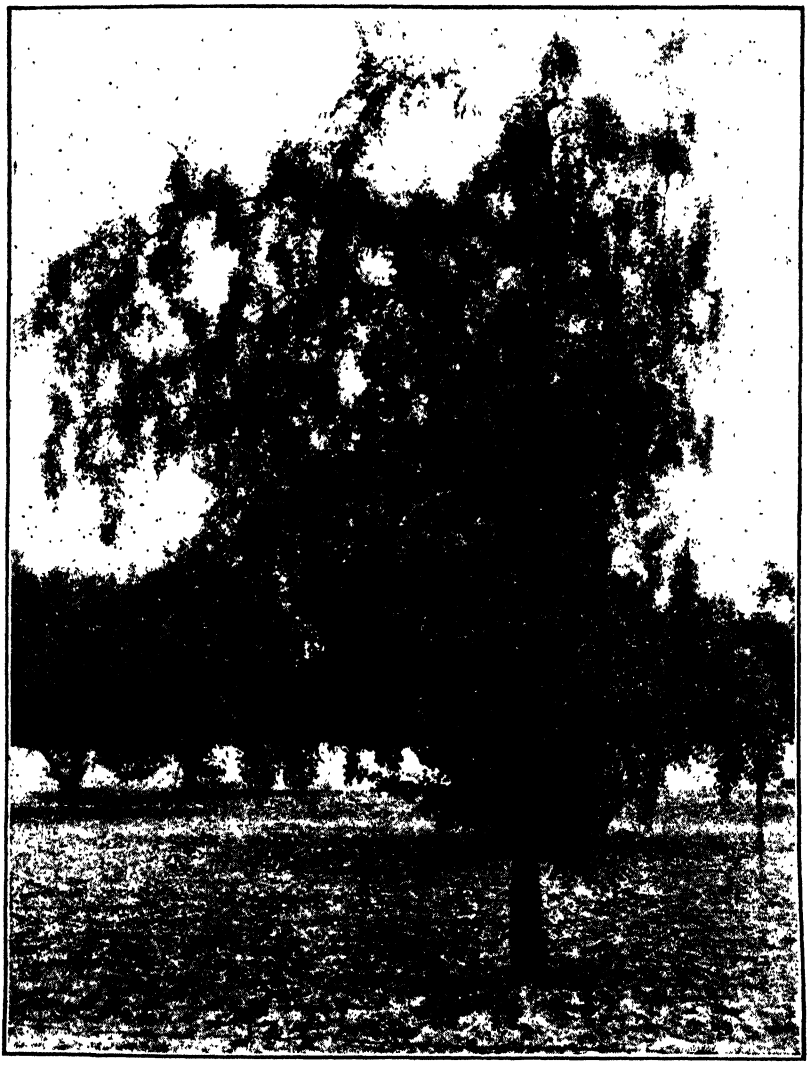

FIG. 44.—Fruiting tree of the jujube at the plant introduction garden, Chico, Calif. This tree is about 18 years old and is a heavy bearer

These are the Mu Shing Hong (S. P. I. No. 22684), the Lang (S. P. I. No. 22686), the Sui Men (S. P. I. No. 38245), and the Li (S. P. I. No. 38249). These varietal names are the ones sent in by Meyer with his notes. The largest of these is the Li, whose rounded-oval fruits are sometimes 2 inches long and nearly that much in diameter.

The Li also has the smallest pit, considered in relation to the amount of flesh. For general purposes, it is probable that the Lang is the best variety. Its pear-shaped fruits are produced in abundance and are easily processed in sirup. This variety is also one of the most readily propagated. Although these are considered the best varieties at present, there are several others which may prove to offer particular advantages after further trials.

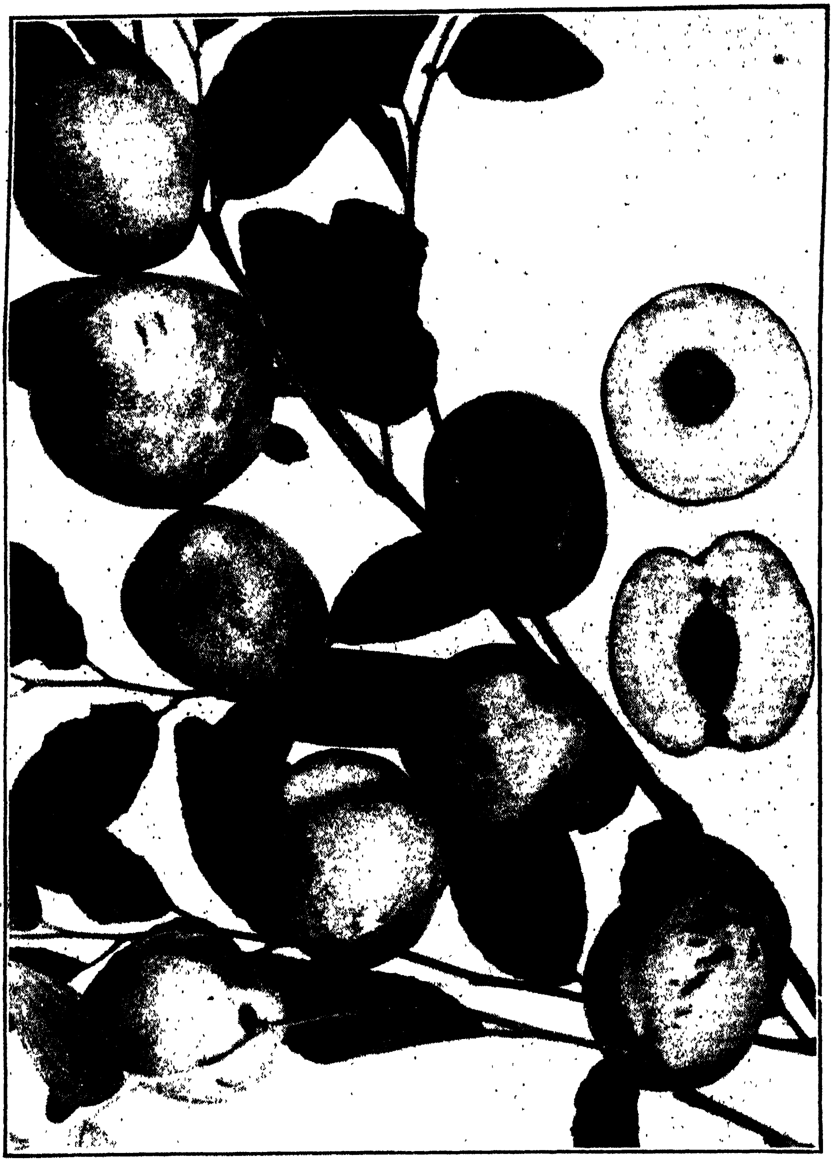

FIG. 45.—Fruits of the Li jujube (S. P. I. No. 38249) grown at the plant introduction garden, Chico, Calif. This variety has the largest fruits of any grown in the United States, has a relatively small stone, and processes well

The jujube is used in several ways. It may be eaten fresh or the dried fruits may be ground and added to bread or cake as a seasoning, or used to make a mock mincemeat. The fresh fruits may be made into a jujube butter. Excellent sweet pickles may be made from the skinned whole fruits. The most satisfactory method to utilize the fruits, however, is as a confection. The skin is punctured or scored in some manner and boiled in sirup, the scoring allowing the sirup to penetrate the fruit easily. This scoring may be done with old safety-razor blades held together by bolts with thin pieces of cardboard between the blades. Or a board may be driven full of nails with the points barely projecting from one side, and the fruits punctured by rolling over the points.

### How Sirup is Made

The sirup is made by using 1 or 2 parts of sugar to 1 of water, according to taste, the lighter sirup allowing more of the fruit flavor to be retained. The perforated fruits are then placed in the sirup and boiled from 20 to 35 minutes, the larger fruits requiring the longer boiling. The fruits are then allowed to cool in the sirup, after which they are boiled again for the same length of time. Then the fruits are taken out and allowed to dry on trays, either in the sun or by artificial means. Drying should be carried to a point where the fruits are firm, but not too hard.

The jujube compares very favorably with the fig in point of edible matter, total sugars, acid, and ash, and contains more protein than the date. It is therefore of high food value.

The immediate future of the jujube is in its culture as a home fruit, and as such it should appeal to growers and residents generally in the drier portions of the Southern and Western States.

C. C. THOMAS.

---

## CHINESE Elm in American Horticulture

Among the many valuable contributions of northern China to American horticulture the Chinese elm (*Ulmus pumila*) stands out as one likely to prove of increasing value to certain sections of the United States. First introduced in 1908 by Frank N. Meyer, agricultural explorer, from near Peking, Chihli, China, the tree is established in a number of places in this country, and seeds and plants are offered for sale by several nurseries in the South and West.

It is a rapid grower, with slender, almost wiry branches. The leaves are elliptical and smaller than those of the American elm. If allowed to assume its natural habit, the Chinese elm develops numerous branches along its trunk, making a rather dense growth from near the base and resembling in some instances large shrubs. It is one of the first trees to leaf out in the spring and the last to shed its leaves in the fall. Throughout the long season the leaves remain a beautiful green and are remarkably free from the usual plant diseases and insect injuries so common in many of the other elms.

### Tree is Very Hardy

It is very hardy and has proved valuable under a greater variety of climatic and soil conditions than any tree yet introduced. Very favorable reports have been received from practically every section of the country. It has proved winter hardy in most trials in the Dakotas, Minnesota, New York, Montana, and other Northern States. Its resistance to drought, alkali, and extremes of temperature render it an especially valuable tree in the Great Plains region where desirable shade trees are few, in the semiarid South and

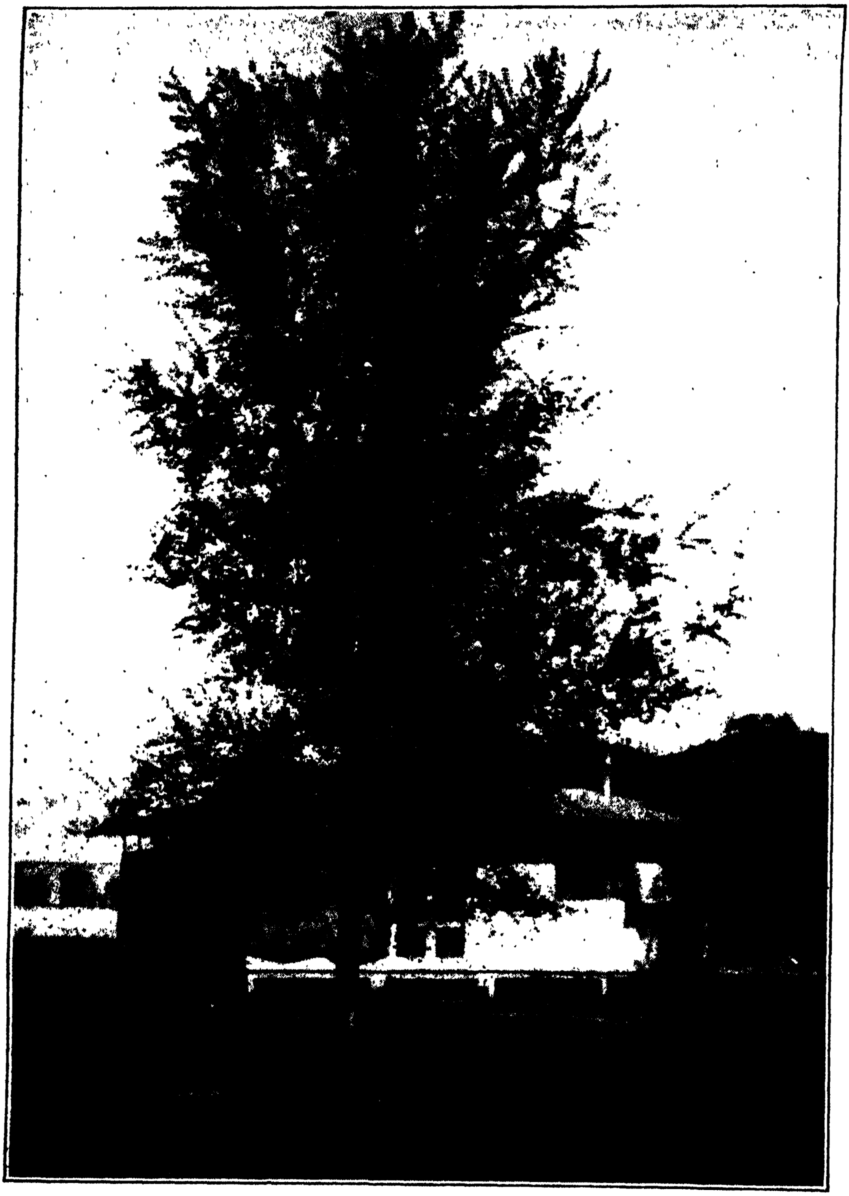

FIG. 46.—A 6-year-old tree of the Chinese elm (*Ulmus pumila*) grown near Yuma, Ariz. One of the few trees which can survive the trying climatic conditions of that region

Southwest, and in fact in almost any portion of the continental United States. (Fig. 46.)

That this elm is a very rapid grower is shown by the following statement from a planter at Bridgeport, Nebr.: Trees planted May 1, 1918, were reported upon as follows on April 7, 1922: "Trees when received were not over 3 feet high and about the size of a lead pencil. On November 1, 1921, by actual measurement, they were 16 to 19 inches in circumference and from 15 to 25 feet high." A report from the Fort Hays Experiment Station at Hays, Kans., commenting upon a tree received and planted in 1913, gives the following information: "Tree is now 46 feet high and has a trunk 21 inches in diameter." In trials in the eastern United States from New York to Florida it has made a good growth and produced good trees, although in this region they have not made as rapid growth as in the Middle West or Great Plains area.

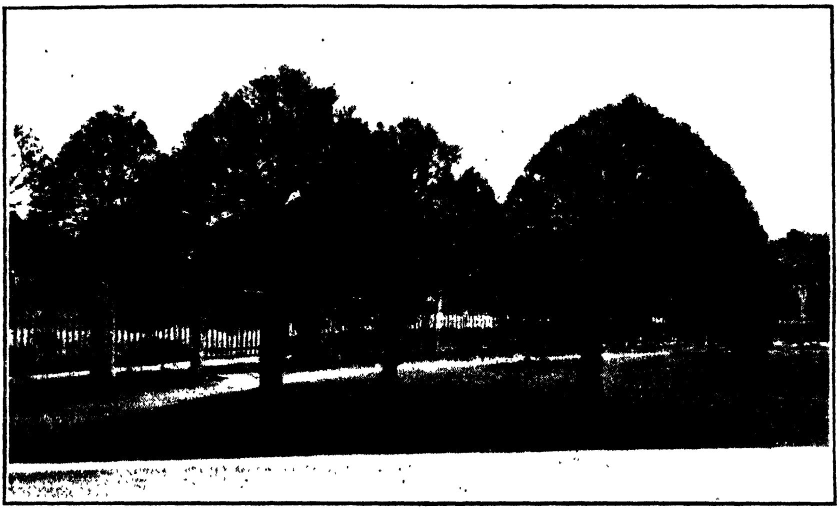

FIG. 47.—Trees of the Chinese elm trimmed to a formal shape. Photographed at Harbin, Manchuria

### Propagation and Uses

This elm can be propagated either from root or stem cuttings, as well as by seeds. The easiest and least expensive method is to use seeds when available from one's own trees or obtainable at a reasonable price. Experience thus far in growing plants from stem cuttings indicates that wood of the new growth taken early in the season is the most reliable and that young root cuttings root readily.

Some of the earlier plantings of this tree in the United States are now producing seeds, so that a domestic supply should soon be available and make importation from China unnecessary. Elm seeds retain their vitality for a short period only and for this reason should be planted shortly after being harvested, when possible. When necessary to keep for some time they should be stored in a way to prevent drying out.

As a shade, windbreak, and avenue tree the Chinese elm has proved to be the most successful introduction of this kind thus far attempted.

A recent report from one of the department's explorers in Manchuria brings out the fact that this tree is used there for hedges 2 to 3 feet high; in some instances being used for screens up to 12 or 15 feet in height. It is also used there for formal plantings, the trunk being trimmed of branches to a height of 6 to 8 feet, with the top portion of the tree trimmed to a conical shape. (Fig. 47.) If the trunk is kept trimmed, this elm will assume a treelike habit and make a splendid shade or avenue tree. Its natural habit of growth also makes it valuable as a windbreak. C. C. THOMAS.

## CHINESE Dwarf Meyer Lemon Introduced

In March of 1908, Frank N. Meyer, agricultural explorer of the Department of Agriculture, while traveling in the vicinity of Peking, China, observed a lemon that was used as a house plant and was regarded very highly by the Chinese. It was grown as an ornamental plant, but the fruit was also considered of excellent quality. Plants of this variety were obtained by Mr. Meyer and carried with him along with other plants on his return to the United States in June, 1908. This was given an "accession number," S. P. I. 23028, and determined as *Citrus limonia* Osbeck. It has since been questioned as to whether or not it may be of hybrid origin, but this is yet to be determined. The varietal name Meyer has been suggested for use in connection with this introduction. Mr. Meyer's note regarding this lemon was as follows:

> (No. 690, March 31, 1908) From Fengtai, near Peking, Chihli, China. Ornamental lemon. This lemon is grown as a pot plant when dwarfed, and is very much appreciated by the Chinese higher classes as a decorative house plant in winter. At that season a small plant often has a dozen large lemons hanging on its branches and sometimes sells for $10. Protect from frost. Can be slipped in sandy soil in flat pots. Chinese name "Hsieu Yuang."

Mr. Meyer landed at San Francisco and took his plants to the department's plant introduction garden at Chico, Calif., in the Sacramento Valley. Here they were grown and propagated for testing in the various citrus areas of this country and for testing as a pot plant farther north. It has been observed at Chico that the plants can be propagated readily from cutting as Mr. Meyer indicated and that they are much more winter hardy than ordinary commercial lemons. It was not killed by a temperature of 13° F. at the Chico plant introduction garden, although the top was killed back severely. A temperature of 24° F. has done no other damage than to discolor some of the leaves.

This lemon is a dwarf-growing plant attaining under favorable circumstances a height of 8 to 10 feet. In general it is a low-growing, bushy plant requiring a space not over 8 feet square. The fruit is slightly larger than that of the Eureka, Lisbon, or other common commercial varieties. It has a very smooth, thin skin, and but little fiber or rag. It is very juicy and mildly acid for a lemon. (Figs. 48 and 49.)

### Experience of American Growers

One experimenter in California in December, 1925, reported as follows:

> The trees, while slow growing, appear to be hardier than either the Lisbon or Eureka. Occupying the same situation in my orchard as these varieties,

they (the Eureka and Lisbon) lost a few leaves during the extreme cold of a year ago, but the trees of Meyer lemon did not suffer any injury to either leaves or tender terminal growth. They fruited the second year from planting and have proved very heavy bearers. The fruit has fewer seeds than either the Lisbon or Eureka, has a smooth, glovelike skin; the center of the fruit is entirely lacking in fibrous growth, carries considerably more juice than any lemon grown by me (I have seven varieties) and we prefer it to any for household use.

An experimenter in Florida reported in the spring of 1926 as follows:

During December of 1925 we had temperatures of 24°, 22°, and 16° F. The plant was partly defoliated at 16° F., but suffered not at all from the other temperatures. All growth appears to be unhurt and we believe it will prove only slightly less hardy than the Satsuma.

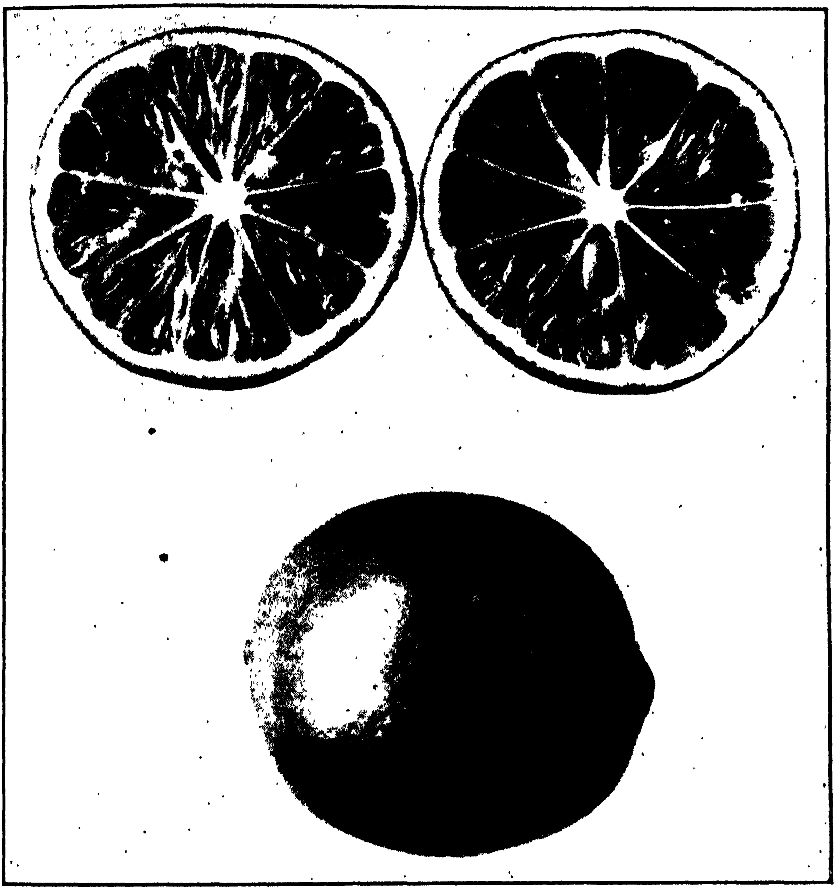

FIG. 48.—Fruits of the Meyer lemon (S. P. I. No. 23028) grown at Oroville, Calif., in 1925

The department has but little exact information regarding yield of fruit, but general observation and reports indicate it as producing well. An experimenter in California reported in December, 1925, as follows:

I planted my tree out-of-doors in the lawn five years ago. The second year after planting it produced 7 fruits, the third year 111 fruits, the fourth year

138 fruits, and this year 25. In 1924 it overproduced and then the frost killed most of the leaves, resulting in a lighter crop this year (1925).

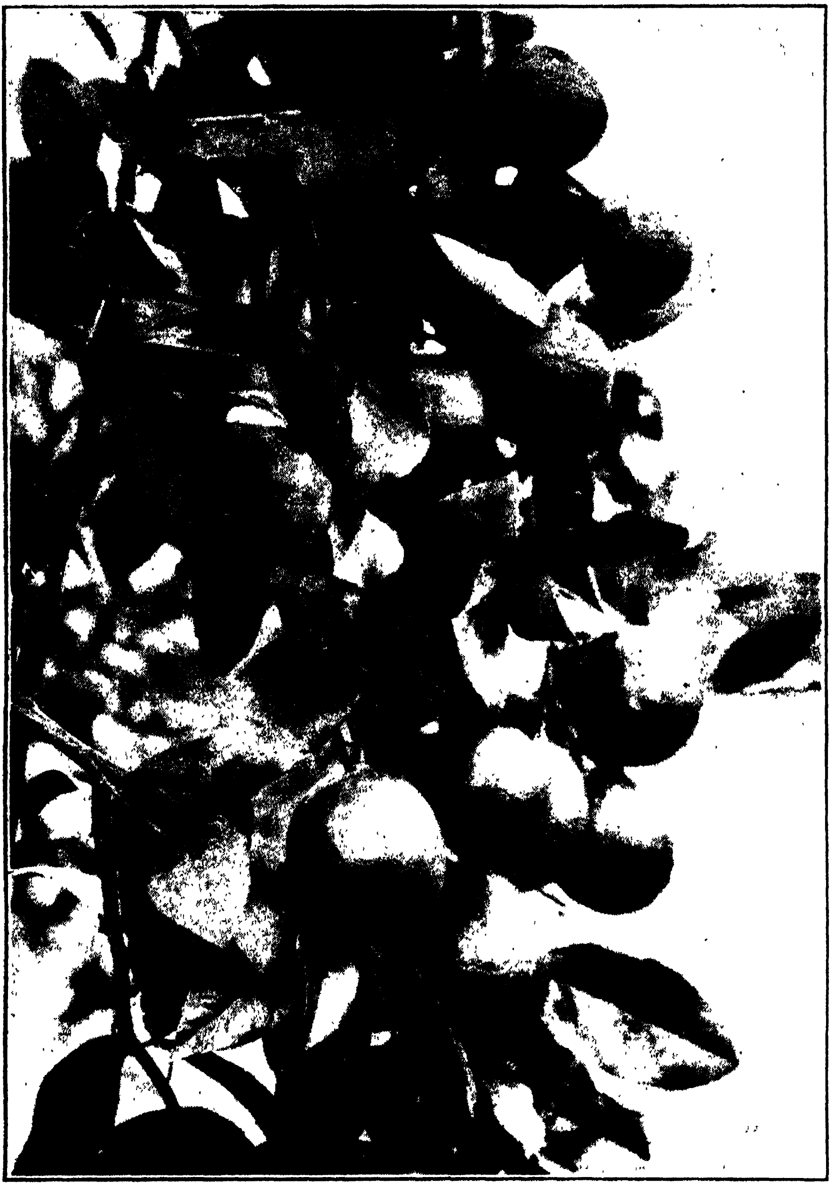

FIG. 49.—Fruiting branch of the Meyer lemon (S. P. I. No. 23028) photographed at the plant introduction garden, Brooksville, Fla.

### Heavy Bearing Tree in Texas

At Brownsville, Tex., a tree 6 feet high bore 132 lemons in 1920 and 240 in 1921; these averaged 8 ounces in weight. At Irvington, Ala., a tree planted in 1918 was reported to have borne several hundred fruits in 1921 and about 1,000 fruits in 1923. However, this same tree died during the cold winter of 1923–24.

The best stock for this lemon has not been determined. Some have reported good results when worked on sour-orange stock, and others unfavorable. It has also been worked on *Poncirus trifoliata*, grapefruit, and mandarin, with opinions varying regarding the relative value of these as stocks. However, since it roots readily from cuttings it perhaps may be safest, until otherwise demonstrated, to grow it on its own roots.

This seems to be a fruit of special value for home use in areas where it can be grown in the open, and it also may have value as a commercial fruit in locations too cool for other varieties to succeed.

ROLAND MCKEE.

## CHRYSANTHEMUMS for the Northern United States

The charm and beauty which the hardy chrysanthemums add to the landscape of the South during late fall could, it is believed, be extended to the northern garden if early-flowering sorts with sufficient hardiness to withstand the rigorous winters of the region can be developed. There are many sorts the roots of which are hardy but because they flower so late contribute little to the floral display of autumn at the North, save in the exceptional season. If these hardy forms can be induced to bloom earlier in the season and at the same time provide flowers of desirable form and color, the approach of winter may be delayed so far as the garden is concerned; for the early frosts which are so destructive to most of the annuals are, as a rule, much less harmful to the hardy chrysanthemums.

The variety of form, the diversity of color, and the wide range in the time of blooming observed in the seedlings of hardy "mums" led to the conviction that this plant might be induced to make a contribution to northern gardens as well as southern gardens.

### Some Bloomed Early

Accordingly, a collection of the earliest blooming sorts to be found in both English and American gardens was brought together for observation and test and to it was added a number of department-grown seedlings considered too early for satisfactory greenhouse culture. The first year a few sorts bloomed as early as the middle of August, but the great majority maintained their ancestral characteristics and refrained from blooming until the first days of November, too late to make any marked contribution to the fall garden, even in the latitude of Washington. The early-blooming plants were carefully marked and were left in the open to take the consequences of the winter. Several survived, and in 1916 seed was gathered from 10 of the earliest flowering, winter hardy sorts. From the seedlings grown from this selection and the original collection, seed was again saved from the 10 earliest bloomers in 1918 and this was repeated again in 1919. By 1922 the collection of selected, winter hardy, early-blooming parent plants had grown to 75. From these parents 13,000 seedlings were grown in 1923 and 125 of them were selected for further trial. In 1924, over 10,000 seedlings were grown from specially selected plants and of these 100 were considered early enough to be parent plants. Through further trial and elimination it is planned to reduce the list of selections to a group of 12 or 15 sorts that will bloom and give a satisfactory range of color and form for use during the first half of September and a like collection which will produce the bulk of their bloom during the last two weeks of September.

### Task Beset With Difficulties

This task has been beset with many difficulties. The July and August flowering varieties are manifestly too early for garden or commercial use but as parents for early-flowering strains they are proving invaluable. Seedling chrysanthemums like other hybrid forms present every possible expression of form and color. In this respect the plant is interesting to work with. In fact a field of seedling chrysanthemums presents a most attractive mosaic when the plants are spaced 1½ by 3 feet and each plant develops to occupy the space allotted it. Besides adding an attractive feature to the trial grounds each fall the work has resulted in the development of early-blooming sorts including a wide range of form and color.

As soon as satisfactory forms of these chrysanthemums are selected the next task will be to multiply them. This will be done to such an extent as to make them available, through the trade, to the gardeners of the North who wish to prolong the floral display of the autumn.

FURMAN LLOYD MULFORD.

## CELERY Disease and Its Control

The black-heart disease of celery is found in its most prevalent and destructive forms in Florida and California, two of the largest celery-growing districts in the United States, in both of which artificial irrigation is used extensively. The irrigation is important, as it will appear later that proper irrigation is the only satisfactory method for the control of the disease. The disease, most destructive in Florida because of the heavy rainfall during March and April following several months of drought, has been known since the early commercial culture of celery. Since, until recently, there were no methods for the control of black heart, the growers have lost heavily from it every year.

The disease attacks principally the tender growing heart of the plant, producing a blackening of the tissues, and hence the common name "black heart." As the disease develops, the entire heart is killed by a typical dry rot, which is often followed by a slimy soft rot, caused by secondary organisms of the *Bacillus carotovorus* group. The malady is nonparasitic in nature and is not to be confused with the common heart rot found mainly in the northeastern United States. The black heart causes a yellowing of the entire leafy portion of the plant, with a loss of the green color, followed by a browning and death of the tissues involved. The diseased plants are worthless and many fields in Florida have been observed in which all the plants were affected.

For many years the celery growers in Florida and a number of experimental workers thought the disease was caused by improper fertilization. In 1906, R. Y. Winters, conducting preliminary fertilizer experiments in the Sanford section, came to the conclusion that the disease was caused by the excessive applications of kainit and nitrate of soda. He also thought that other adverse conditions for plant growth, such as unbalanced water relations, improper mixing of fertilizer, and the attack of the plants by blights, were favorable to the occurrence of the disease, but he had no experimental data to support these general conclusions.

The writer conducted fertilizer experiments with celery in the Sanford section over a period of five years, using over 60 different fertilizer combinations—the ammonia, potash, and phosphate being derived from as many different sources as possible. Nitrate of soda was applied to one plot at the excessive rate of 1 ton to the acre. Other forms of ammonia and potash were applied in the same manner and there was not a single instance in which the disease appeared that would indicate that fertilizer from different sources had any relation to the disease. On the other hand, the disease was readily produced under field conditions by allowing the soil to become excessively dry and then flooding. After such treatment the disease would appear within 48 hours. It was also produced by removing healthy plants from the soil and placing them in jars of water over night.

### Difference in Susceptibility

A considerable difference in the susceptibility of certain varieties to black heart was found. Of all those tested the Old Golden strain proved to be the most susceptible and Meisch's Wonderful or Special strains the most resistant to the disease.

Celery black heart has been controlled experimentally and in a practical way by Florida growers by first selecting a strain of celery that is highly resistant to the disease, and then carefully regulating the supply of water throughout the growing period of the plants. Celery is a water-loving plant, but it will not stand excessive flooding, especially if it has been stunted during growth. It is necessary, however, to harvest the crop before it has reached maturity, as mature plants are very susceptible to the disease if other unfavorable conditions occur.

ARTHUR C. FOSTER.

## CITRANGES and Some Related Hybrid Fruits

The breeding of cold-resistant citrus fruits suitable for culture in the southern part of the Cotton Belt has been in progress for many years. A large group of hybrids known as "citranges" were first produced by crossing the commercially worthless trifoliate orange of Japan with the ordinary sweet orange. The citranges are unlike either parent, and serve chiefly as hardy substitutes for the lemon. The Rusk citrange has been more widely distributed than the others, its prolific nature, evergreen habit, and handsome appearance, especially when carrying a full crop of bright orange-red fruits, giving it value as an ornamental in addition to its fruits.

In 1909, crosses were made between the citrange and kumquat, resulting in the creation of the citrangequat. Of these, the best known is the Thomasville, a tree of compact, upright habit, evergreen, and which starts bearing at an early age, carrying its fruit from late summer into the winter months. These fruits resemble in shape a large oval kumquat, but have an acid, limelike juice, making them excellent for marmalade, preserves, and ade. The gooseneck fruit spur and clawlike calyx points (fig. 50) are unique characters which make the fruit easy to identify. The citrangequat inherits the kumquat's habit of sustained winter dormancy, with resulting hardiness, and so may be grown in regions much too cold for ordinary citrus varieties. It has, too, the unique immunity to citrus canker possessed by its kumquat parent, and so meets the need for a home-grown fruit that will not help in spreading this most serious of all citrus diseases should there be another infestation in the Gulf States.

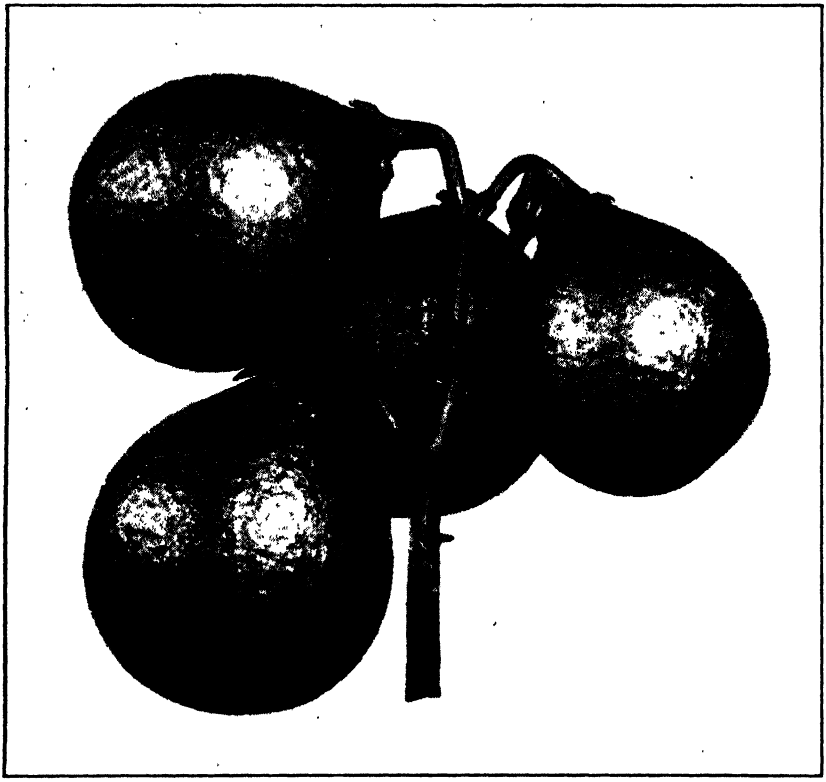

FIG. 50.—Fruits of the Thomasville citrangequat. The gooseneck stem attachment and clawlike calyx points are characteristic of this hybrid

### Trifoliate Orange Valuable

The trifoliate orange, while worthless for fruit production, is an important rootstock for citrus, especially the Satsuma orange. It has a number of serious disadvantages, however, since it is susceptible to citrus canker, fails to grow in very light sandy soils or the black waxy and heavy silt soils of southern Texas, and dies at the root when the budded top happens to be killed by a severe freeze such as sometimes visits the Gulf coast region. The Rusk citrange and Thomasville citrangequat, on the other hand, produce vigorous sprouts from the old roots after a freeze and the trees may be rebudded and a grove reestablished in two or three years. Both show, in budding experiments, a perfect compatibility with the Satsuma orange, and buds grow readily on these stocks. Both are sufficiently hardy to be proof against cold injury in the Gulf States and have a wide range of adaptability to soils not suited to the trifoliate orange. The quality of fruit thus far produced on these stocks is in no way inferior to that grown on the trifoliate.

Both the Rusk and Thomasville, however, produce few seed, so that although they come true to seed their rapid propagation is something of a problem. This problem has apparently been solved by the discovery that cuttings may be rooted in a "solar propagating frame"—a rooting bed using sunlight for bottom heat. Fine twig cuttings with leaves attached may be rooted in six to eight weeks and the root systems so developed are in no way inferior to those of seedling plants. The use of cuttings, furthermore, insures a uniformity not possible with seedlings, while the saving of time as compared with planting seed will more than offset the expense and trouble of rooting the cuttings. Field tests of these stocks are being made, though it will require a few seasons before all factors that enter into their successful commercial use can be determined with certainty.

WALTER T. SWINGLE.
T. RALPH ROBINSON.

## CITRUS Aphid—A New Pest in Florida

During the last three years there has occurred in Florida a violent outbreak of an aphid pest quite new to citrus orchards. Epidemics of this kind are not unknown to students of aphids, but in the history of citrus culture in Florida such an event is unique, and the rapidity with which the insect multiplied was observed with dismay by the growers of citrus fruits. Special meetings were held to discuss the situation, an emergency appropriation was made available to State workers, and the department undertook intensive studies centering in its Orlando laboratory.

The outbreak had its inception in the vicinity of Tampa, where there are extensive plantings of favored varieties. By the spring of 1924 the aphids were mutiplying by the millions and sweeping eastward through the citrus belt. Under optimum conditions not only was the foliage heavily curled, but branches and trunks were green, as if painted, with a crawling mass of aphids.

The insect had never been recorded on citrus trees. Its identity was unknown. Its origin and probable future therefore remained problematical. As far as could be determined it resembled most closely a species called *Aphis spiraecola*, known only on spirea in more northern latitudes. Transfer tests from spirea to citrus and from citrus to spirea and a study of the offspring on these plants proved the two to be identical. The spirea aphid of the North was running wild on citrus in the South.

This gave the first clue. Entomologists know that, viewed biologically, there are two kinds of aphids. One kind finds its optimum conditions in very hot dry weather; the other multiplies most rapidly in moist cool weather. It was believed that the aphid on spirea belonged to the latter class. It was known also that an outbreak demands two things—an abundant host or food supply and a physical environment optimum for the pest but depressing to its natural controls. A study of the climatic conditions in the citrus belt over a series of years as compared with the conditions immediately preceding the outbreak was therefore undertaken.

### Climatic Cause Indicated

It was found that preceding the outbreak there were warm winters and cool moist weather during the time the trees were coming into flush. The records, therefore, gave the picture of a typical epidemic due to unusual climatic influences. It was believed that a return to warm, dry, spring weather would change the situation as follows: The new growth would shoot rapidly and harden quickly, thus reducing the food supply. The reproduction rate of the aphid would be lowered. The insect parasites and predators would be given a chance to multiply rapidly. And with the warm summer rains disease-producing organisms would attack the depleted and weakened aphid population.

The usual epidemic history was therefore predicted—a rise and rapid spread to a maximum infestation followed by a gradual decline to a point at which the insect would be a relatively minor factor. Very little was known with assurance. No outbreak of this kind had been studied in a quantitative way. Existing information was vague and generalized.

Two problems therefore presented themselves. (1) There was needed a satisfactory artificial control to protect the trees during the progress of the epidemic, and (2) it was important to obtain definite information on the factors at work during the growth and decline of the outbreak.

The first need was met, in part at least, by the development of aphid sprays and dusts and by fumigation, this last method being sponsored by State workers. It was found, especially as the epidemic began to decline, that protection was needed only while the new growth was in a succulent condition, but that treatment at this time must be repeated and thorough if the infestation was at all severe.

### More Complicated Problem

The second problem was more complicated. It concerned numerical records, not only regarding the insect itself but with respect to all the agencies involved in the increase or reduction of the aphid population. The task was a large one. By a sort of mutual understanding the State workers took up the study of the insect itself, while the Federal workers gave special attention to the interrelation and importance of the various agencies involved.

This latter study led to some unexpected records. A minor point will illustrate. In a large number of the younger groves the trees were found to contain many spider webs. Even the smaller webs captured many hundreds of winged aphids. Each winged aphid was the potential mother of many young. Moreover, each was a migratory form capable of carrying the infestation to new foliage. A determination of the average number and size of webs per tree and the average number of aphids per web, together with the rates of reproduction and normal mortality, gave a figure showing that things as far-removed from citrus culture as spider webs had a definite influence on reducing the infestation.

This study of the epidemic as a whole is still under way. The results to date, however, would make too long a story to tell here. But when the outbreak of the citrus aphid passes into history, as it is now slowly passing, the data accumulated will enable us to understand better, to predict more accurately, and to control more effectively the course of similar epidemics in the future.

A. C. Baker.

## CLOTHING Expenditures of Farm Families

If the question were asked as to whether farm families spend as much on clothing as city families the answer would probably be a firm and emphatic "No." For the idea has been commonly accepted that the farmer puts much less of his hard-earned cash on his back than does the city dweller. Some facts are now at hand by which this opinion can be checked up. The Bureau of Home Economics has recently made a study of clothing expenditures during one year of 1,337 farm families in four States. These figures show, when compared with similar figures for city families, that there is little difference after all in the amount spent for clothing by farm and city families except for those having relatively large incomes.

The average clothing expenditure of 1,337 farm families for a year ended in 1923-24 was $225. This was 14.4 per cent of the average expenditure of $1,559 for all items of the family living, including the rent, food, and fuel furnished by the farm. City families with about the same total expenditure spent on the average $238 for clothing, according to a study made in 1918-19 by the United States Bureau of Labor Statistics of 12,096 families in industrial centers throughout the country. This difference in clothing expenditure of $13 is certainly not large. Moreover, clothing cost more and took a larger share of the family income in 1918 than in 1923 when the farm study was made.

### Same Comparison on Lower Incomes

And the figures for families of less than average income tell the same story. It is only in families having incomes well above the average that a significant difference in clothing expenditures of city and farm families appears. With a total expenditure of about $3,000, for example, the farm families spent $476 or 15.8 per cent for clothing, while the figures for city families jump to about $500, or 16.7 per cent.

The city wife spends slightly more on clothing than the farm wife. A comparison between the clothing expenditure of husbands and wives, except in the higher-income groups, shows that the city husband in the 12,096 families studied by the Bureau of Labor Statistics, purchases more clothing than his wife, whereas the farm wife averages a higher clothing expenditure than her husband except in the families that spend less than $1,200 a year for all their living. However the farm wife spends less, on the average, than her husband from the time she is 35 until she is 50 years of age. During this period the children are demanding an increasing share of the family income, and the wife's clothing allowance is reduced to meet the situation. The husband's clothing expenditures are also curtailed, but not to the extent that the wife's are.

With an increase in the family income the wife immediately begins to expand in her clothing purchases, buying probably more and better garments than before. On the average her annual clothing expenses increase between $4.50 and $5 for every $100 increase in the total family expenditure. Her husband's clothing expenses do not increase so rapidly with the increased welfare of the family. In the families with total expenditures of less than $1,800, the husband's clothing expenditure increases about $4 with every $100 increase in the total family expenditure. In families, however, that spend more than $1,800 on all their living the husband's clothing allowance increases on the average only $1.36. The clothing expenditure of the husband is less affected by changes in the size of the family or in the income than is that of his wife.

### Girls Spend More Than Boys

The clothing demands of the men and boys in families that spend less than $1,200 on their living are more adequately met than those of the women and girls. The men and boys spend more money on clothing at every age except between the years of 18 and 22. As the income increases, however, the girls spend more on clothing than the boys, except during the years of 3 to 8 when the boy's clothing amounts to more than the girl's. At 19 years of age in all income levels the daughter's clothing costs more than that of any other member of her family, and, on the average, more than it will ever cost again unless fortune places her in a higher income group. In such an event her clothing expenditures will of course increase. The son does not reach his maximum clothing expenditure until he is 21 years old. Then it does not amount to as much as that of his 19-year-old sister, but it is more than he will ever spend again if he is a part of an "average" family, and the total family expenditure remains approximately the same.

### Expenditures Higher on Outer Garments

The way in which the clothing allowance is divided among the different articles of clothing changes as the children grow older, or as more money is spent on clothing. The proportion of the total clothing costs spent on headwear and outer garments, for example, increases with each older age group, and that allotted to undergarments and footwear decreases correspondingly. In general daughters over 16 years of age spend about 60 per cent of their clothing money on headwear and outer garments, whereas only about 49 per cent of the clothing money for girls under 16 is spent on the same type of garments. Sons of the same age groups spend a larger proportion of their clothing allowance on headwear and outer garments than the daughters do, averaging approximately 63 per cent for sons over 16 years, and 55 per cent for sons under 16.

With an increase in the clothing allowance boys and girls under 9 years of age spend more in proportion on footwear and undergarments and less on headwear and outer garments. Husbands, also sons over 9 years, devote a larger proportion of their allowance to outer garments with each increase in the clothing allowance, whereas daughters between 9 and 21 years of age spend a decreasing percentage on outer garments, and an increasing proportion on undergarments. The proportion allotted to footwear decreases alike for both sons and daughters over 9 years of age. Wives and daughters 21 years old and over spend a larger proportion for outer garments and headwear, and a decreasing percentage on undergarments and footwear with each increase in their clothing expenditures.

Clothing represents approximately 15 per cent of the family's total expenditure. It pays, therefore, to devote time, care, and forethought to the purchase of clothing. A clothing budget, especially if worked out on a three-year basis, is a great help in obtaining a more adequate and balanced wardrobe.

**CLUBS for Farm Boys and Girls** Boys' and girls' 4-H club work is a system of instruction given rural boys and girls by the United States Department of Agriculture and the State agricultural colleges in cooperation with local forces. This instruction is given by means of farm, home, and community demonstrations for the purpose of improving rural practices. Through club work rural boys and girls learn how to work, achieve, and make of themselves efficient, public-spirited, useful citizens.

The term 4-H signifies the four things which must be trained by the boy and girl to insure success in club undertakings—head, heart, health, and hands. The mind, or head, of the boy and girl must be trained to think, plan, and reason, and the heart to be kindly and sympathetic toward the work and toward associates, so that all may work together; the health must be improved and kept good for efficiency and enjoyment; and the hands must be trained to be skillful. The symbol of the 4-H club is the four-leaf clover containing an H on each leaflet, the clover signifying the purpose for which the first clubs were created—soil conservation.

The extent to which 4-H club work reaches farm boys and girls may be appreciated by the fact that in the United States during 1925 a total of 565,046 club members, between 10 and 21 years of age, were enrolled. These young people carried on a total of 1,079,604 club projects in agriculture and home making. They were organized for the most part into 41,000 local groups or clubs, each with an adult leader. There were about 48,000 such local leaders who supervised the activities of the boys and girls in these clubs. The work of the club members and their local leaders was directed by 2,925 county extension agents in the counties following plans outlined by the State club leaders.

FIG. 51.—Henry Latson, Michigan farm boy, and successful dairy-club member, who is now joint owner with his father of a modern dairy farm

### Many Demonstrations Given

Demonstrations in food, clothing, poultry, farm crops, livestock, and the like were conducted on the farms and in the homes by rural boys and girls. In their home surroundings the 4-H club members have demonstrated to their neighborhoods the desirability of following certain better practices in agriculture and home making. The achievements of these farm boys and girls have been substantial as the records of their accomplishments show.

FIG. 52.—Helen Brown, Washington farm girl and poultry-club member, who became a poultry authority in her neighborhood and financed part of her college education through her poultry flock

The two examples following are typical of the work and influence of club members. Henry Latson of Michigan made his club activities fit into the work on his father's farm. The calf of which he became owner was the first purebred animal on the farm. Through successive years, his demonstrations proved the desirability of dairying in his neighborhood, with the result that the dairy farm now owned by father and son is but one of the many fine dairy farms in that section.

Helen Brown of Washington became the poultry authority in her neighborhood through her club demonstration. She perfected the business side of her work so that her profits assisted materially in financing her college course.

One of the more recent developments in extension work with farm boys and girls has been the "young farmers' clubs" in which the older rural young people have been interested. Thus 4-H club work has provided the incentive for farm young folks in a community to maintain their contact with extension work until they are sufficiently mature to affiliate with its adult organization.

### Eleven Million Farm Boys and Girls

According to the census of 1920, there are more than 11,000,000 rural boys and girls in the United States. One of the important functions of the agricultural colleges and the United States Department of Agriculture in their cooperative extension work is to teach these rural boys and girls some of the inspiring things in agriculture, give them some vision of its possibilities as a life job, to assist them in the actual carrying on of a farm or home-making project in which they have particular interest, and to help them learn how to assume their part in solving their community problems.

R. A. TURNER.

## COLLOIDS and Soil Behavior Possibilities

One may spend his lifetime cultivating a soil and then die ignorant of how it will behave under many conditions. The soil expert aims to find out more with less work. He is trying to find out exactly how a soil will behave under different treatments by examining it in the field and in the laboratory. His purpose is a degree nearer achievement as the result of recent studies of the clay or colloidal material in soils. New facts regarding the nature of this material and its relation to properties of the whole soil have been discovered. By taking these facts into consideration the soil expert will form a better judgment than he has hitherto regarding the behavior of soils under different conditions.

Studies show that the very fine or clay material in soils is made up of particles which are much smaller than had been supposed. One ounce of a heavy loam soil may contain 10 billion millions of such particles. Luckily these particles stick together. If they did not, clay soils would have washed away years ago. This clay material is now coming to be called "colloidal material," since it is found to be related to a group of other sticky materials, including glue, which are known by chemists as colloids.

### Colloids Governing Factor

Many properties of the whole soil, such as stickiness, retention of water, and capacity for holding plant food, are governed almost exclusively by the colloidal material. Obviously then, in judging how a soil will behave it is important to know how much colloidal material it contains. But a determination of the mere quantity of colloid is not sufficient; the kind of colloid must also be determined, since different soils may contain colloids which are very different in character. Because of differences in the kind of colloidal material present some soils that contain a high percentage of colloid hold less water and plant food and are more friable than other soils containing less colloidal material.

It now seems that if both the quantity and kind of colloidal material in a soil are known it should be possible to predict fairly well how the soil will behave. Although the larger soil grains influence certain soil properties, it is not much exaggeration to say that a soil is known by the colloid it contains.

P. L. Gile.

## COMBINE Harvesters in the Great Plains

Use of the combine-harvester in the Great Plains has increased very rapidly during the past five years. Only a few machines were being tried in 1918 or 1919, but with improvements in the mechanical features of the small combine the machines rapidly increased in popularity. A great many machines were sold in 1925 and 1926 and in some localities in the area practically all of the 1926 wheat crop was harvested with the combine.

The development of the small, prairie type harvester-thresher has given the farmer of the Great Plains a practical machine which enables him to complete his harvest and threshing rapidly, with a comparatively small amount of labor. A machine having a 15 or 16 foot width of cut, pulled by a 15 horsepower tractor and operated by 2 or 3 men exclusive of grain haulers is capable of harvesting 400 to 600 acres during a reasonably dry season. A machine of this type should cut and thresh 500 acres in 15 days of actual cutting.

A smaller machine having a width of cut of 8 or 10 feet, designed for operation by a single man, is capable of handling 250 to 300 acres in 15 days. With the introduction of the smaller machines the use of combines is increasing on farms with smaller acreages of grain and on farms where the operators hesitate to make the investment necessary for the purchase of a larger combine.

The labor of harvesting and threshing is reduced from approximately 3 man-hours per acre[3] where a binder is used or 2 hours[3] where a header is used to about 0.75 hour per acre with the combine. The reduction in size of crew enables the operator to do a larger proportion of his harvest work with the labor available on the farm. The operator is relieved of much of the expense and dependence on transient labor during harvest.

A properly adjusted combine will compare favorably with a header in saving grain in the field and in short grain will save a larger proportion of grain than will a binder. With short straw, fewer heads are left on the field and the shattering loss is somewhat reduced. The loss of grain in the threshing operation itself should be no greater than in a stationary thresher, and may be expected to vary between 1 and 2 per cent of the grain threshed.

---

[3] GRIMES, W. E., HODGES, J. A., NICHOLS, R. D., and TAPP, JESSE W. A STUDY OF FARM ORGANIZATION IN CENTRAL KANSAS. Dept. Bul. 1296, illus., 74 pp. 1925.

Where the grain stands in the field for some time after ripening there is some loss from shattering and a greater risk of loss from storm. Most farmers who use combines delay harvest from 6 to 8 days after it would be possible to begin with a binder and from 2 to 4 days after the grain is ripe enough to cut with a header. This delay in starting harvest increases to a certain extent the risk from storm loss while standing. On the other hand, risk of grain losses in the stack or shock is eliminated.

### New Problems Created

Some changes in farm organization and some new problems in grain marketing are likely to result from an extensive use of the combine-harvester in the wheat-producing sections. The reduction in harvesting costs, together with the advantage of operating sufficient acreage to make the best use of the harvesting equipment, should tend to make the wheat acreage per farm approximately the maximum acreage which can be harvested with a single combine. In most sections this would mean a substantial increase in the wheat acreage per farm. The lower production costs should cause wheat to replace more of the competing crops on land which is suitable for the use of the combine.

Some farmers who have a small acreage of wheat find it advisable to own a machine cooperatively with their neighbors. More often, the combine owner with a small wheat acreage completes the harvest season by doing custom cutting for others. In either of these ways, by sharing the investment or by increasing returns from the combine through custom work, farmers with a wheat acreage less than the total capacity of the combine find the machine a profitable investment.

### Shortens Harvest Season

The general use of combines shortens the harvest season in a given locality. Where practically all the grain is threshed three or four weeks after the grain ripens, the problem of marketing or storing is an important one. Few wheat growers have adequate facilities for farm storage and the greater share of the grain is placed on the market as it is threshed. Dry grain in good condition for storage can be readily moved from the local to terminal elevators, but wheat with a high moisture content offers more difficulty. Many farmers are inclined to begin "combining" before the wheat is entirely ripe, particularly if the field ripens unevenly, and the grain is placed on the market with a high moisture content. In rainy or wet seasons, the desire on the part of the farmer to cut his wheat as rapidly as possible results in placing on the market wheat that is too wet for storage. Few local elevators are equipped to dry or handle moist wheat satisfactorily and most of them refuse to accept wheat with a high moisture content.

In some localities the prevalence of weeds in the fields offers some difficulties to combining. Proper adjustment of sieves will remove the common weed seeds, but some weeds, particularly the Russian thistle, give trouble because of the difficulty of separating the moist weed tips from the grain.

The combine-harvester has been used more for harvesting wheat than for other crops but other grains are handled satisfactorily.

The combine is used to a lesser extent for harvesting oats, barley, rye, and grain sorghums. Such crops may present some problems, one of which is the difficulty of saving straw where feed is needed on the farm. A further use is made of the combine in harvesting such seed crops as beans, seed clover, and alfalfa, as they shatter badly from the continued handling necessary to cut and thresh in separate operations.

L. A. Reynoldson.

## COOPERATIVE Livestock Commission Agencies Thriving

Farmers in this country have demonstrated that they can market their livestock successfully through their own business organizations. They have set up in the terminal markets cooperative livestock commission agencies, owned and controlled by stockmen. These agencies handled in 1926 over 150,000 carloads of livestock, or nearly 11,000,000 animals, including sales of stock for producers and purchases of stockers and feeders for farmer customers. These two services, selling livestock for producers and purchasing stock for feeders, are the two main functions of the terminal cooperative agencies in this country. The first of these terminal selling agencies was started in 1917. There are 25 of them now in operation, most of which have been organized in the last five years. Their growth since organization has been so rapid that many of them stand first in volume of business in the markets where they are operating.

Approximately 65 per cent of the livestock handled by cooperatives at terminal markets is the business of local cooperative shipping associations. The other 35 per cent is contributed by stockmen who ship individually or in multiple-owner lots, or who truck in their stock to the market. At some terminal markets the cooperative selling agencies handle practically all of the business of the local associations shipping to those markets.

The members of these organizations are producers of livestock. A board of directors is elected by the membership at large. The directors in turn choose a manager who is responsible for the details of operation and for the carrying out of the business policies of the association. Nearly all of the associations are of the nonstock type. They are adequately bonded for the protection of the agencies and shippers doing business with them.

In their actual operations on the market, these associations sell cattle, hogs, and sheep and buy stockers and feeders. Livestock which is consigned to them is received, yarded, fed and watered, sorted and graded if necessary, and sold to the best advantage by salesmen of the association. It is bought by packer buyers, traders, order buyers, butcher buyers, and other operators on the market, and also by livestock producers and feeders. The agencies do not assume ownership of the livestock that is consigned to them. The shipper remains owner until the transaction with the actual purchaser is complete.

### Methods of Payment

Collections are made by the commission agency; marketing expense, such as commissions, freight, yardage, feed, and insurance, are deducted and the net returns deposited in the city bank, which is the correspondent of the shipper's country bank, the same day the livestock is sold. The deposit is made to the credit of the country bank, which when notified places the returns to the credit of the shipper. Bank cashier's checks are issued occasionally upon request by the shipper. Returns for stock shipped by truck are usually paid by company checks.

Livestock is purchased for the customer's account by the cooperative association and shipped to his ranch or feed lot as he may direct. The purchaser may or may not be present on the market. If he sends in an order for stockers or feeders, he indicates the species and grade of animals desired and usually states the maximum price he is willing to pay. A stocker and feeder buyer of the association takes the order on the market and fills it to the best of his ability for the interest of the customer. If the purchaser is present when the transaction is made, he may give the agency a check for the amount due directly, but the usual practice is for the association to draw a draft on the purchaser's bank, adding the buying commission and other regular charges to the cost of the livestock.

In addition to the two main functions of selling and buying livestock, some of the terminal cooperative agencies have set up credit corporations and, through the medium of the Federal intermediate credit bank, are financing livestock farmers in their feeding operations. This has resulted in a saving to stockmen in some sections of about 1 to 2 per cent in interest charged.

Some of the terminal cooperative organizations have established livestock pools. These have handled principally lambs and cattle. The lambs are purchased on the ranches, principally in Wyoming and Montana, and are shipped direct to feeders in the Middle West. The cost of all the lambs and cattle and the expenses of buying them are pooled and each feeder pays the average cost for the stock which he receives. The cattle are purchased principally in Texas and are shipped direct to Corn Belt feeders.

### Large Savings Effected

Since the terminal cooperative firms began doing business on the markets, they have saved to the farmers, in reduced commissions and in amounts paid back to shippers in the form of cash refunds, approximately $4,500,000. These savings have been possible because of the large volume of business handled by the terminal associations. In 1926 they handled on an average over 15 per cent of the total livestock on the markets where they operated. Savings might have been still further increased but for the necessity, well recognized by cooperatives, of maintaining an organization sufficiently large to render efficient service on "peak days" as well as during the slack periods.

Briefly, some cooperative associations on the terminal markets have accomplished the following: (1) They have demonstrated that they can render efficient service at reduced cost; (2) they have raised the general standard of service rendered at the markets through the competition they furnished; (3) they have obtained better service for stockmen by improving the old and creating new services; (4) they have developed cooperative leaders in their own organizations.

C. G. Randell.

## COOPERATIVE Marketing Mainly Dependent on Business Management

The form of organization in a cooperative enterprise is perhaps only of minor importance as compared with management. Wisely planned and intelligently directed management is by far the most important element in business success and lack of it the most certain cause of failure. The marketing of agricultural products is a business undertaking and the cooperative association that undertakes the job must adhere to the fundamental principles of business. The practices may differ widely between various cooperative businesses, as they differ in commercial business organization, but the fundamental principles usually remain the same.

The management problems of a cooperative may often appear different, and some are different, from those confronting commercial businesses, but in wrestling with these problems the cooperative needs to observe the same fundamental business principles that permeate all successful business institutions to-day.

What do we mean by this important phase of business called management? In a broad and practical sense business management is the control and direction which is exercised over all the activities of the organization. It is not limited to any one phase, but includes office operations, accounting and pooling, merchandising, market analysis, membership relations, and many other activities.

### Responsibilities of the Board

The control and direction of a cooperative can not be left to any one individual. In any business there is a group of individuals to whom has been delegated the responsibility of formulating the policies and directing their execution—the board of directors. Every member of the board has a definite share in the responsibility of formulating sound policies and seeing to it that they are properly carried out.

In speaking of management, particular emphasis should be given to the duties and responsibilities of the board of directors, as the directors play a most important part in the efficient operation of cooperative associations. It is well to remember, in business management, that, unless a man has sound business sense and is peculiarly adapted to acting as manager of a business, or to functioning as a director or officer, he may prove detrimental rather than helpful, although personally of the highest type. A man might be the best farmer in the community and the most loyal member in the association, and yet not be fitted to help direct its business operations. Many cooperative enterprises have been wrecked because the board of directors lacked an understanding of management problems. Internal petty politics, too, have often hindered the effectiveness of the management.

One of the serious weaknesses of many cooperatives is found in the tendency of members of boards of directors to shirk their responsibility. Too frequently the individual member elected to the board looks upon his selection as a director in the light of an honor conferred upon him in recognition of his standing in the community and as carrying with it no responsibility. Such an attitude is unfortunate, and until every director comes to feel that he is accepting the trusteeship for the successful conduct of the business, cooperative marketing will fail of its full measure of success.

### Directors are Trustees

Membership on the board of directors is a trusteeship which carries with it certain responsibilities and duties toward the successful conduct of the organization's business. The members upon whom this trusteeship has been placed must inform themselves regarding the principles of business and about the operations of the business for which they are responsible. The importance of each director being thoroughly informed about the operations of his organization, and concerning the broader business principles, upon an understanding of which hangs much of the organization's future progress, can not be overemphasized. There is many a cooperative organization to-day whose progress is being slowed up because of the lack of a forward-looking program and wise direction.

The board of directors and the executive staff (usually consisting of the manager and responsible department heads) of a cooperative enterprise are charged with the responsibility of formulating policies and directing their execution. While each section has its own definite and distinct responsibilities, it is essential that these two small groups work together closely in dealing with the many problems that arise in conducting a business.

### Duties of Directors

Broadly speaking, the board of directors is charged with (1) the formulation of policies, (2) selection of a competent manager to carry out these policies, (3) ascertainment that these policies are actually put into execution, and (4) knowledge of the results they bring about.

The board's job in formulating policies is a most important one. Before board members can formulate sound policies they need to seek facts. The manager should be in a position to assist the board in obtaining available facts and in the interpretation of their significance. In becoming acquainted with the business it is important that the directors form conclusions only on the basis of facts and that every vestige of prejudice and preconceived opinion be cast aside. They can not be guided by opinions of members and others. Hearsay evidence is often fatal to successful operation.

In selecting a competent manager the board of directors is called upon to perform one of its most important duties. With the average board of directors of a farmers' cooperative this often presents one of the most difficult tasks. The average farmer has had but little contact and experience with big business operations and has only a limited knowledge of the essential qualifications that are indispensable to successful executive work.

In ascertaining whether or not policies have been satisfactorily carried out and in studying the results obtained, one frequently finds the board apparently at a loss for a yardstick with which to measure the progress made. Unfortunately, instead of attempting to weigh the results of management by careful study and analysis of available facts regarding the operations, too often the board members spend their time meddling with petty and insignificant details of day-to-day affairs.

### Selecting a Manager

The manager and the executive staff are responsible for carrying out the policies laid down by the board, as well as attending to the details of operation. The manager should be selected because of his ability to carry out policies and handle administrative matters. The handling of details must not be interfered with by the board. The manager and his executive staff must be free to work out the details and seek results in their own way.

In a measure, management will succeed only to the extent that a real effort is made by the board and executive staff to answer the questions of price, demand, and merchandising problems, on a basis of actual facts rather than on the basis of mere opinion. In this respect a certain amount of research, merely as an aid to management, particularly with the large-scale cooperatives, is highly important and helpful to the board in shaping its program. The board needs statistical information on price history as a basis for determining the price and sales policy. It needs information as to what factors determine demand and a knowledge as to the grades suited to the particular markets they are serving. A statistical analysis of available data will often throw some very helpful light on old and new markets, their peculiarities and needs. In the case of some cooperatives, technical research will help develop new products and by-products which can utilize excessive supplies. Commercial research, however, should be looked upon only as a tool and a helpful guide in the development of the marketing program and more efficient operation. It is not a substitute for intelligent work and good judgment.

### Selling Program

In any program of selling farm products a cooperative marketing association is first confronted with the important problem of developing a sound and effective price and sales policy. It is only through the development and successful carrying out of such a policy that the members are able to obtain the full benefits from their organization.

The boards of directors are responsible for the formulation of a sound price and sales policy for the association. In discharging this important responsibility they need to know the factors which determine the price for the commodity which they are handling, the reaction of price to changes in supply, what the effective demand is and how it is reflected in the price, the probable seasonal and other changes in price under varying economic conditions. In all these matters the manager and other members of the executive staff can be of considerable help and their advice should be sought. They should make available to the board full information about supply, probable market demand, and price behavior. All of this is vital to the board in shaping its selling program.

In popular discussion there are two theories as to what constitutes the best price and sales policy for a large-scale farmers' cooperative marketing association, which undertakes to perform the marketing functions of carrying the product and feeding it into the consuming channels. One of these assumes that it is the aim of a cooperative association to effect such control of a product as to enable it to dictate an arbitrary price, without reference to supply and demand conditions. The other theory assumes that an organization handling farm products can not maintain prices which are out of line with economic conditions, and that in the long run its members will receive the largest benefit through the development of a price and sales policy which attempts to adjust supply to demand.

### Limitations of Price Fixing

It is, of course, possible to fix a price, but it is not possible to make the customers pay that price. There is practically no agricultural commodity which is so essential to human existence that substitution can not be made for it, at least in part, and this possibility of substitution destroys any effective arbitrary control of price over a period of time. Usually a brief analysis of the price history of various commodities and its relation to some of the more evident demand and supply factors will illustrate the difficulty that a cooperative association would encounter in attempting to fix prices arbitrarily.

The aim of the selling program of a cooperative should be a service to customers of the product handled. Broadly speaking, it must sell according to market demand. Such a program will usually bring the most satisfactory results in the long run.

A thorough study of price and demand history of a commodity and a knowledge of present and potential supply are essential before the correct selling program can be determined for that commodity. What might constitute a satisfactory selling program for one commodity might not bring the desired results with other commodities. Because of ever-changing economic conditions, it is unlikely that the sale of the crop in equal periodical installments would constitute the type of a sales program which an organization would want to adhere to strictly at all times. Demand is not equally active at all times, and to force the sale of a commodity in order to satisfy the "equal installment" program would probably result in making unsatisfactory price concessions.

### Importance of Seasonal Trends

A large-scale cooperative marketing association handling wheat or cotton, for instance, certainly should give some attention to the seasonal trends in the price of the commodity it is handling. Some very helpful information on the seasonal price changes can usually be obtained through a careful examination of the seasonal movements of individual years over a long period. It is not possible for an association to take advantage of seasonal changes unless some reliable means for forecasting these seasonal changes can be found.

Further research, both by large cooperatives and State and Federal agencies, is needed on the whole question of price behavior of farm commodities.

But in addition to the seasonal price movements, there are usually short-time up-and-down swings in the market. These continue for varying lengths of time. The strongest demand for a commodity usually comes during periods of rising prices. On the other hand, manufacturers and dealers generally do not want to buy when the price is falling because of the belief that it will go lower. It would seem that a program of selling could be evolved by some of the large cooperatives which would take advantage of short-time swings in the price movement by selling the commodity in response to demand which is usually strong during periods of rising prices, and by not forcing sales during the periods of price recession. Such a selling program would probably tend to result in a somewhat better-than-average price.

An effective selling program must, of course, go further than merely taking advantage of upswings in the market. It also involves the adoption of satisfactory grades, perhaps standardized grades, and these must always be lived up to if the cooperative is to maintain the confidence of its customers. The association must know the needs of its customers in order that it may provide for satisfactory terms and methods of sale. As already indicated, the aim of selling must be effective service to customers.

CHRIS L. CHRISTENSEN.
A. V. SWARTHOUT.

## COOPERATIVE Marketing to Be Forwarded by Educational Program

The basis of sound progress in cooperative marketing is an appreciation of the essential marketing services to be performed by marketing organizations and a better understanding of the possibilities and limitations of the movement. This was recognized by Congress in the act approved July 2, 1926, creating a division of cooperative marketing. A paragraph of this act authorizes the division "to promote the knowledge of cooperative principles and practices and to cooperate, in promoting such knowledge, with educational and marketing agencies, cooperative associations, and others."

As an immediate program, the division proposes to cooperate in organizing and conducting short courses for members and employees of cooperatives, county agents, agricultural students, and others interested in cooperation.

In most instances, these schools will be conducted by the agricultural colleges. It is planned, however, to enlist the active support of the cooperative associations in the States or regions in which the schools are held. Each important association should be represented on the program, in order that the school may be stimulated and guided by a consideration of the practical problems which these organizations have to meet, if for no other reason. The associations also should be interested in increasing their members' knowledge of cooperation and in improving the efficiency of their employees through education.

The subject matter presented at these schools will vary with local conditions. It is not intended to present an extensive theoretical discussion of cooperative marketing, but rather to bring to the foreground the fundamentals of marketing; and the policies, problems, and accomplishments of the cooperative associations marketing the products of the State. To do this intelligently, however, it will be necessary to present as concisely as possible the principles and practices of cooperative marketing and the trends and present status of the movement. It is also necessary to give consideration to factors that determine the price of farm products in order to form a reliable estimate of the possibilities of cooperation and evaluate the efficiency with which the cooperative organizations of the region are operating.

### May Lead to United Action

In general, schools of this kind will be valuable in so far as they inculcate the right attitude toward cooperative marketing on the part of the members and contribute toward the business efficiency of the organizations. They should also serve to bring the cooperative associations within the region closer together, and perhaps lead to some form of united action in meeting their common problems.

The limits of this article do not permit discussion of other methods which may be employed for the dissemination of correct information regarding cooperative marketing. Short courses in the local communities given under the joint auspices of the cooperative organizations and the agricultural colleges, work with the boy's and girl's clubs, the agricultural high schools and civic organizations, all offer opportunities for making cooperation a part of the economic philosophy of the rural and urban people. The development of these schools carries with it the responsibility of presenting sound and constructive information which will guide the producers in carrying out their cooperative marketing programs. It is important, therefore, to obtain the active cooperation of the leaders in cooperative marketing and of State and Federal workers engaged in economic research.

A. W. McKay.

## COOPERATIVE Marketing Recognized in Numerous Laws

The right of farmers to market their products collectively through their own organizations has gained rapid recognition during the last few years. This recognition has been reflected in many laws designed to enable farmers to accomplish this purpose. All but two of the States now have statutes expressly providing for the incorporation of cooperative associations. Thirty-eight of the States have enacted substantially the same form of law. A majority of the States have passed cooperative marketing laws within the last 10 years. Most of these statutes were passed within a shorter period of time. There is no Federal statute providing for the incorporation of cooperative associations, but there are Federal statutory provisions defining the status of cooperative associations under the Federal antitrust laws.

Prior to the enactment of State statutes expressly authorizing the formation of cooperative associations, such associations were formed from time to time in various States under the ordinary business corporation laws. The formation of associations under such statutes was not satisfactory because the business corporation laws were not drawn with the needs of cooperatives in mind. They reflected the commercial rather than the cooperative viewpoint. Many of these statutes did not permit of the organization of nonstock organizations. Generally, they provided that the holder of stock should be entitled to as many votes as he held shares of stock, thus providing for the dominance of capital and not permitting the equality among members which is essential to cooperation. These statutes contemplated the payment of dividends upon a stock rather than upon a patronage basis. As a result of these conditions and others, those interested in cooperation early in the growth of the movement found it essential to have statutes enacted expressly providing for the incorporation of cooperative associations.

### Laws Authorize Contracts

Nearly all of the statutes which have been passed providing for the organization of cooperative associations authorize associations formed under them to enter into contracts for limited periods with their members for the delivery of their products for marketing. Associations are also authorized to include in their contracts and by-laws provisions with respect to liquidated damages; that is, the associations are authorized to stipulate in their contracts and by-laws reasonable sums which members are required to pay if they fail to deliver their products for marketing in accordance with their agreements.

Such statutes also usually authorize the courts to decree the specific performance of contracts of associations formed under them and to enjoin members from disposing of their products outside of associations. State courts have in many cases upheld the right of cooperative associations to recover liquidated damages and have held that they are entitled to the specific performance of their contracts and to enjoin members from violating them.

As cooperative associations began to be formed in increasing numbers, leaders in the movement were disturbed for fear the associations might be held to be organizations in restraint of trade or in violation of the antitrust laws. They urged that there was an inherent and fundamental difference between the condition and circumstances of isolated farmers largely dependent on the caprice of the seasons and those engaged in other pursuits. Only a few associations were prosecuted for alleged violation of the antitrust laws, but there was always the fear that prosecutions might be instituted at any time. On account of this fact, cooperative leaders early in the growth of the movement, and beginning about 1890, were instrumental in having various States enact laws designed to give cooperative associations standing under their antitrust laws, and now a majority of the States have statutory provisions dealing with this matter.

### Exemptions from Antitrust Laws

Practically all of the statutes that have been enacted within the last 10 years providing for incorporation of cooperative associations provide that any association formed under them " shall not be deemed to be a combination in restraint of trade." Cooperative leaders in 1914 were instrumental in bringing to the attention of Congress the need for a declaration by it that cooperative associations, because of their form or existence, were not to be regarded as in violation of the antitrust laws. The result was section 6 of the Clayton Act which provides, in part, that " Nothing contained in the antitrust laws shall be construed to forbid the existence and operation of labor, agricultural, or horticultural organizations, instituted for the purpose of mutual help, and not having capital stock or conducted for profit, or to forbid or restrain individual members of such organizations from lawfully carrying out the legitimate objects thereof; nor shall such organizations, or the members thereof, be held or construed to be illegal combinations or conspiracies in restraint of trade, under the antitrust laws."

It will be observed that section 6 of the Clayton Act does not cover the case of cooperatives organized with capital stock, but, on the other hand, is confined strictly to nonstock organizations. The courts have construed this section to mean that an organization is not to be declared in violation of the antitrust laws simply because of its existence and operation, but, on the other hand, they have held that organizations of the type referred to therein are amenable to the law if their conduct is not in accordance therewith.

Because of the fact that section 6 of the Clayton Act referred only to nonstock organizations, and because many felt that this section was not as clear as it should be, cooperative leaders continued to seek for further legislation with respect to the relation of organizations of farmers to the antitrust laws. As a result, on February 18, 1922, the Capper-Volstead Act became a law, which states expressly that "persons engaged in the production of agricultural products as farmers, planters, ranchmen, dairymen, nut or fruit growers may act together in associations, corporate or otherwise, with or without capital stock, in collectively processing, preparing for market, handling and marketing in interstate and foreign commerce, such products of persons so engaged."

### Conditions Imposed on Cooperatives

There are certain conditions in the act which cooperatives desirous of obtaining the benefits thereof must meet. Such associations must be operated for the mutual benefit of their members as producers, and they must not " deal in the products of nonmembers to an amount greater in value than such as are handled by it for members." In addition, an association to obtain the benefits of the act must restrict each member to one vote in the affairs of the association or else the association must " not pay dividends on stock or membership capital in excess of 8 per cent per annum." The act provides that, in the event the Secretary of Agriculture shall have reason to believe that any association operating thereunder monopolizes or restrains trade in interstate or foreign commerce to such an extent that the price of any agricultural product is unduly enhanced by reason thereof, he shall file a complaint against such an association and, following a hearing, if he finds that this is true he is directed to issue an order to the association requiring it to cease and desist from monopolization or restraint of trade. Up to the present time no complaints have been issued by the Secretary of Agriculture and no facts have been presented to him involving any association, indicating that it has unduly enhanced the price of any agricultural product.

The general principles and methods of cooperative marketing have been involved in cases that have been passed upon by the supreme courts of 21 States within the last 6 years, and they have been upheld in every instance. During this period there have been *no cases decided by appellate courts which have held that cooperative associations were illegal.*

### Recent Decisions Favorable

Some of the earlier decisions involving cooperative associations held either expressly or by implication against the principles of cooperation, but, as indicated, within the last 6 years the supreme courts of 21 States have uniformly rendered decisions favorable thereto. During this time, in each instance in which an appellate court has decided a case against a cooperative association, the opinion did not involve the basic principles of cooperation but rather rested upon the interpretation of the marketing contract, or upon some other fact not involving the general principles and methods of cooperation. The decision of the Supreme Court of the United States under the grain futures act upholding the right of cooperative associations of grain farmers to have their own representatives on the floors of grain exchanges, by implication approves the principles of cooperation.

## CORN Borer Has Invaded Corn States

The European corn borer has invaded the Corn Belt. It is present in the Maumee River Basin and has crossed the eastern boundary of Indiana. What are we going to do about it?

For two years past this pest has destroyed the growing corn throughout a large part of Kent and Essex Counties in southern Ontario. The spectacle presented by the complete ruin of these crops over more than 400 square miles, as viewed by the leading agricultural authorities of our large corn-growing States, has rendered the question of corn-borer control one of paramount importance.

Since 1920, when an intense and widespread infestation of this pest was discovered in southern Ontario, the department has realized that because of the facility of flight possessed by this moth nothing within the power of man could prevent the eventual invasion of the Corn Belt, and it has laid its plans accordingly.

During the intervening years the department has conducted a thoroughgoing scientific investigation of the whole problem both in this country and in Europe. This inquiry has resulted in demonstrating that the control of this pest lies primarily in the application of cultural methods of combat, such as the harvesting of the crop in a scrupulously clean manner and the subsequent disposal of the stalks, cobs, and fodder by shredding, burning, feeding, or ensiling them. To be effective this must be done previous to the emergence of the moths or by May 1 following the harvest.

A less desirable alternative is the clean plowing down of all corn débris, preferably during the autumn of its harvest. Exhaustive experimental work has shown this method to be fairly effective, but only where every vestige of the corn plants was either plowed entirely under or where the débris remaining after plowing was carefully gathered and burned. Where such methods of culture have prevailed in Europe, which is the native home of the borer, the insect does little or no injury. On the contrary, where careless methods of handling the crop obtain and the stalks are allowed to remain from year to year, the corn borer often reduces the yield from 25 to 50 per cent or more.

### No Short Cut

A thorough study of the problem has revealed no short cut, no easy method of subjugating the corn borer. It has therefore become obvious that for much of the Corn Belt the solution of this problem lies primarily in a modification of present methods of corn culture. This fact has been recognized not only by the department but also by the States of Pennsylvania, Ohio, Michigan, Indiana, and New York, which have issued mandatory regulations designed to obtain the necessary action on the part of corn growers within the infested regions. In brief these requirements are as follows:

All cornstalks, remnants of stalks, and cobs of each year's corn crop, in fields, buildings, stacks, or elsewhere, if not fed, made into silage, or shredded, shall be destroyed by burning or by plowing under completely or by a combination of burning and plowing, before May 1 of the following year.

As Congress recently has appropriated $10,000,000 for such work, the department has undertaken a comprehensive control campaign which is being waged in cooperation with State and county organizations throughout designated areas in the States previously mentioned. In the conduct of this work the farmers will be paid for such extra labor performed by them as is additional to that which is usual and normal in ordinary farm operations. The maximum rate for extra labor allowance authorized is not to exceed $2 per acre for field or sweet corn, for each acre of such corn grown on such farms as shall successfully pass inspection as to compliance with the State regulatory requirements.

### Canada Moves to Protect American Growers

The Province of Ontario, Canada, recently promulgated similar regulations, the enforcement beginning with October 1, 1926. This action is of the greatest importance to American corn growers and especially those of Michigan and Ohio. This is true because there is good reason to believe that much of the recent increase in infestation, which has become so apparent there, was due to the arrival of swarms of moths from severely infested fields in Ontario, where until recently little or nothing in the way of clean-up work has been attempted. Ruined fields of corn extending over hundreds of square miles remained untouched because the crop was a failure and the growers had become discouraged. This condition permitted millions of corn-borer moths to emerge during the summers of 1925 and 1926 and to fly across the international boundary into the cornfields of Michigan and Ohio. The newly effective Canadian regulations should therefore be hailed as a boon to the farmers in the United States because they should result in shutting off a most dangerous source of further severe infestation.

### Agricultural Engineers Help

At the suggestion of the department the agricultural engineers of Ohio State University, with the cooperation of the large manufacturers of farm machinery, have developed and placed on the market at a reasonable cost attachments for most of the corn harvesters now in general use, that will cut the corn practically at the ground line and thus aid the growers materially in adopting the changes in harvesting methods necessary to combat the pest. These ingenious men have also designed a machine which picks and husks the ears and converts the remaining stover into a finely divided residue which either may be used as silage or returned directly to the land as fertilizer, with little or no increase in costs over those incurred by present harvesting methods.

It is believed that by the aid of these mechanical contrivances and the conduct of a thoroughgoing publicity campaign the necessary changes in corn culture can be obtained without serious shock to the corn-growing industry.

An extremely important part of the present campaign for the repression of the corn borer, and one which apparently is not thoroughly appreciated by the public at large, is the inspection and quarantine service as conducted by the Federal Bureau of Entomology and the Federal Horticultural Board in cooperation with the various States. This service aims to prevent the transportation and consequent spread of the corn borer through the various avenues of commerce. During the shipping season for green corn this service operates inspection stations on all main highways leading out of the areas known to be infested by the pest. At such stations all vehicles are stopped and inspected to insure that corn containing borers shall not be carried by such means into uninfested territory.

That this inspection service is an effective and valuable means of preventing the rapid spread of the pest over long distances is strikingly shown by the fact that during the corn-shipping season of 1925 nearly 2,500,000 automobiles were thus inspected in western New York, Ohio, Pennsylvania, and Michigan. From these were taken 171,502 ears of corn which contained 1,972 corn borers. As many of the automobiles from which such corn was taken were bound for points as far west as Chicago, it is apparent that the interception of this infested corn undoubtedly served to prevent the establishment of the pest in the heart of the Corn Belt years and perhaps a decade in advance of its possible arrival there through such natural means as the flight of the moth.

### Annual Scouting Campaign

In addition to its other important functions, the inspection service conducts annually a scouting campaign to determine the geographical limits of the spread of the pest from year to year. As a result of this, it becomes possible to alter the quarantine regulations in accordance with the annual spread of the pest and to locate quarantine stations at points where such dangerously infested corn as that previously mentioned will be certain of interception.

To help in the combat with the corn borer, the work of importing the insect enemies of the pest from Europe was begun several years ago, and this has been carried on with increasing vigor yearly. In all some 10 species or kinds of these parasites have been liberated, of which five species are known to have become established. Many hundreds of thousands of these have been turned loose to work their will on the corn borer, but it may be 20 years before they become numerous enough for their effect upon the borer to become noticeable. In the meantime, and very likely also after these parasites become effective, the cultural methods of combat previously described must be relied upon to render corn growing profitable wherever the corn borer thrives.

### The Real Combat Has Only Begun

The fight to prevent this truly formidable pest from robbing the fertile Mississippi Basin of its greatest crop has only just begun. If success is to crown our efforts, this fight must continue in an earnest, thorough-going, and persistent manner for years to come.

Fear has been expressed in some quarters that the advent of the corn borer means the doom of profitable corn growing in America, but this need not be true if the growers will respond to the department's warnings before it is too late.

W. R. Walton.

**CORN Breeding in New Experiments** The results of varietal comparisons and of extensive breeding experiments have shown that the older methods of corn breeding were unable to increase the productiveness of better yielding varieties significantly. They also have shown that simple mass selection of seed ears from productive plants of an adapted type was practically as efficient as the elaborate ear-to-row method which had been advocated so widely. A better knowledge of the laws of heredity made clear why progress under the older methods was limited and, of even more importance, pointed to selection within self-fertilized or selfed lines as a sound basis for corn improvement. It is with methods of corn breeding based upon the principle of selection within selfed lines that this article is concerned.

The first step in breeding corn by selection within selfed lines is to self-pollinate a number of plants of the variety or varieties to be used. (Fig. 53.) Seed from the better ears produced is planted in ear rows and plants in these rows are self-pollinated. This procedure is continued during several generations, only the better ears from the better plants in the better rows being selected each year.

The effects of self-fertilizing corn are immediate and obvious. Defective characters which have been suppressed in the hybrid condition of ordinary corn come into expression. There is a cumulative decrease in vigor and productiveness, which is most rapid following the first self-fertilization and which becomes gradually slower with each successive generation. There are marked differences in the vigor and appearance of different lines. As self-fertilization continues the plants within individual lines become more and more uniform, thus accentuating the differences between lines. After six or seven generations of self-fertilization, approximate constancy is reached, after which there is little further reduction in vigor and the lines breed more or less true.

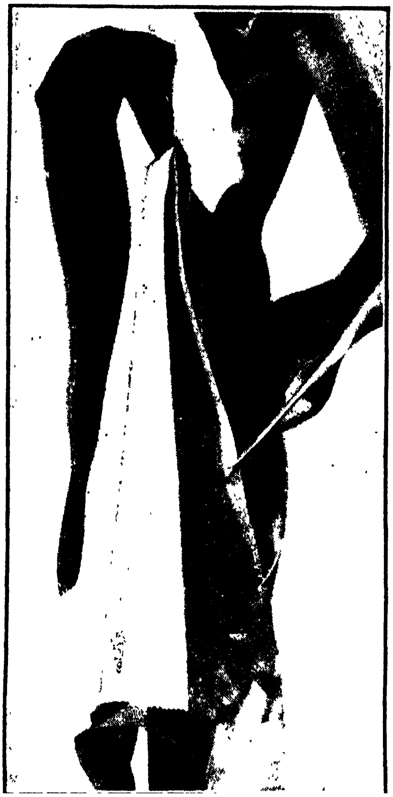

FIG. 53.—A corn plant bagged as in hand pollinating. Shoots and tassels are protected from contamination with stray pollen by bagging. At the proper time pollen from the selected tassel is applied to the silks of the selected ear shoot, which again is bagged. In self-pollinating, the pollen and silks are those of the same plant

### Lines Used in Hybrid Combination

It is these lines, themselves inferior to the original variety, that the breeder uses in hybrid combination of one kind or another in obtaining larger yields of corn. As the lines become uniform, crosses are made between unrelated lines in various ways to determine those that are best in hybrid combination. The number of lines is reduced, by elimination of the poorer ones, to the two, four, or more that are to be used in producing seed for general planting. Three methods of utilizing selfed lines have been suggested, (1) single crosses, (2) double crosses, and (3) synthetic varieties.

Single-crossed seed is produced by growing two selfed lines, A and B, in alternate rows of an isolated plat and pulling the tassels from the plants of one line, as A, before they have shed pollen. The seed produced on the detasseled A plants then represents the cross A×B, which may be planted in the general fields.

Double-crossed seed is produced by crossing two single crosses. This requires maintaining three isolated plats, two smaller plats for the production of the two single crosses and a larger plat for producing the double-crossed seed to be used in general field planting. Double crossing is a device for overcoming the poor quality and high cost of single-crossed seed consequent to its production upon the relatively weak plants of the selfed lines.

Seed selected from fields planted with either single-crossed or double-crossed seed is much less productive than the crosses themselves. Consequently, crossed seed must be produced anew for each year's planting. The use of synthetic varieties does away with the need for growing crossed seed each year. In producing a synthetic variety many selfed lines which yield well in all combinations are intercrossed and then grown as an ordinary variety. Increased yields of corn have been obtained experimentally from single crosses, double crosses, and synthetic varieties. As yet, however, there is no evidence as to which of these methods will prove most profitable. This will depend not only upon the yields that can be obtained but also upon the practicability of seed production and distribution under the different methods.

### Caution Necessary

Several years must elapse after the beginning of a program of corn improvement by selection within selfed lines before the success of the program can be demonstrated. As the methods are new, therefore, the evidence of their efficiency is not as complete as is desirable. At the same time, increased yields have been reported in every experiment in which these methods have been tried. Crosses which have been high yielding in one season have tended to be high yielding in other seasons, and crosses involving similar parentage have tended to behave similarly. The results of these experiments, therefore, have been consistent. On the basis of these experiments it seems probable that crosses can be obtained for many sections which will yield 20 to 30 per cent more than the best available varieties.

It should not be understood that all crosses are high yielding. Many yield less than the parent variety. The best ones can be determined only by careful experiments extending over several years. For this reason, and because of the time and cost involved in preliminary self-pollinating, the method is one for the experiment station rather than for the grower. Corn growers having the ability and willingness to do the right thing at the right time may find opportunity for profit in producing crossed seed after the best combinations have been determined experimentally. For the present, however, crosses of known productiveness are available for very few sections.

Much remains before the details of producing and distributing crossed seed corn commercially can be determined. Furthermore, few crosses have been tested sufficiently to warrant their recommendation. Finally, adaptation is as important in crossed seed as it is in ordinary varieties, so that the fact that a cross is high yielding in one locality is no evidence of its value in a different environment. Caution therefore should be exercised in buying seed corn just because it is a single or double cross.

At the present time the production of crossed seed corn from selected selfed lines has not progressed far enough for practical utilization in more than a very few localities. It promises much, however, as a means of increasing corn yields.

Frederick D. Richey.

## CORN Consumption in Europe

The average corn crop of Europe outside of Russia in the five years 1921–1925, inclusive, was 505,000,000 bushels, with net imports in the same years of 204,000,000 bushels. Corn production is confined to the southern part of the continent, with Rumania, Yugoslavia, Hungary, and Bulgaria as the only countries having an exportable surplus. Italy ranks next to Rumania and Yugoslavia in corn production, but has no surplus for export.

Very little corn is used for human food outside of the corn-producing areas, but in the northern countries of Europe it is used extensively for livestock feeding and for industrial purposes. The British Isles, including Ireland, imported an average of 76,000,000 bushels annually in the years 1921–1925, inclusive. It is roughly estimated that of these imports one-third is used for poultry feeding, from one-third to one-half for feeding other kinds of livestock, and the remainder chiefly for distilling and starch manufacture. In relation to population and area, Denmark and the Netherlands are the largest consumers of corn in northern Europe. In Denmark corn is used as feed for cattle, hogs, and poultry. In the Netherlands it is not only used for feeding but also for distilling.

For feeding poultry there is a universal preference in northern Europe for Argentine corn because of the small, round, hard kernel. Many poultry feeders are under the impression that chickens can not swallow the larger flat kernel of the American corn. In Germany very little corn is used for feeding except in the extreme southern part of the country which is supplied largely from the Danubian countries. In the industrial areas of Germany some corn is used for distilling and starch making, and there has recently been some development of corn-sugar and corn-oil manufacture.

Table 2 indicates roughly the relative importance of the more important European countries as consumers of corn:

TABLE 2.—*Indicated consumption of corn in principal European countries—average 1921–1925*

| Country | Production | Net exports (−) or net imports (+) | Indicated consumption |
|---|---|---|---|
| | *Million bushels* | *Million bushels* | *Million bushels* |
| Rumania | 143 | −24 | 119 |
| Italy | 95 | +13 | 108 |
| Yugoslavia | 109 | −13 | 96 |
| United Kingdom [1] | | +76 | 76 |
| Hungary | 58 | −2 | 56 |
| Spain | 26 | +14 | 40 |
| France | 15 | +19 | 34 |
| Netherlands | | +33 | 33 |
| Germany | | +33 | 33 |
| Bulgaria | 23 | −4 | 19 |
| Denmark | | +17 | 17 |
| Czechoslovakia | 10 | +6 | 16 |
| Belgium | | +16 | 16 |
| Portugal | 11 | +2 | 13 |

## COTTON of American-Egyptian Variety in U. S.

Three-quarters of a century ago there was developed in Egypt a new commercial type of cotton which has become that country's chief source of wealth. Egyptian cotton is related to the American sea-island type and is noted for the length, strength, and fineness of the fiber. The different varieties range from about 1⅛ to 1½ inches in staple. The annual cotton acreage of Egypt during the five years 1921 to 1925 averaged approximately 1,768,000 acres, or about one-third of the total cultivated area. The average annual production during the same period was the equivalent of approximately 1,354,000 American bales (of 478 pounds net weight).

The good qualities of Egyptian cotton were soon appreciated by English and later by American spinners. The strength and fineness of the fiber make it peculiarly adapted for the manufacture of sewing thread, fine dress goods, and tire fabrics. During the past five years the annual imports into the United States have averaged the equivalent of approximately 201,000 American bales.

FIG. 54.—A field of Pima cotton in Salt River Valley, Ariz., ready for the pickers

More than 25 years ago the Department of Agriculture began to investigate the possibility of producing Egyptian cotton in the United States. Cotton is grown in Egypt entirely under irrigation, in a climate characterized by long, hot, rainless summers. Finding that this type of cotton is not adapted to the main Cotton Belt, the department concentrated its efforts in the irrigated districts of Arizona and southern California, where conditions similar to those of Egypt are encountered.

### Selection Gave Good Results

Rather unsatisfactory results were obtained with the varieties introduced from Egypt, but by selection from one of them there was developed in Arizona in 1908 a new variety to which the name

"Yuma" was given. This cotton averaged in staple about 1$\frac{7}{16}$ inches. Field tests and spinning tests of the fiber by manufacturers showed its suitability for commercial production, and in 1912 the department furnished seed to farmers for planting a few hundred acres in the Salt River Valley of Arizona and the Imperial Valley of California. The acreage of American-Egyptian cotton in these States increased rapidly during the next five years, and in 1917 the production amounted to about 16,000 bales.

Meanwhile, another variety, the "Pima," had been developed at the United States field station, Sacaton, Ariz., by selection of a very distinct plant discovered in a field of Yuma cotton. The new variety was characterized by finer, lighter-colored, and longer fiber, having an average staple of about 1$\frac{9}{16}$ inches. After being tested for several years, its superiority to the older variety could no longer be doubted, and it was decided to substitute Pima for Yuma. It is not easy for an entire community to replace one variety of cotton by another without mixing the seed, but, fortunately, the cotton growers of the Salt River Valley were well enough organized to carry out this undertaking successfully. Since 1918 the entire acreage of American-Egyptian cotton has consisted of the Pima variety. Statistics of production are given in Table 3. They indicate that for the 14 annual crops of lint and seed the gross return to the growers has been approximately $73,500,000.

TABLE 3.—*American-Egyptian cotton: Production and estimated value to the growers of the 14 annual crops*

| Year | Lint produced (bales of 478 pounds net weight) | Estimated gross return to the growers | | |
|---|---|---|---|---|
| | | Lint | Seed | Total * |
| 1912 | 375 | $39,000 | $5,000 | $44,000 |
| 1913 | 2,135 | 197,000 | 28,000 | 225,000 |
| 1914 | 6,187 | 483,000 | 50,000 | 533,000 |
| 1915 | 1,095 | 119,000 | 11,000 | 130,000 |
| 1916 | 3,331 | 700,000 | 86,000 | 786,000 |
| 1917 | 15,966 | 5,482,000 | 620,000 | 6,102,000 |
| 1918 | 36,187 | 9,793,000 | 1,300,000 | 11,093,000 |
| 1919 | 40,437 | 16,440,000 | 2,000,000 | 18,440,000 |
| 1920 | 92,561 | 13,275,000 | 1,200,000 | 14,475,000 |
| 1921 | 37,094 | 5,500,000 | 520,000 | 6,020,000 |
| 1922 | 32,824 | 5,152,000 | 643,000 | 5,795,000 |
| 1923 | 22,426 | 3,859,000 | 476,000 | 4,335,000 |
| 1924 | 4,319 | 1,070,000 | 109,000 | 1,179,000 |
| 1925 | 20,053 | 3,920,000 | 401,000 | 4,321,000 |
| Total | 314,990 | 66,029,000 | 7,449,000 | 73,478,000 |

The acreage and number of bales produced have fluctuated greatly from year to year. The peak was reached in 1920, when the keen demand of the tire industry for this kind of cotton and the very high prices paid during the winter of 1919–20 led to the planting of 240,000 acres in Arizona and California. The reaction from this boom, together with the general financial depression throughout the country, caused a great drop in prices and a long delay in marketing the 1920 crop. At this time tire manufacturers began to substitute shorter cottons for the high-priced extra staples and the demand for the latter by this industry is now relatively small. On the other hand, manufacturers of fine dress goods have increased their consumption of Pima cotton and there has been no great difficulty in disposing of the crops produced during the last four years. Production since 1921 has been confined to the Salt River Valley in Arizona.

### Importance of Pure Seed

The Department of Agriculture has constantly emphasized the importance of pure planting seed in the production of cotton and particularly of the long-staple cottons, since their value depends largely upon their uniformity and an even-running fiber can not be grown from mixed or mongrelized seed. Cotton varieties are popularly supposed to "run out" after a few years, but there is no evidence that this will happen if the seed for planting is taken each year from well-isolated fields and is ginned with precautions to prevent mixing with other seed.

The Salt River Valley farmers, when they began to grow American-Egyptian cotton, followed the recommendation of the Department of Agriculture and organized themselves as a pure-seed community. Cotton breeders of the department, with the cooperation of the University of Arizona, have aided them by roguing each year a limited acreage, removing the undesirable or "off-type" plants. The seed from the rogued acreage is increased under guarded conditions the following year and the seed from the increase fields is distributed for general planting the second year after the roguing was done. Thanks to the hearty cooperation of the associations of farmers and of the gins which have handled the planting seed, this procedure has been followed so effectively that there is no evidence of deterioration in the protected stock of Pima cotton since it began to be grown commercially.

It was relatively easy to keep the planting seed pure during the first 10 years of the industry, for during that period the whole Salt River Valley was a "one-variety community," Yuma and afterwards Pima having been practically the only cotton grown. Beginning with 1922, however, there has been a large acreage of upland cotton in the valley and this has made it harder to keep the Pima seed supply uncontaminated. Up to this time, however, the difficulties have been overcome successfully and an ample supply of pure Pima seed will be available for planting in 1927.

### Marketed in Free Competition

American-Egyptian cotton is marketed in free competition with the vastly larger crop of similar cotton produced in Egypt. Half or more of the Egyptian crop consists of the Sakellaridis variety, which staples about $1\frac{7}{16}$ inches, and is very fine and strong. Although some American manufacturers of fine goods prefer Pima to "Sakel" cotton when prices are equal, they are, as a rule, unwilling to pay more for the former. The postwar depression in Europe has lessened the demand there for fine goods manufactured from very long-staple cotton, with the result that Sakel now reaches the American market in large quantities at relatively low prices.

Pima cotton at Salt River Valley points usually sells for about double the price of middling upland, but on December 1, 1922, the difference in price in favor of Pima was only 28 per cent and on the same date in 1923 only 14 per cent of the price of middling. These abnormal price relations, together with the greater cost of picking and ginning Pima cotton and the widely held belief that it is much less productive than "short staple" cotton, caused many of the Salt River Valley farmers to abandon Pima and plant upland varieties. It is estimated that of the total cotton acreage of the valley, upland cotton constituted 55 per cent in 1923, 94 per cent in 1924, and 63 per cent in 1925.

The average annual yield of lint per acre in Salt River Valley during the four years 1922 to 1925 was 260 pounds for Pima cotton and 326 pounds for upland cottons, the Pima yield having averaged 80 per cent of the upland yield. The best available data on cost of production indicate that it costs about $13 more to produce 260 pounds of Pima cotton per acre than to produce 326 pounds of upland cotton per acre. The price at Phoenix, Ariz., on December 1, during the four years 1922 to 1925, averaged 26¼ cents for upland (grade middling) and 40 cents for Pima (grade 2). It is computed that with middling upland at 26¼ cents, Pima should sell for 38 cents to be equally profitable under average conditions of yield in the Salt River Valley.

The yield of Pima cotton in the Salt River Valley has averaged only slightly more than one-half bale per acre. Nevertheless, much higher yields, amounting in numerous instances to 1 bale (500 pounds) per acre, are obtained every year on some of the farms in the valley. Some of the land in this locality was never suitable for growing this kind of cotton and much more of it has been rendered relatively unproductive by too many successive crops of cotton. There is good evidence that frequent rotation with alfalfa is very beneficial to the yield of cotton. By restricting the Pima acreage to areas naturally well-adapted to this crop and by using methods of rotation and irrigation which experience has shown will keep the soil in good condition, the average yield could be much increased. The adoption of such a policy would go a long way toward making it easier to produce Pima cotton in the Salt River Valley in competition with "short staple" and to market it in competition with cotton imported from Egypt.

THOMAS H. KEARNEY.

## CORN Varieties Resistant to Rot Disease

The corn-rot diseases are an important factor contributing to a lower yield per acre and a poorer quality of grain. These diseases may cause a reduction in stand, a seedling blight, a rotting of the roots, a reduction in vigor, barrenness, nubbin production, delayed maturity, and a rotting of the ears.

Proper selection of seed and the breeding of strains of corn resistant to the rot diseases are effective methods that are being used in reducing losses from these troubles. Seed selection and breeding are not the same thing. One can not take the place of the other. And yet they are both very essential in any program of corn improvement. The two operations complement each other. Seed selection may accomplish much in reducing losses from disease and unfavorable conditions of weather and soil while superior and better varieties are being developed. When such strains and varieties have been perfected and made available for the corn grower it will require much careful seed selection to maintain the disease resistance and agronomic qualities of these improved strains.

In breeding for disease resistance the pure-line method has been used. This method involves the production of inbred strains by continued self-fertilization and selection, followed by the recombination of the better inbreds, after 5 to 10 years of selfing, into first generation crosses, double crosses, and synthetic varieties that possess high disease resistance and other necessary qualities.

### Combination of Qualities Needed

An inbred strain resistant to one disease or to one set of environmental conditions is not necessarily resistant to all other diseases or to injury from other unfavorable soil and climatic environments. Strains highly resistant to Pythium root rot may be very susceptible to Gibberella seedling blight, and strains highly resistant to Diplodia ear rot may have a low resistance to injury from light frosts in the fall. Again, strains may be highly resistant to the seedling blight diseases and be comparatively susceptible to both Gibberella and Diplodia ear rots.

In the selection of strong inbreds it is necessary to subject these strains to several different sets of conditions and to determine their reaction to diseases important in each particular locality. In many sections this would include resistance to corn smut, as well as resistance to the root, stalk, and ear rot diseases. It appears possible to find and develop inbreds that combine a high resistance to the principal rot diseases and to smut, and also have them possess considerable merit in such physiologic and genetic qualities as ability to germinate and grow under comparatively cold soil conditions, ability to make the best possible use of the nutrient materials available in the soil, resistance to lodging and stalk breaking, and high resistance to cool weather and light frosts in the early fall.

The planting of the same inbreds on soil that has been in corn for a number of years, and, at the same time, in an adjacent field that has not grown corn for several years, furnishes an opportunity to compare the abilities of the strains to resist an unfavorable soil complex and also to observe the way in which they react to a favorable soil complex. Such comparisons are more valuable when a part of the old cornland has received heavy applications of barnyard manure, phosphate, and lime if necessary. The value of the comparisons is further increased when plantings are made on at least three dates, extending from the beginning to the end of the normal corn-planting season.

### Temperature Requirements Vary

Some inbred strains have been found which give a very unsatisfactory stand when early planting is followed by cold weather. Other inbreds do well under the same unfavorable conditions. (Fig. 55.) Frequently those that do so poorly under conditions usually accompanying early planting have a satisfactory field stand and make a good growth when planted later. Results from laboratory experiments under controlled temperature conditions indicate that inbred strains vary greatly in their temperature requirements for germination and early growth. Some will germinate and grow under comparatively cold soil conditions. To obtain satisfactory

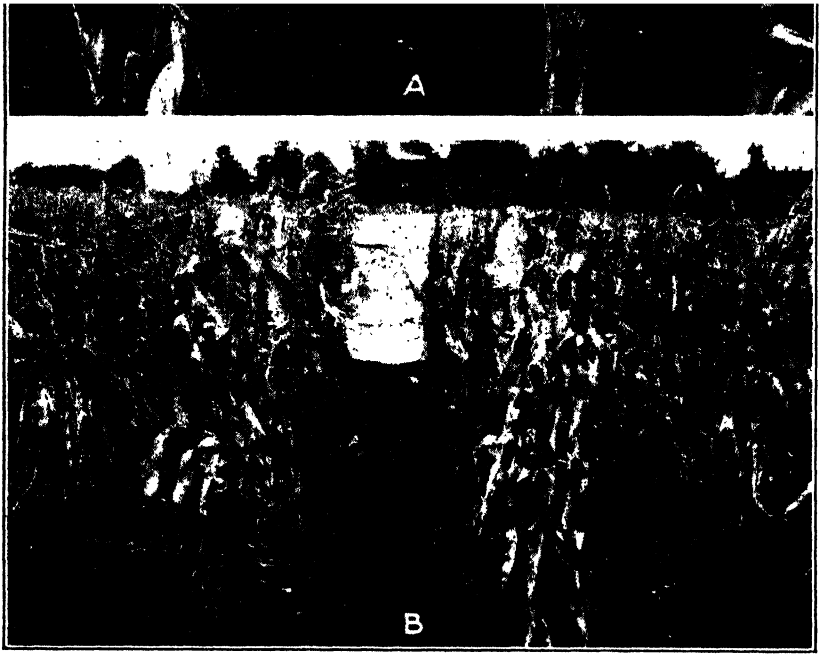

FIG. 55.—Cold-susceptible and cold-resistant strains. A, An inbred very susceptible to injury from a temperature of 24° F. on May 25, at which time the corn was approximately 5 inches high. A later planting of the same strain had a satisfactory stand. B, An inbred highly resistant to the unfavorable weather conditions described above

stands of other strains it is necessary to delay planting until the latter part of the corn-planting season.

Another great advantage of a series of dates of planting is the opportunity afforded to compare the abilities of the inbreds to withstand a short period of drought without injury and to resist lodging during a heavy windstorm. Frequently either a drought or a heavy

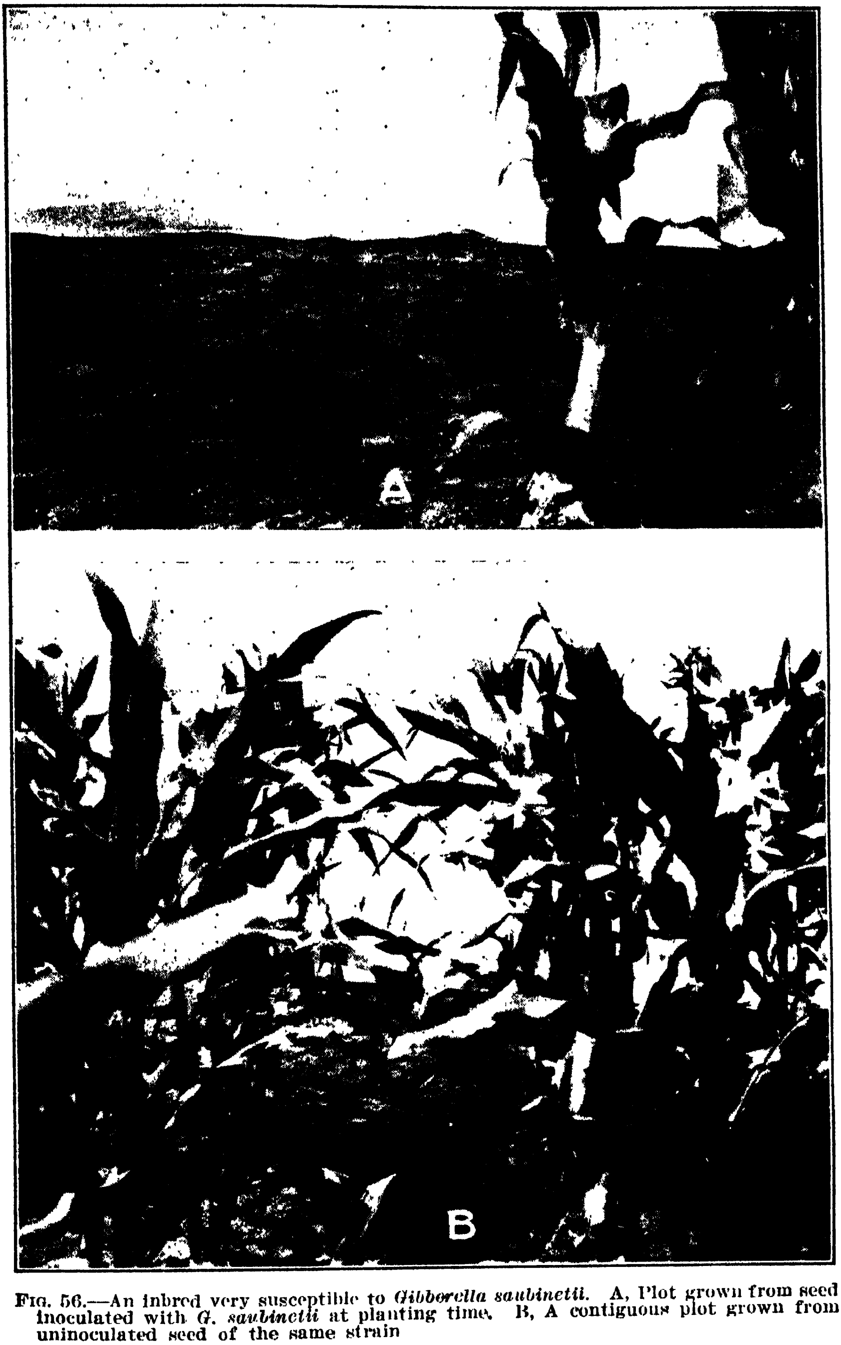

FIG. 56.—An inbred very susceptible to *Gibberella saubinetii*. A, Plot grown from seed inoculated with *G. saubinetii* at planting time. B, A contiguous plot grown from uninoculated seed of the same strain

windstorm will hit one of the plantings in the silking stage at which time strains with weak and inefficient root systems are easily detected. Field plantings under varying soil conditions at different dates of planting, over a period of years, thus give much definite information concerning the physiology and genetics of the various inbred strains of corn and their recombinations.

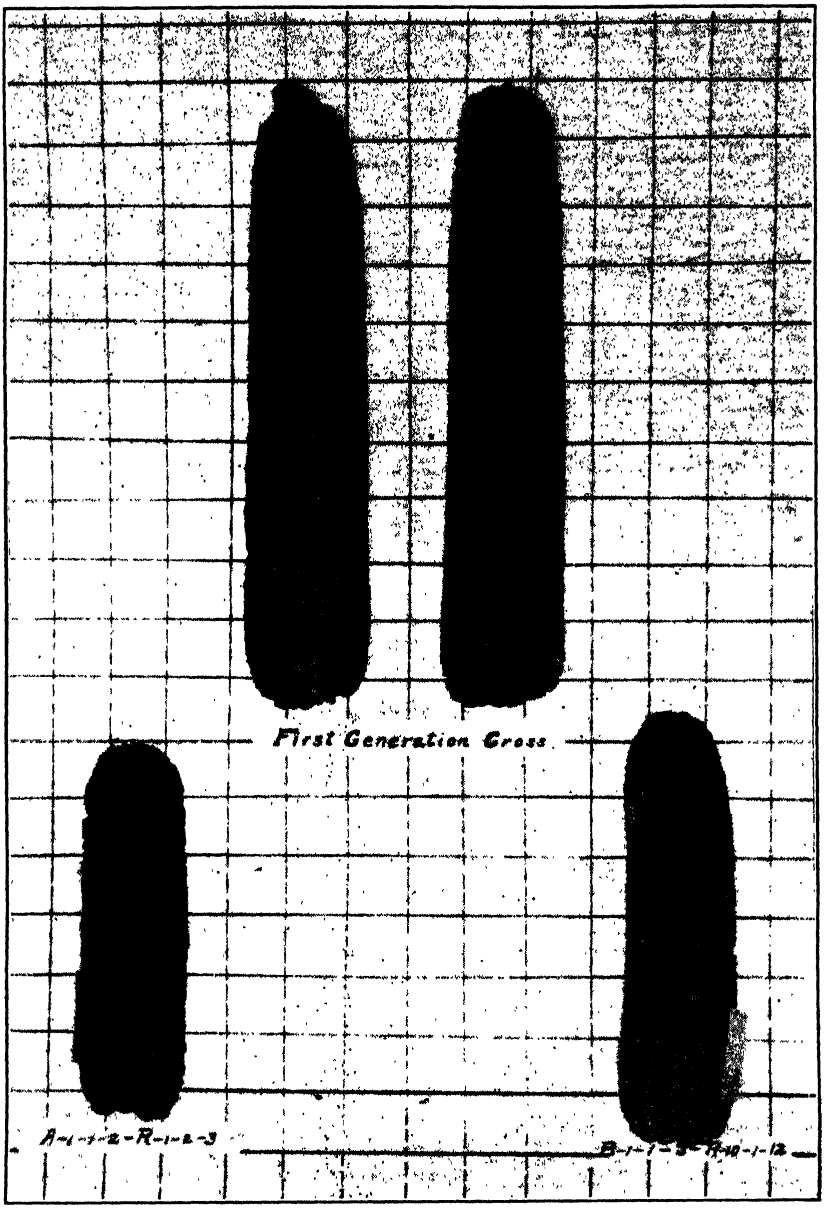

FIG. 57.—Ears of two strong inbreds and their first-generation cross. This cross and other good recombinations have consistently yielded from 15 to 35 per cent more than ordinary open-pollinated corn

In addition to the above-described methods for arriving at some decision regarding the relative merits of inbred strains and crosses the same strains and crosses of corn have been subjected to inoculation with pure cultures of organisms. As one aim of the inoculation experiments has been to determine resistance and susceptibility to specific diseases, an attempt has been made to use productive land that has not grown corn for a number of years. In many cases virgin prairie sod was available.

### Cool Soil Favors Scab

It has been found that *Gibberella saubinetii* (Mont.) Sacc., the wheat scab organism, does most damage to corn under comparatively cool soil conditions (below 68 to 70° F.). The injury also is more severe in a rather dry soil. Thus in testing for resistance to this particular disease-producing organism, plantings are made at early and intermediate dates. In addition to inoculation experiments at Bloomington, in central Illinois, inoculation studies have been conducted with the same inbreds and others at Madison, Wis., and at other points in Illinois, planting at intervals of a week to 10 days throughout the corn-planting season.

Much variation in resistance and susceptibility to Gibberella has been observed. Some strains have been found that were so susceptible that only a few straggling plants survived in the inoculated plots. (Fig. 56.) Other strains were intermediate in their reaction to this organism. A few have been highly resistant under conditions usually encountered in the field.

Further studies have been made by inoculating with a pure culture of *Diplodia zeae* (Schw.) Lev., an organism causing seedling blight and ear rot. A species of Pythium causing root rot also has been used. A few strains have proved highly resistant to both of these disease-producing organisms. Field experiments have been supplemented by laboratory and greenhouse studies.

### Opportunities in Corn Breeding

The recombinations of some of the inbreds that are high in disease resistance (fig. 57) and that also have a wide range in physiologic function have been giving increased yields of sound grain ranging from 15 to 35 per cent more than ordinary corn. In many cases these increased yields seem to have been obtained with little excess drain on the limiting nutrient elements of the soil. Furthermore, the recombinations of strong inbreds have been affected less adversely by unfavorable soil and climatic conditions than has ordinary corn. Disease resistance, when combined with other important physiologic qualities, becomes very valuable. Thus scientific corn breeding promises eventually to make its contribution to the safety of the investment of the American corn grower and also to the conservation of the natural wealth of our agricultural soils.

## COTTONSEED Crushing Industry Grows

To the Chinese probably belongs the credit for making the first use of cottonseed oil, for their records show that in the seventeenth century in China cottonseed were sometimes ground and fed to oxen and that an oil suitable for illumination was obtained. In America the first mention of cottonseed oil is found in the records of Doctor Otto of Bethlehem, Pa., dated 1768. In England in 1783 a prize was posted, by the Society for the Encouragement of Arts, Manufacture, and Commerce, for a practical method for extracting oil from cottonseed. On March 2, 1799, a United States patent was issued to C. Whiting covering a process for extracting cottonseed oil.

It was not until 1826, however, that practical extraction of the oil was attempted in a small mill located in Columbia, S. C. In 1832 a second mill was established in Florence, Ga. Early extractions were used for illumination purposes or in the manufacture of soap.

It was not until 1855 that it was suggested that cottonseed oil was an edible oil and it soon became an adulterant or substitute for olive oil. Some time after 1880 cottonseed oil was introduced into hog lard to temper the lard for use in cold climates. From then on, the history of the use of cottonseed oil from its surreptitious incorporation with lard to its position as an open competitor of both lard and butter is filled with the intrigues of competitive industries.

In 1860 there were seven establishments for the manufacture of cottonseed oil in the United States. This number fell to four in 1867. But from that time the number has increased rapidly. There were 26 in 1870, 45 in 1880, and 872 in 1914. Since 1914 there has been a decided tendency toward consolidation, not only in management but in the construction of larger units and the abandonment of mills of small capacity. In 1914 there were 68 mills that crushed less than 1,000 tons each, and only 12.5 per cent of the mills crushed over 10,000 tons each; but in 1925 there were only 18 mills that crushed less than 1,000 tons each, and 32.6 per cent of the mills crushed over 10,000 tons each. The growth of the industry is shown in Table 4.

TABLE 4.—*Growth of the cottonseed-crushing industry in the United States*

| Year | Number of mills | Seed crushed | Value of products | Remarks |
|---|---|---|---|---|
| | | *Tons* | *Dollars* | |
| 1826 | 1 | | | Columbia, S. C. |
| 1831 | 1 | | | Natches, Miss. |
| 1847 | 1 | | | New Orleans, La. |
| 1860 | 7 | 50,000 | 741,000 | 3 in Louisiana; 1 each in Missouri, New York, Rhode Island, and Tennessee. |
| 1874 | | 84,000 | 2,530,000 | |
| 1875 | | 123,000 | 3,970,000 | |
| 1880 | 45 | 182,000 | 7,290,000 | |
| 1890 | 119 | 1,023,000 | 19,790,000 | |
| 1900 | 357 | 2,479,386 | 42,411,835 | |
| 1904 | 717 | 3,345,370 | 69,310,624 | |
| 1909 | 810 | 3,827,301 | 107,528,204 | |
| 1914 | 872 | 4,847,628 | 156,036,437 | |
| 1917 | 728 | 4,251,680 | 360,736,000 | |
| 1920 | 675 | 4,069,166 | 156,513,000 | |
| 1925 | 530 | 4,605,227 | 240,855,000 | |

### Development Has Been Haphazard

Taken as a whole, the cottonseed-crushing industry may be said to have had a rather haphazard development. It began with the purpose of obtaining one valuable product, oil, from a material that had long been considered an offensive nuisance. Up to that time cottonseed had been used for planting; fed to cattle with caution, lest they be poisoned; and, when rotted, occasionally used by more progressive farmers as a manure. So offensive a nuisance did the annual accumulation become that as measures necessary to the protection of the public health, laws were enacted regulating its disposal.

Preparation of the oil and its utilization has ever been uppermost in the minds of those engaged in the industry, to the passive and general neglect of other phases of the business. Improvements and changes in methods have resulted rather from the critical demands of the consumers of the products of the mills than from initiative within the industry.

The demands of the refiners of oil necessitated a careful study of its extraction and of the factors influencing its quality, for not only did the producers have to meet the demands of the refiners, but, indirectly if not directly, they had to meet the problems of increasing the consumption and especially of combating the opposition of producers of other oils with which cottonseed oil soon became a serious competitor.

An early effort was made to dispose of the residual cake, first as a fertilizer and later as a cattle feed; but the efforts to encourage the use of the cake when ground into meal, as a cattle feed, met with prejudices, owing largely to the disastrous results of feeding highly concentrated foods without regard to food values. These prejudices coupled with laws regulating commercial feeds and fertilizers in turn brought about a thorough study of this product.

### Residual Fiber a Problem

The residual fiber found on cottonseed after they have been ginned has always been a problem to the crushers. If the fuzz is absent, that is, if the seeds are what are known as slick seed, it is exceedingly difficult to make a sufficient separation of the meats and hulls so as to make possible a full recovery of oil. Moreover, the presence of the excess hulls reduces the value of the cake. When the seed are fuzzy, the usual condition of upland cottonseed, if the residual fiber is not removed before crushing, portions of the meats can not be freed from them, and more or less oil is absorbed by them, thus occasioning losses. On the other hand, the cost of removing the residual fiber often offsets possible savings in meats and oil. As the delinting of the seed is of questionable economy, the controlling factor has been generally the cost of the process rather than the value of the linters produced. At first it was thought inadvisable and unnecessary to remove much of the residual fiber—only enough to facilitate the separation of the meats and hulls, and certainly not more than that which would permit the resulting linters to complete with cotton lint. The product so obtained, found ready sale as a form of cotton and was used for spinning and batting.

Gradually, as methods of extraction improved and the demand for the oil increased, better delinting of the seed and separation of the meats were effected, and linters became blends of the residual cotton and of the seed fuzz. The quantity of this form of cotton, generally spoken of as the "cut" per ton, rose between 1900 and 1910 from about 25 to 50 or more pounds per ton of seed. As a result much of the linters became hardly fit for spinning and their use was diverted to the manufacture of mattresses and other feltings and to industries requiring them as a source of cellulose.

During the World War the demands of the Government for material for explosives forced an even more intensive delinting. So complete did the delinting then become that the long fibers were cut or broken, practically all of the fuzz was removed, and even the seed coat itself was so closely abraded that considerable hull particles were included in the linters so produced.

### Uses Found for Linters

As yet, however, no discriminating market had developed demanding a study of the character of this product. With the coming of peace, however, it was found that linters could be used in the manufacture of a great number of valuable articles and that the different blends of the long and the short fibers obtainable by adjustments of the delinting machines, were each specially fitted for the manufacture of a particular group of products into which the linters could be converted.

This diversity of uses resulted in a more discriminating market and increased price differentials. In 1900 linters brought less than 1 cent a pound; during the war the price was fixed at 4½ cents a pound, but soon after the war the price paid for the highest types was above 14 cents, while the lowest type brought about 2½ cents. Out of these circumstances a demand arose for a scale or grades on which the oil mills might remove linters and the consumers of linters might purchase. In May, 1924, the industry made a joint request that the United States Department of Agriculture study the commodity with a view to constructing standard grades.

These studies disclosed (1) that the long fibers found in linters were chiefly composed of the abnormally soft and weak fibers that because of their flaccidness had not fluffed during the curing of the seed cotton but had remained matted about the seed and thus escaped ginning; (2) that the uses for which linters had found a place were directly correlated to the different blends of long fibers and seed fuzz that resulted from the variations in the mechanical settings of the reginning or delinting machines.

The third finding was that there were certain characteristics, such as color, harshness or softness, smoothness or neppiness that were usually peculiar to certain geographic sections, possibly in some way related to climate, soil, or cultural methods, and that these sections might roughly be grouped as the southeastern States of the Cotton Belt, the Mississippi Valley States, and the western or Texas-Oklahoma district.

The fourth result of the studies was the finding that both the sectional characteristics of linters and the blends of fiber were discernible to the eye as well as discoverable through the sense of touch.

### Situation Reduced to Order

These four determinations enabled the department to bring into order factors which had appeared a hopelessly confused hodgepodge. The gamut of linters was reduced to seven groups or grades, each grade representing the three sectional characters of linters as well as the mixtures or blends of fibers usually to be found in individual bales. These grades passed the test of a year's use as tentative standards and on August 1, 1926, they became the official standard grades for American cotton linters, promulgated under the cotton standards act.

G. S. MELOY.

## COTTON Growing in One-Variety Communities

The lines of progress to be followed in the improvement of the cotton industry are becoming more clearly defined. Increasing costs of production in the United States are stimulating the development of cotton growing in many countries, so that in a few years the effects of competition may be felt. If high prices continue, the foreign competition undoubtedly will increase, and less of our cotton will be exported unless it is of better quality than the foreign product. Our short, uneven, low-grade cotton that competes in foreign markets with the cotton of India and China is becoming unsalable, except at prices that are entirely unprofitable to the grower.

The production of larger quantities of inferior low-grade cotton has been accompanied by a corresponding decrease in the production of the better staples, and manufacturers have been complaining of the increasing difficulty of obtaining the large, even-running lots of fiber they require. Automobile-tire manufacturers in particular are becoming alarmed as they find it more and more difficult to locate adequate and regular supplies of fiber from 1 to 1$\frac{3}{16}$ inches in length, used largely in tire construction.

It is unnecessary to grow any of the very short and irregular cotton that the foreign buyers are beginning to reject, to become a "drug on the market," and depress the prices even of the better staples. There is no occasion to grow cotton of less than 1-inch staple in any part of the United States, and staple up to 1$\frac{1}{8}$ inches or longer can be grown over a much wider area than is now producing such fiber. The continued planting of inferior varieties and irregular "gin-run" seed is a mark of the backward state of our cotton industry that should be corrected as rapidly as possible.

### Superior Varieties Bred

Superior varieties have been bred that are as early and as productive as any of the inferior short-linted sorts, and are adapted to conditions in the different cotton-growing regions. The problem of utilizing such varieties and replacing the inferior seed stocks has also been studied carefully, and a simple method has been found that opens the way to a general improvement of production.

In order to utilize superior varieties of cotton, adequate supplies of pure seed must be developed and maintained. This is a self-evident basic requirement for improved production, but one that has been almost entirely neglected in the past. Much of the crop still is raised from mixed gin-run seed (which should have been sent to the oil mill instead of being planted), but there is no supply of really good uniform seed to take its place. Of the approximately 500,000 tons of seed required to plant the American cotton crop, fully 90 per cent is of mixed "gin-run" quality.

The present system does not provide or even permit the production of adequate supplies of pure seed. Though there are thousands of farmers in each of the cotton-growing States who appreciate the need and are anxious to plant and to raise good seed, the farmer as an individual finds himself practically powerless when he attempts to establish and maintain a pure stock of cotton. On account of the public gins that regularly mix the seed of different varieties together, and the crossing of the different kinds in the fields, cotton varieties "run out" rapidly under the usual conditions of production. (Fig. 58.)

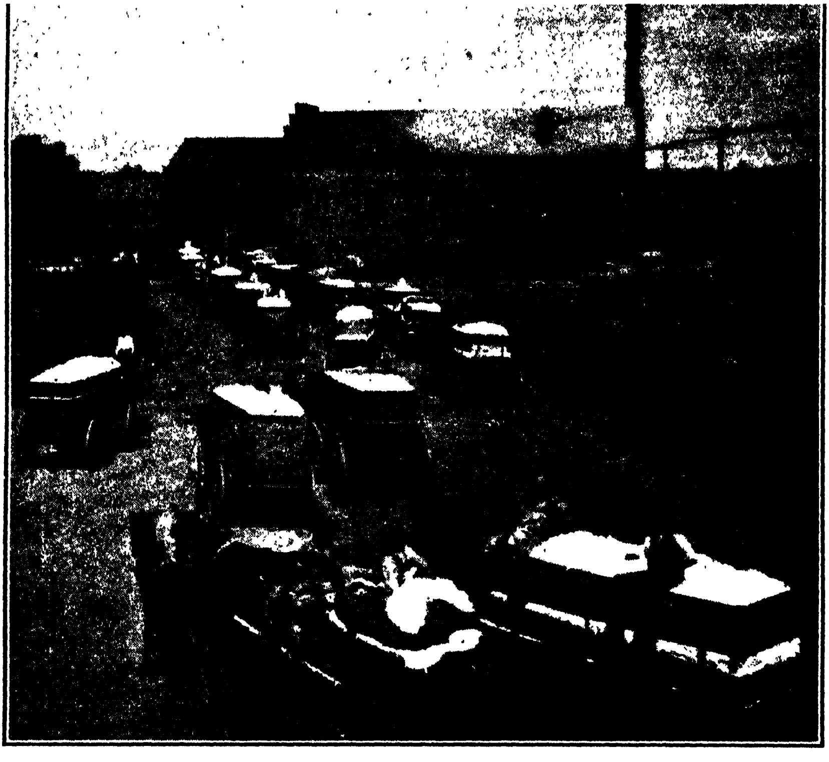

FIG. 58.—Wagonloads of seed cotton, each from a different farm and each with a different variety. These follow each other at the public gin where the seed from the different loads is unavoidably mixed. The subsequent planting of mixed seed is followed by cross-pollination in the field and varietal deterioration. In communities where the farmers grow only one kind of cotton there is no mixing of seed at the gin and the purity of the variety can be maintained

### Pure Seed in One-Variety Communities

It is only in communities where the growers organize and restrict themselves to the planting of one kind of cotton that the seed can be kept pure, and the regular production of a superior variety is made possible.

Organization may be urged upon cotton growers for the same general reasons as for other crops, but cotton has a special community feature, the product of many farmers going to the same gin. The cotton industry should have been placed on a community basis when public gins supplanted the former system of private or plantation gins, but methods changed gradually and consequences were not considered. Ginning is done with less labor by the modern high-power equipment, but the public gin system has made it very difficult to keep seed pure, or to have superior varieties in general cultivation.

The present system of growing cotton from mixed seed was not devised by anybody, and serves no purpose that would not be served much better on a one-variety basis. Not only are the crops smaller and the fiber of poorer quality under the present system, but the industry is burdened with a complicated and expensive system of grading and classing of the present irregular crop, in attempting to make up the "even-running lots" that the manufacturers require.

The planting of one kind of cotton injures nobody, but is to the advantage of every producer. It is the simplest and cheapest improvement that could well be imagined, and yet the most fundamental and effective improvement. The basis of production is changed from mixed gin-run seed to pure uniform seed at no loss or expense to the farmer that is not at once repaid many fold.

### Twofold Advantage in Plan

The advantage of community production comes in two ways—the community cotton is of better quality and can be sold at a higher price. An individual farmer, if he is able to get good seed, may raise as good a crop as a farmer in an organized community, but he has a smaller chance of getting a higher price for a few bales than his neighbors who planted gin-run seed. It is no satisfaction to the farmer to raise better cotton if he can get no more for it. A few bales of good cotton can not be sold at the full price, but communities can sell in commercial quantities. The community conditions are necessary to get the full price for the cotton, on the basis of a regular production of large quantities of uniform fiber through a period of years.

The advantages to be obtained by community production of such a variety as the Acala were estimated several years ago at 5 cents a pound, a figure which was reached in some of the sales of the last season in California. The advantages have been so definitely recognized in California that a special act was passed by the State legislature in 1925 for the protection of one-variety communities.

The one-variety communities, by producing commercial quantities of the same kind of cotton every year, are establishing special market relations that unorganized communities could not possibly attain. The community product as a whole is of standardized even-running quality, much more uniform than the miscellaneous product of mixed-variety communities can be made by the most careful sorting and classing of the bales. (Fig. 59.)

In the modern manufacturing industry, cotton is required in large quantities of uniform fiber. Manufacturers are not interested in a few bales of cotton or a few hundred bales. Their problem is to have a regular supply of thousands of bales of the same kind of cotton, not in one season only but a supply that can run through a long period of years.

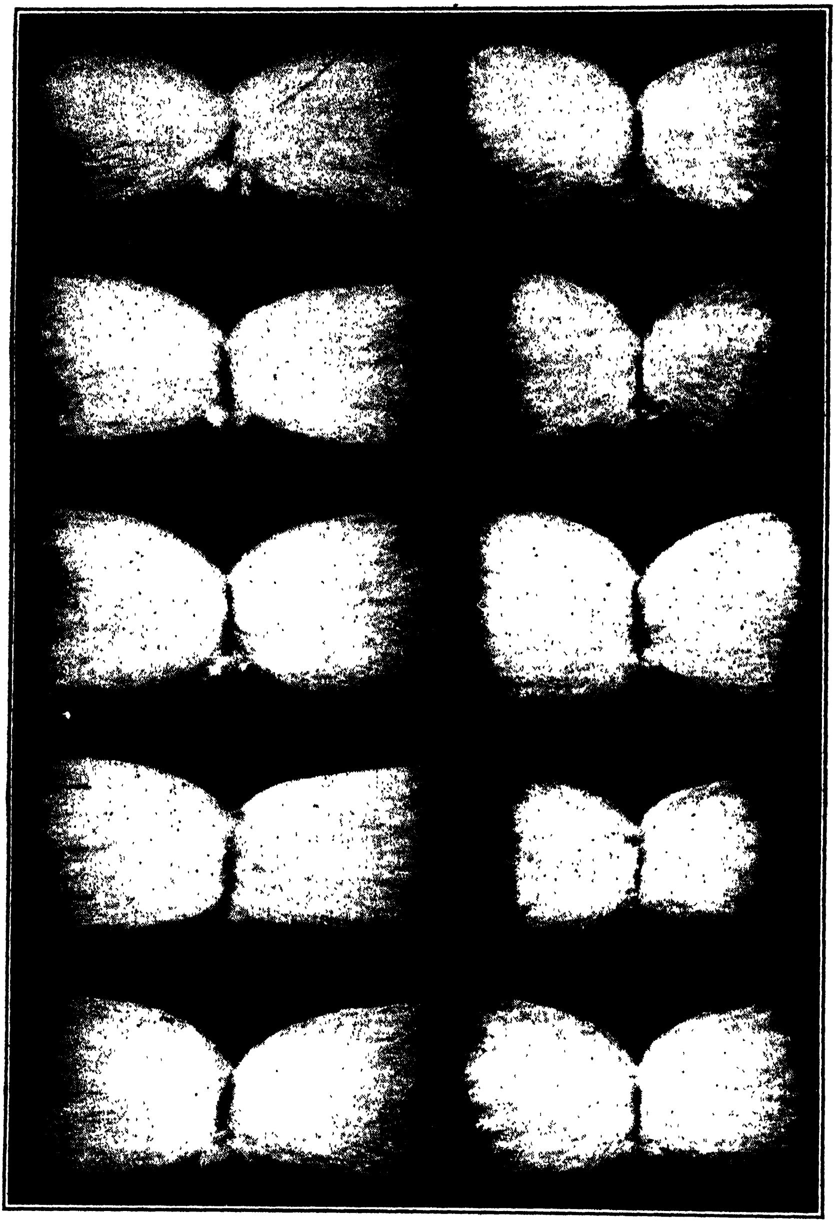

FIG. 59.—On left, uniform fiber of superior quality produced in a one-variety community from pure selected seed of one kind of cotton; on right, irregular and wasty fiber of poor quality produced in a mixed-variety district from "gin-run" seed. (Natural size)

From the nature of the cotton plant, it is out of the question to produce uniform fiber from mixed seed, but the farmers of organized communities become more skillful as they become more familiar with the behavior of one variety, so that larger and more uniform crops can be obtained.

From the experience of the organized progressive communities in California, it is plain that the growing of one variety is a basic improvement of the system of production, essential to a full utilization of superior varieties and of other improvements. So many other advantages are being demonstrated that it can be only a question of time for the community system of production to become general.

C. B. Doyle.

---

**COTTON Lint Research** Cotton is probably our best example of a strictly commercial farm crop. No part of it is consumed on the farm in the raw state. Some of the seed may be used for planting and some may be fed to cattle, but not to best advantage. The custom is to sell even the seed to an oil mill and to buy cake and hulls for feeding and seed for planting.

The most important problem connected with the marketing of this product is that of determining its quality as expressed by the trade in terms of grade, staple length, and elements of character, including luster or brightness, drag, and uniformity. The process of determination is known as classing.

Even when cotton is classed by the most expert of classers, there often arises a difference of opinion as to its classification, for cotton classing at its best is nothing but the best judgment of cotton classers.

Cotton is grown primarily to be spun into yarns, most of which are to be woven into cloth for countless uses. The higher the quality of the cloth, the greater must be the utility of the raw cotton used in its making. The value of the cloth depends, other things being equal, upon this utility.

Just as the chemist and his laboratory are necessary as a check upon the judgment of a feed inspector, so are the cotton fiber, spinning, and cloth laboratories essential to a proper checking of the work of cotton classers, for only in this way is it possible to define and describe accurately any logical set of standards for grade, staple, and character.

The farmer is as much concerned in the accuracy of cotton standards as the spinner or the manufacturer, because he should be paid for his cotton in accordance with its spinning quality, or spinning utility. If he is to produce cotton of a higher quality, as is persistently demanded by spinners and the trade generally, he must be paid for the extra effort necessary to produce this quality. So long as he is unable to see any difference in his remuneration between the growing of cotton of low and of high quality, he will remain indifferent as to quality and devote his efforts to the production of quantity.

### Cotton-Fiber Laboratory

In accordance with this demand for greater accuracy in cotton classing, the Bureau of Agricultural Economics, working in cooperation with the Bureau of Plant Industry and certain State colleges and experiment stations, has developed a cotton-fiber laboratory within the department and a cotton-spinning laboratory at Clemson College, S. C., in cooperation with Clemson College. These studies, though rather new, are beginning to yield information upon which a solution of the more important problems of cotton production, marketing, and manufacture may be based.

The grower stresses productivity in a variety of cotton, but the manufacturer demands high spinning quality as the chief requisite. A correlation of the requirements of grower and manufacturer may be effected by the production of a cotton possessing not only productivity but also high spinning value.

FIG. 60. -Laboratory maintained by the Bureau of Agricultural Economics in Washington, D. C., where all fiber investigational work is conducted and where determinations of the final yarn strength and of moisture in the cotton are made. This laboratory is equipped with the most modern humidifying and dehumidifying systems and testing machines

As a first step plant breeders and cotton organizations have been studying various cultural methods as applied to the development of early-blooming, storm-resisting cottons of the big-boll type producing not only a large yield per acre but a high percentage of lint cotton, and varieties have been developed which are very satisfactory from the standpoint of yield. It remained to be determined as a second step whether such varieties would prove equally satisfactory from the standpoint of spinning value.

Thus the spinning tests of the cotton-testing project of the Bureau of Agricultural Economics have been developed in direct response to an evident need and resultant demand. The project has great possibilities as a link between grower and manufacturer in that spinning test data show the grower which productive varieties best meet the demand of the manufacturer and acquaint the manufacturer with the varieties which possess high spinning quality. The market necessarily must feel the favorable effect of any movement which shows the interests of producer and manufacturer to be identical. The constant and increasing demand for tests and test data reflect the practical value of cotton testing.

A method of measuring those factors which determine spinning quality of cotton was the need. This field of research must supply information upon which to establish standards for strength and uniformity of staple, in addition to those for grade and color which are now in universal use. Such standards would be of great service in the marketing of cotton and would accomplish more than any other one thing in getting farmers to improve the quality of the staple.

### Spinning Tests Conducted

Some 60 spinning tests have been conducted during the past year. These tests include (1) eastern and western cottons representing the nine white grades of the universal standards for American upland cotton; (2) cotton from various sections of the Cotton Belt, that is North Carolina, South Carolina, Texas, Oklahoma, Arizona, New Mexico, and California; and (3) two varieties imported from Egypt.

These tests were conducted at Clemson College, S. C., in cooperation with Clemson Agricultural College, and, with the exception of those of the nine white grades and the two Egyptian varieties, were made at the request of cooperators.

Fiber investigations have been continued throughout the year with a view to searching out the relationship between the characteristics of fibers and their spinning value. These studies, as well as the yarn-strength tests, were made in the laboratory at Washington, D. C.

Research in raw cotton supplies scientific data on many factors. Among them are (1) the relative waste, spinning, and bleaching qualities of different grades, staples, and varieties of cotton subjected to various cultural and weather conditions; (2) determination of the varieties of cotton best suited to particular localities; (3) determination of the effect of varying the conditions of gathering, ginning, baling, compressing, and handling cotton; (4) spinning data for an economic study of the problems pertaining to the production and marketing of cotton; (5) spinning data on the specific yarn numbers into which special cottons may be manufactured for use in connection with cotton utilization problems; and (6) data regarding fiber length and strength and other factors in an effort to correlate these characteristics with yarn strength.

Spinning quality is governed largely by grade, length, strength, and uniformity of staple. Although weather conditions during the growing and harvesting seasons are an important factor in determining the quality of cotton, the varietal characteristics of body and uniformity of staple are also important factors, and these can be largely controlled by the grower. The spinning tests and fiber investigations so far made indicate that the length of the staple accounts for approximately 61 per cent of the strength of the yarn and that the strength of the staple accounts for about 11 per cent of the strength of the yarn. The department's tests have consistently shown that a lack of uniformity in staple increases waste, causes high end breakage in spinning (thereby lowering the production in manufacture) and produces yarn irregular in diameter and strength.

### Pure Varieties Best

An interesting fact brought out in a number of spinning tests is that pure varieties are superior to mongrel cotton in respect to waste, strength, and evenness of yarn. and in machine efficiency, and that mixed cotton of irregular staple is unsatisfactory for general spinning purposes. This lack of quality caused by the irregularity of the staple is usually reflected in the market price of the cotton, and although this fact may be obscured in country buying it is evident in the larger markets. In cotton manufacturing one of the most particular operations is the selection of uniform bales of like quality, suited to the specific work at hand. This selection is facilitated by production of superior varieties and the advantages of the reduction of the hazard of mixed staples are now generally recognized. When a community is equipped with test data showing to what degree each of its leading varieties possesses the two qualities of productivity and spinning value, that community is fitted to make an intelligent choice of the variety best suited to its particular conditions.

From the manufacturer's point of view, the selection of uniform, even-running, and well-ginned lots of cotton is essential. To bring about a closer coordination between the spinner's requirements and the farmer's product, spinning tests have been made of the different standard grades of American upland white cotton. These tests show that the percentage of visible waste follows the grade, ranging from approximately 5½ per cent on grade No. 1 or middling fair to 14½ per cent on grade No. 9 or good ordinary, and that the finishing qualities of the lower grades are not so satisfactory as those of the higher grades. These standards for grade and staple, established by the Department of Agriculture, not only facilitate the selection of even-running lots of cotton but serve to acquaint the growers with the qualities that should be attained in both breeding and production. They also aid the grower in obtaining a price more commensurate with the quality that he produces.

Results of tests of picked and snapped cottons from Texas and Oklahoma, although not presented as conclusive, indicate that snapping as a method of harvesting lowers the grade of the cotton by about two grades; that, with efficient boll-extracting equipment, the strength and uniformity of the cotton are not noticeably affected; that the percentage of visible waste in snapped cotton is not materially greater than in picked cotton of equal grade; and that, taking these results as typical, at the officially quoted prices and under the conditions which prevailed in 1925, snapping cotton resulted in a loss to the grower of $7.29 a bale as compared with picking. But there were times during the year when greater discounts were assessed against the cotton, because it had been snapped combined with the fact that it was sold in the seed, the losses in these cases running approximately from $14 to $27 per bale. It should be stated that the farmer resorted to snapping because of a dearth of pickers. His loss due to snapping was probably less than would have been the case had he resorted to pickers.

### Spinning Value Testing

Up to the present time plant breeders have been unable to obtain determinations of the spinning value of new varieties of cotton until the production was large enough for spinning tests and it usually required a period of years to produce such a quantity. In case these new varieties failed to meet spinning requirements, their development was an economic loss to the grower and to the cotton industry as a whole. A real need existed for an adequate laboratory method by which the breaking strength of yarn could be predetermined by the use of a small sample of raw cotton, even so small a quantity as the product of one plant. Such a method was developed and a device invented by the Bureau of Agricultural Economics in cooperation with Clemson Agricultural College.

This method was first used with considerable success in a test of eight lots of cotton grown in South Carolina during 1925. In an effort to correlate the length and strength of fiber with yarn strength the eight lots of cotton used in this test were graded and stapled, and then spun into yarn, which was tested by the usual skein method. Representative samples of the raw stock were tested for strength by this laboratory method by means of which several thousand fibers in bundle form were broken simultaneously. From the data thus obtained the statistical division of the Bureau of Agricultural Economics developed two equations by which the strength of 28s and 36s yarn may be estimated with some degree of accuracy when the length and strength of the raw cotton are known. Upon applying this method to 33 lots of cotton grown in North Carolina, South Carolina, and Texas, the staple length of which ranged from thirteen-sixteenths to 1¼ inches, the estimating formula for strength of 28s yarn as originally developed was subject to but slight change.

This method will no doubt be subject to further slight change as more extensive tests are conducted and as various factors influencing yarn strength, as yet undetermined, are measured with some degree of accuracy. But the results already obtained indicate the possibilities of the method. Of the 33 lots of cotton tested by this method, only 11 showed a variation of more than 6 per cent between the actual and estimated strengths of 28s yarn.

## COTTON in the Texas Plains Area

Near the south end of what we now call the Great Plains, once known as a part of the " Great American Desert " lies that well defined geographic area called the Staked Plains. Until about 1860 this region was the winter range of the buffalo. After the Civil War, the region was gradually occupied by cattle, at first temporary and later permanently.

Practically everybody, assumed that the lands could never be crop-farmed; hence, stockmen, by a somewhat lenient interpretation of the Texas land laws, acquired the large areas, often amounting to hundreds of thousands of acres, that were necessary to the profitable use of the natural short-grass forage of the region, and settled down to cattle and sheep raising. As early as 1885 settlers demonstrated in many parts of these Plains that crops of certain kinds could be produced, at least part of the time, and the crop farmer has gradually pushed his way into the very heart of this stronghold of the big range stockman.

Census reports show an increase of about a million acres in cropped land on the Staked Plains between 1919 and 1924, and rapid expansion is still going on. By 1925 practically all the stock was removed from the region and any of the land could be bought for farms. Coincident with this expansion of the farm land area railroads have built new branches, new towns have come into being, old towns have doubled and trebled their populations, good roads have been built, schools and colleges have sprung up, and business has prospered. Perhaps the most surprising thing about this expansion of the crop-farmed area is the part which cotton has played in the reorganization.

### Further Development Possibilities

The explanation of this rapid expansion of crops into a region from which crops, especially cotton, were supposed to be forever debarred is one of the interesting agricultural stories of the last 10 years. And there are still millions of acres in native grass, that may be and perhaps will be cultivated.

The land above the cap rock is level to gently rolling and the tillable soils are mostly light and easily worked when properly moist; hence, cultivation of large fields with large equipment is easy. These new soils are now fertile; hence, the application of fertilizers is unnecessary, at present. The weeds of world-wide distribution are not yet common in this region and it is possible that some of them never will be.

Even the scanty and at times insufficient rainfall is advantageous from at least two points of view. The dryness keeps out many weeds that would otherwise come in and makes weed killing easy work as compared with what must be done in a humid region. This same dryness has so far rendered the cotton-boll weevil harmless in the region and will probably continue this service.

Perhaps nothing has been quite so important to the crop farmer of this region as the introduction of the various sorghums, unless it be the adaptations of these crops to special regional requirements brought about by the work of the Federal and State agencies concerned. The permanence of crop farming in the region seems almost to rest upon the production of kafir and milo and Sudan grass, or their immediate relatives. These are the common feeds for livestock of the region and the varieties now available can be depended upon there with as much assurance as wheat or corn in the more humid regions. Together with livestock these crops alone make possible a type of farming in no way dependent upon cotton and assure the continuance of crop farming in this region.

### Reliability of the Cotton Crop

The appearance of cotton as a reliable crop in this region was a surprise to everyone but those concerned in its introduction. Cotton has been produced in merchantable quantities in every county included in the Staked Plains region, though the areas cultivated have been progressively smaller toward the northern, western, and southwestern borders. Correlating this known distribution with available data concerning soils, climate, and relief of the region, the following generalization may be made: Cotton may be expected to produce crops worth harvesting, at least part of the time, in this general region, on sandy or loamy soils that do not puddle, where the normal annual rainfall is 17 or more inches, of which 75 per cent or more falls during a growing season that averages 185 or more days.

Cotton is probably descended from dry-land ancestors. Cultivated cotton possesses two dry-land characteristics which are important to the farmer: (1) It will wait relatively long periods for rain if it has established a root system, and (2) a decrease in the available soil moisture during the growing season causes the plant to begin blooming and fruiting. The first of these characters warrants the farmer in feeling little anxiety about yields, if he can get a good early stand, and the second makes him plant the seeds close together in the row and omit the chopping, so that plants will be somewhat crowded and begin to set squares early.

The two principal physical difficulties farmers must overcome are soil blowing and poor germination of seed. These both result from weather conditions (cold, dry spring) that vary in intensity from year to year with the climatic cycle of the region. Unfortunately, they are likely to occur together and both are worse in a dry year. Cotton will grow and is grown on the heavier soils, but with considerably increased risk.

Crops planted in deep furrows, in long, straight rows, laid off across any slope the land may have and, if possible, at right angles to the prevailing wind direction, is the farmer's answer to the farm practice problem. A two-row lister planter with a six-mule team and a set of fenders, knives, disks, and points have made it possible for him to plow and plant the land in one operation, if necessary, and to cultivate the crops with much less man and horse labor than is expended by the negro cotton farmer farther east.

### Tractors for Row Cultivation

The tractor adapted to the cultivation of row crops is important in this region, since it enables the farmer to get his seed planted when the soil is in the proper condition, thereby getting a good early stand. A cotton picker that, experimentally, has done the work of 12 or 15 hand pickers and has done it better is already a reality. Improvements in ginning processes have made practicable the harvesting of the unopened bolls by cheap methods. A variety of cotton better adapted to the conditions and practices of this region is a possibility if not a probability from the breeder's standpoint.

With these improvements, all of which tend to reduce the cost of production, it seems safe to reach the following conclusions as to the physical possibilities of cotton production in this region: (1) Cotton farming along the eastern half of the Staked Plains is assured; (2) as one moves westward the growing season becomes progressively shorter and drier and the risk of failure in cotton growing increases rapidly as the western boundary of the plains is neared; (3) cotton can be grown in the New Mexico counties of the Staked Plains only part of the time.

Under such conditions what may be a fair estimate of the probable further expansion of the cotton-producing area in this region?

Considering the Staked Plains as a whole, if proper allowance be made for waste land, there are over 15¼ millions of acres of land that may be used for crops and pasture in Texas and more than 4¼ millions in New Mexico.

If we assume that the eastern half of the region in Texas can be organized safely on the basis of 40 per cent of the tillable area in cotton, the western half on a basis of 20 per cent in cotton, and the part in New Mexico with 10 per cent in cotton, and that total be reduced one-third to eliminate the heavy soils of the region upon which cotton is quite uncertain, we get approximately 3,200,000 acres that may go into cotton.

### Area Harvested in 1924

The total area of cotton harvested in 1924 in this region was 1,269,600 acres, with an average yield of 149 pounds of lint per acre, in Texas, and 22,700 acres, with an average yield of 85 pounds per acre, in New Mexico. A conservative estimate of the probable expansion of the cotton acreage in the Staked Plains region based upon physical conditions alone then becomes about one and one-half times the acreage in cotton in 1924. This expansion would mean an increase in production of approximately a half million bales.

What of the economic conditions? Detailed studies of owner and part-owner operated farms in Lubbock County, Tex., show that the average net income per farm received for its operation by the family for the year, after paying all interest on borrowed capital (and including the value of that part of the family living furnished directly by the farm as part of the farm receipts), was for 139 farms, over $3,000. Three men lost money, 10 per cent of them made less than $1,000, but 13½ per cent made over $5,000, and the remainder made between $1,000 and $5,000. These incomes were obtained on farms averaging 232 acres in size, valued at $68 per acre, with 37.6 per cent of the land in harvested cotton having an average yield of 148 pounds of lint, selling at an average price of about 20 cents per pound. The average net worth of these farmers when they settled in the region was just over $5,000 per man and on March 1, 1925, the corresponding figure was $18,000, the difference having been made by the operation of the farm and its own increase in value in an average period of operation of 5.84 years.

The figures are taken from a large enough number of farms to furnish reliable averages for the county and the county is one of 8 or 10 that have had closely similar experience within the last decade. All things considered they probably present a picture of that part of the Staked Plains which can most surely rely upon cotton farming as a basic industry.

E. O. Wooten.

## COTTONSEED Grades Are to Be Issued

Under the present system of purchasing cottonseed for crushing purposes, the prices paid by the oil mills are reflections of the average quantity and quality of the oil and cake recoverable from the seed. As the quantity and the quality of both the oil and the cake are affected by local conditions and customs, quotations become sectionalized because of local seasonal conditions and known cultural and handling practices. As a rule no rewards are paid on local markets for seed of higher yields of either quantity or quality. Moreover, values are frequently upset by reckless competition for seed.

During the crushing season of 1925–26 the Department of Agriculture began a study of cottonseed to determine whether it is possible to grade them for crushing purposes in the primary markets. These studies indicate that cottonseed may be graded on the basis of their kernel content and official grades will be established as soon as the necessary apparatus and proper methods for grading are worked out.

Of the total value of the four products of cottonseed—oil, cake or meal, hulls, and linters—the combined value of the oil and cake constitutes between 85 and 90 per cent; therefore, the factors in the raw seed that affect the quantity and the quality of these two products are paramount in determining the value of the seed at the time of purchase.

### Oil in the Kernels

The oil is contained in the kernels or meats and the meal is ground cake to which, in some instances, hull bran is added as a diluent in the production of meal of a standard protein content. The kernel content has been found to vary from 40 to 60 per cent or from 800 to 1,200 pounds of kernels per ton of seed, owing to combinations of foreign matter, both dirt and water, and to variations in the relative proportions of hull and kernel correlated with the size of the seed and the thickness of the hulls.

Considerable variation is found in the oil content of the kernels, the range being from about 25 to approximately 40 per cent, but this variation in oil is largely offset by the fairly constant inverse ratio correlation found to exist between the oil content and the protein content, which permits varying quantities of inert hull to be blended with the cake in forming meal of a standard protein content. The result is that the difference in value between seed of equal kernel content, but of extremes of oil content, is much more narrow than is the difference in value of seed of equal oil content, but of extremes of kernel content. Thus, the quantity of the kernels, or meats, per ton of seed is the first factor influencing the value of the seed.

### Kernel Content Basis

As a result of these findings it has been suggested that the grading of cottonseed for oil-mill purposes might be done in the primary markets on the basis of the kernel content.

If the average kernel content, at a standard of moisture, be taken as a basis, increases of kernel—the result of growing improved varieties and of the use of better cultural and handling practices—will receive rewards, and contra, reductions in kernel content below the basis which result from poor cultural methods and improper handling practices will receive due discounts.

Studies of quality are now being carried on. These are being directed (1), to determining what transitions in cottonseed are deleterious and their causes, (2) to finding accurate methods for determining the percentage of deterioration, and (3) to evaluating degrees of damage.

**COUNTY Extension Agents** The extension system as developed since the Smith-Lever Act went into effect on July 1, 1914, has been based on placing a technically trained and practically minded agricultural agent and home demonstration agent in each rural county of the United States where there is sufficient farming population to justify the expenditure required, and a boys' and girls' club agent and a negro agent in counties where there is a demand for the services of such agents and where sufficient funds are available.

These agents make their homes in the county in which they work and have a centrally located office usually equipped with files, record facilities, telephone, and other office equipment. An automobile for field work and needed clerical assistance are frequently provided for by the county authorities. The agents systematically visit among the farming people of the various communities in their counties, suggest demonstrations and improvements on the farms and in the homes in the communities visited, and are consulted by farmers and members of their families in the office or over the telephone. These county extension agents serve as a connecting link and as a clearing house for information between the State colleges of agriculture, the United States Department of Agriculture, and the local people.

The county extension agents are called upon to handle a great many matters of importance to farmers and farm women, some of which require highly specialized training. To meet this situation, a corps of extension specialists in such subjects as agronomy, horticulture, farm management, foods and nutrition, textiles and clothing, and marketing is usually maintained, with headquarters at the State agricultural college, to help the county extension agents with their more specialized problems. Supplementing the State specialists is a small corps of Federal extension specialists, who carry to the States matters which the Federal Government has ready for extension and who act as carrying agents and a clearing house of information for all the States. It is, likewise, through these various county, State, and Federal extension agents that the State and Federal research forces are kept advised as to the needs of the farmers for additional research.

To assist these field agents, most State colleges of agriculture have developed strong editorial departments to prepare instructive publications and to keep the public informed of extension progress through the press.

### Growth in Extension Staff

The extension staff in 1914 included 881 county agricultural agents, of which number 678 were in 15 Southern States. Of the latter, 38 were negro agents working with negro farmers and farm boys.

There were 349 home demonstration agents, all of whom were located in the Southern States. These agents gave about a third of their time to the work, their main activity being the promotion and instruction of girls' canning clubs. Of these home demonstration agents, 12 were negro agents devoting themselves to the problems of the negro farm family. The various States employed approximately 221 full and part time specialists, most of whom were in the Northern and Western States. In addition to the above State and county field forces, there were various supervisors for the several lines of work.

On June 30, 1926, the cooperative extension personnel had grown to 2,270 county agricultural agents and 114 assistant agents well distributed throughout the States. Of this number, 163 were negro agents. There were 968 county home demonstration agents and 21 assistant agents. The larger number of home demonstration agents were located in the Southern and Eastern States. Of these home demonstration agents, 107 were negro agents located in the Southern States. In 1926 all home demonstration agents were giving practically full time to the work. There were also 128 county boys' and girls' club agents and 12 assistant club agents.

## COW-Testing Tales Prove Breeding and Feeding Pay

The 10 true tales told in this short article may not be stranger than fiction, but it is believed that each contains an element of human interest and teaches a valuable lesson in dairying. The tales are taken from the results of cow-testing association work, a cow-testing association being an organization of dairy farmers who cooperatively employ a man to test their cows for economical production of milk and butterfat. The tester visits each farm one day each month, weighs the feed and milk of each cow in the herd, tests the milk for butterfat, and figures the results.

1. High production per cow and large income over cost of feed are usually found together. This holds true for the cows in each cow-testing association, for cows in many associations combined, and even for cows in the individual herd.

One large cow-testing association herd furnished the yearly production and income records of 106 dairy cows. These records were sorted into three groups with an average butterfat production of 100, 200, and 300 pounds, respectively. The cows of the 100-pound group had an average yearly income over cost of feed of $16 per cow; those of the 200-pound group, $70; and those of the 300-pound group, $109. On an average, the cows of the third group produced three times as much butterfat per cow as those of the first group, and they brought in more than six times as much income over cost of feed.

### Poorest Cow's Earnings

2. In one cow-testing association the poorest cow brought in just enough income over cost of feed in one year to buy a 2-cent postage stamp. A man would have to milk a large number of such cows over a long period of time to obtain enough net income to buy himself a pair of shoes.

3. In a certain cow-testing association in the year 1924–25 one herd was fed no grain. Perhaps the owner thought he was saving

money. In dollars' worth of feed per cow he fed his cows less than was fed to any other herd in the association.

It seems probable that the cows in that herd went to bed hungry every night, but before the end of the testing year they got even with their owner. As compared with other herds in the association, they produced the least milk and butterfat per cow and brought in the lowest gross income per cow and the lowest average income over cost of feed. It never pays to try to save money by starving dairy cows.

4. In the Ottertail, Minn., cow-testing association in 1924–25, the average production of all the cows on test was 7,983 pounds of milk and 299 pounds of butterfat. That is a good record of production, but associations that produce 300 pounds of butterfat a year per cow are more numerous now than they were a few years ago.

On an average all the cows on test in the association returned a little more than $3 for every dollar's worth of feed consumed. But the best part of the story, from the standpoint of the farmer, is that on an average each cow returned yearly $101 income above feed cost.

A cow that returns $3 for every dollar spent for feed is a good feed market. A cow that each year returns $100 above feed cost is a good labor market. If a farmer owns a herd of such cows and desires to increase his yearly salary $100 all he needs to do is to keep another cow like those he already has.

### How Useful is Guesswork?

5. Sometimes we hear a dairyman say that he does not need to join a cow-testing association because, without testing, he knows how much his cows are producing. Does he? Figures recently received from two cow-testing associations show that he does not know with any great degree of accuracy.

At the time they joined the cow-testing association, 14 farmers estimated the production records of their dairy cows. Each farmer estimated the milk production of his cows, and 5 of them also estimated the production of butterfat. Altogether, the estimates included the yearly milk production of 102 cows and the yearly butterfat production of 48 cows.

Compared with actual production of milk and butterfat as shown by the cow-testing association figures, the error in the estimates for both milk and butterfat varied from less than 1 per cent to more than 50 per cent. On an average the error was 25 per cent on production of milk and 28 per cent on production of butterfat.

6. In one year's time a scrub cow produced 146.8 pounds of butterfat. Her daughter sired by a scrub bull produced 126.3 pounds, and the granddaughter sired by the same scrub bull produced 99.7 pounds, just a trifle more than the world's record for a goat. The owner finally woke up, sold the scrub bull to the butcher, and purchased a good registered bull.

In many of our dairy herds to-day, culling should begin with the elimination of the sire. Breeding to inferior bulls may pull production down as fast as the culling of low-producing cows builds it up.

7. A city girl was working on cow-testing association records. After spending about a week checking feed records from all parts of the country she remarked: "It seems to me that the cows that live on straw don't give very much milk."

She had learned in a week what some men do not seem to learn in a lifetime—that straw is not a first-class feed for dairy cows.

### Low Producers Cause Loss

8. During the year 1924–25, there were in one cow-testing association two herds of 21 and 9 cows, respectively. The larger herd averaged 158 pounds of butterfat a year per cow; the smaller herd averaged 294 pounds. The larger herd averaged $32 in income over cost of feed per cow; the smaller herd averaged $74. In total income over cost of feed, the 21-cow herd and the 9-cow herd were about equal.

From local sources it has since been learned that although the owner of the larger herd has a big farm, he is about to lose it because of low-producing dairy cows. It has also been learned that although the owner of the smaller herd is still a renter, he has saved some money and is about to buy a farm. He expects to pay for it from the profits of a larger herd of high-producing dairy cows.

9. It is important that a dairy cow should have a large return for a dollar spent for feed but, to the owner, it is vastly more important that she should have a high annual income over cost of feed. If a cow eats $50 worth of feed and returns $100 she returns $2 for every dollar spent for feed. If a cow eats $100 worth of feed and returns $200, she also returns $2 for every dollar spent for feed. The returns per dollar spent for feed are the same in each case; yet one cow has a yearly income over cost of feed of $50, and the other a yearly income over cost of feed of $100, or exactly twice as much. The figures are not imaginary because they represent what frequently takes place in cow-testing association herds.

For example, in one association in 1925, herd No. 4 had an average yearly butterfat production of 221 pounds per cow; herd No. 1, a production of 399 pounds. As there was only 2 cents difference in the price received per pound of butterfat, the figures are fairly comparable. Herd No. 4 ate $47 worth of feed per cow and returned $100, thus leaving $53 income over cost of feed per cow. Herd No. 1 ate $95 worth of feed per cow and returned $189, thus leaving $94 income over cost of feed per cow. In each case the cows returned approximately $2 for every dollar spent for feed, but the cows in herd No. 1 had almost twice as much income over cost of feed per cow as those in the other herd.

All the figures the tester records in the herdbook are of interest to the owner, but he is most interested in income over cost of feed per cow. That is the income from which the wide awake, up-to-date, progressive dairy farmer may swell his bank account.

### Feeding Too Much for Profit

10. Though the well-fed dairy herd is generally a high-producing and profitable herd, it is possible to feed too much for profit. This was the case with one herd that had an average butterfat production per cow of 376 pounds. At the end of the testing year that herd had eaten so much that the average cost of feed per cow was $44 more than the entire gross returns from the sale of butterfat.

Evidently the owner of this herd was trying for first place in the association in average production of butterfat per cow, but even in that respect he did not succeed because his herd ranked third in average butterfat production. He did succeed, however, in placing his herd at the foot of the list in average income over cost of feed, because no other member of the association was as careless about feed costs.

It is seldom that a cow-testing association herd is overfed to any great extent. One of the arguments for cow-testing association work is that it enables the farmer to follow the rule, Feed grain according to known production. That farmer broke this rule, for which he was forced to pay a heavy penalty in loss of income.

These 10 true tales indicate the great value of cow-testing association work. Production and income climb together. The owner of low-producing cows may work hard but he earns little. The cow that is poorly fed is not a paying proposition, but the high-producing cow is an excellent feed market. The cow-testing association records prove that it pays to keep good cows and to feed them well.

J. C. McDowell.

**COW-Testing Associations a Factor in Low-Cost Dairying** Economical production is the keynote in successful agriculture to-day. This is especially true in the dairy industry. The dairyman who produces milk at a low cost per pound of butterfat is in a safer position than his neighbor who does not. The records from thousands of cow-testing association herds prove conclusively that on the average the high-producing cow is the most economical one, the high-producing herd is the most economical, and the association with the higher production is likewise composed of more economical animals.

The position of the cow-testing association herds among the dairy herds of our country is an enviable one. The directory of these organizations for January 1, 1926, shows 777 in operation testing 327,000 cows on 19,000 farms. By July 1, 1926, the movement had a further gain, and at that time approximately 840 associations were in active operation. These herds—some purebred and some grade—are on a high plane in the dairy production world.

It is estimated that the average dairy cow in this country produces 4,368 pounds of milk per year, which contains about 175 pounds of butterfat. The records recently tabulated for thousands of cow-testing association cows indicate that they average slightly more than 7,200 pounds of milk containing about 282 pounds of butterfat. In a study of 18,000 yearly individual cow records it was found that cows producing 175 pounds of butterfat had a return over feed cost of $34 per year, those with a production of 282 pounds returned $68 after the feed had been paid for, and those with a production of 300 pounds returned $74. The difference in gain between the 282 and the 175 pound cows is 61 per cent in production and 100 per cent in returns above feed cost. Between the 300 and the 175 pound cows this difference is 71 per cent in production and 118 per cent in returns above feed cost. Two cows of the 175-pound-production group would not furnish as much income over feed cost as one cow of the 300-pound group.

### Returns from Cows Compared

In 50 associations in Michigan tabulations have been made to show the relation between the production of butterfat and the returns per cow after the feed had been paid for. The following figures show this relation for six groups of cows in that State averaging from 150 to 400 pounds of butterfat a year.

**Table 5.**—*Relation of butterfat production to income over cost of feed and other factors*

| Average production of butterfat per year (pounds) | Cows | Butterfat | Value of product | Total feed cost | Returns over feed cost |
|---|---|---|---|---|---|
| | *Number* | *Pounds* | *Dollars* | *Dollars* | *Dollars* |
| 150 | 337 | 154 | 85. 31 | 50. 00 | 35. 31 |
| 200 | 1, 022 | 203 | 112. 15 | 59. 55 | 52. 60 |
| 250 | 1, 788 | 251 | 140. 15 | 66. 75 | 73. 40 |
| 300 | 2, 011 | 299 | 166. 49 | 73. 93 | 92. 56 |
| 350 | 1, 575 | 348 | 199. 04 | 82. 47 | 116. 57 |
| 400 | 902 | 397 | 226. 87 | 90. 31 | 136. 56 |

It will be noticed from the above table that as butterfat production increased from 154 pounds to approximately 300 pounds, or 94 per cent, the returns over feed cost increased from $35.31 to $92.56, or 162 per cent.

In an association made up of 400 dairy cows producing on the average 154 pounds of butterfat per annum the returns over feed cost would be $14,124. On the other hand, an association in which the cows averaged 300 pounds of butterfat would return $37,024 after paying for feed. Therefore, the same quantity of butterfat would be obtained from 206 cows of the 300-pound class as from 400 cows of the 154-pound class. Furthermore, the returns over feed cost for the 300-pound association would be $4,943 more than for the association averaging 154 pounds, and nearly 200 fewer cows would need stable room, feed, and care. Surely it pays to keep the higher producing class of dairy cows.

Large numbers of individual herds in this country have averaged over 300 pounds of butterfat per cow per year, and many associations have reached this high mark. Of 563 associations whose records have been summarized in the past 12 months, 171, or 30.4 per cent, have exceeded the average of 300 pounds per cow. In one State with records of 40 associations, 5, or 12½ per cent, have exceeded this mark, and in another State with 92 associations tabulated, 51, or 55.4 per cent, have done likewise.

To be sure, all the cows on test in association herds are not, as a rule, uniformly high producers. This is especially true of herds during the first year of testing work. Cows are like human beings in that a considerable number of them live beyond their income. Through the cow-testing association records the cows that eat up their income are located and are sent immediately to the butcher by their intelligent owner.

### Results of Cow Testing

Earlier tabulations of cow-testing association records did not show so large a percentage of high producing herds and associations.

Years of operation of these testing organizations have had their effect. The records of tested cows tabulated about six years ago show an average production of 6,077 pounds of milk and 247 pounds of butterfat. Compared with this, the present average of 7,200 pounds of milk and 282 pounds of butterfat, shows a gain of more than 18 per cent in production over that period. This increase has been made in spite of the fact that new associations have been organized, bringing in new herds that have never been tested before. It could not have been made unless the lessons derived from the keeping of records had been heeded.

The history of a cow-testing association in Iowa with cows testing 300 pounds of butterfat is a glowing tribute to the efforts of the tester and members in applying to their herd management the lesson revealed by the records.

In June, 1923, a group of cooperators in Linn County, Iowa, organized a cow-testing association. Since most of the members were using purebred sires they were on the right track as far as the breeding problem was concerned. The first year's testing showed an average production of 275 pounds of butterfat per cow, which was 17 pounds more than the average production of the cow-testing association cows in that State.

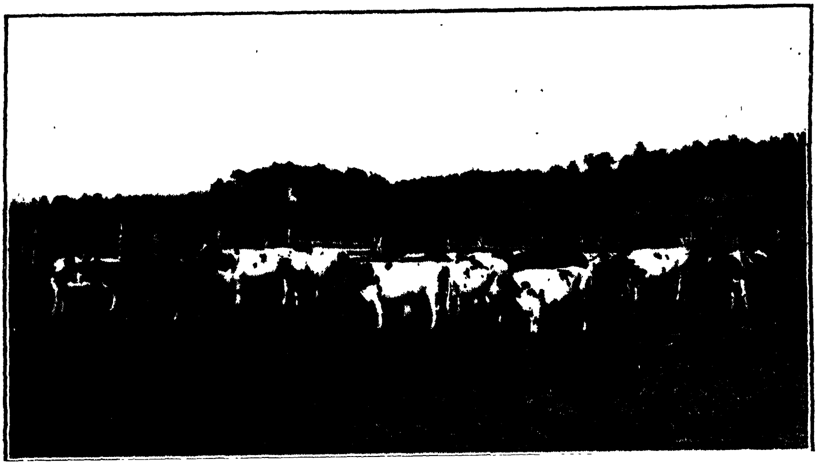

FIG. 61.—A herd of grade Holstein cows in a Virginia cow-testing association whose yearly average per cow was over 300 pounds of butterfat

Reorganization of this association for a second year was easily accomplished, and at the end of that testing year the records showed an average of 301 pounds of butterfat per cow.

The third year's testing showed a further gain, with an average of 325.9 pounds of butterfat per cow. At the end of the third year the 13 herds that had been on test from the beginning averaged 364.4 pounds of butterfat per cow.

### Fourth Year's Work Started

The fourth year of testing is under way at the present time, and the value of the work has been demonstrated so conclusively in the community that two associations are now in operation. Not only has the association work itself grown, but the adoption of better practices in the related farm enterprises necessary to better dairying has also kept pace. During the past year the number of members growing soy beans has increased 50 per cent, and the number growing alfalfa has increased 300 per cent. The tester is in constant touch with the feed markets and suggests the use of purchased concentrates when the price will justify their use. All but three members have silos, and every member feeds his cows according to known production.

It is the aim of the members at all times to make the greatest use of home-grown feeds. To do this they plan to grow the proper kinds of feeds, to obtain large yields, and to market these feeds in the most efficient way. The higher the production of the cows the better the market becomes.

Few, if any, cow-testing association herds will be found that make the 300-pound mark during the first year of testing. This may occur, of course, if the herd owner has previously kept records of his individual animals and used them as a guide in improving his herd. High-producing herds are the result of the application of intelligent business methods and are not hit-or-miss occurrences.

Practically one-third of the present-day cow-testing associations are in the 300-pound class. The members, in general, have followed the constructive guidance of testers in the close selection of their dairy cows, proper feeding methods and approved breeding practices. This has resulted in the building of these associations to a high level of production.

## CRATES for Livestock Built to Fit the Animals

The breeder loses when stock is shipped in crates that are too small for the animals. The stock is cramped and often injured thereby. The accompanying illustrations (figs. 62 and 63) show standard types of crates developed by the Forest Products Laboratory, cooperating with the University of Wisconsin and the Wisconsin Livestock Breeders' Association. The cow crate allows plenty of head room with the stanchion on the inside, and will take mature cows of any breed of dairy cattle. The same proportions may be used in building crates for larger or smaller animals.

Special features of these crates are (1) slats nailed close together a foot or more above the floor to prevent leg injury; (2) a simple and very convenient end gate; (3) a floor nailed crossways on skids for strength; (4) diagonal braces to prolong the life of the crate.

The simplest method of construction is as follows: Build the floor first, nailing the floor boards squarely across the two skids (cow-crate skids are 2 by 4 inches; hog-crate skids are 2 by 2 inches). Build each side separately, nailing the slats inside of the two uprights, driving the nails through from the inside and clinching them on the outside. Next, put on the diagonal braces and nail uprights and braces firmly to the floor. Nail the slats and braces to top and front end. Build the rear-end gate. Lastly, in the cow crates, put in the stanchion.

Light wood should be used and sevenpenny nails for the 1-inch lumber, with larger nails for the heavier material.

Bills of material for cow and hog crates follow, the first figure signifying the number of pieces required for the length mentioned.

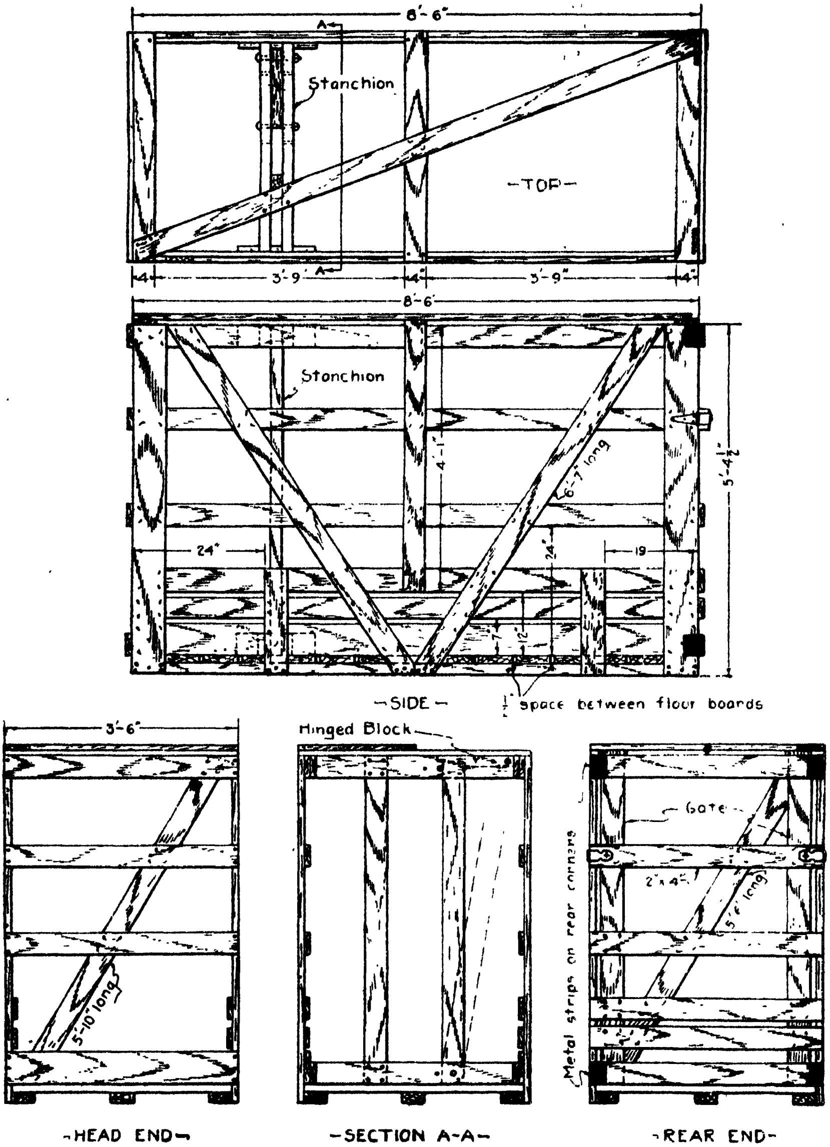

FIG. 62.—Working plans for cow crate

## Credit for the Farmer

The year 1926 was in general a period of abundant loanable funds and declining interest rates. Though costs of agricultural loans as a rule showed little variation over short periods of time, the interest and discount rates on such loans to some extent followed the general trend during 1926. This is true in a limited way of personal and collateral credit for agricultural purposes and even more so in the field of farm-mortgage credit.

### Personal and Collateral Credit

Particular interest centers at this time in the operations of the Federal intermediate credit banks and of the various agricultural-credit corporations organized primarily to take advantage of the discount facilities offered by these banks. The intermediate credit banks being regional institutions can not deal direct with individuals but they do loan direct to cooperative organizations, although their primary purpose is to rediscount agricultural paper for banks, agricultural-credit corporations, and other financial institutions. On June 15, 1926, the interest rate on direct loans by the intermediate credit banks was reduced from 5 to 4½ per cent and on July 1 the rediscount rate was reduced from 5 to 4¾ per cent.

The volume of direct loans of the 12 Federal intermediate credit banks on December 31, 1926, was roughly $52,704,000, representing an increase of about a million dollars over the amount of such loans outstanding on the corresponding date of 1925. The rediscounts of these banks on December 31, 1926, amounted to $39,757,000, representing an increase of $13,500,000 over the rediscounts outstanding at the beginning of the year. Of these rediscounts at the end of the year, approximately $23,864,000 represented paper discounted for agricultural-credit corporations, and about $15,542,000 represented discounts for livestock-loan companies. The remaining $351,000 represented agricultural paper discounted for banks. The service of the Federal intermediate credit banks has been materially greater than the volume of their loans would indicate. As a readily available source of discount for longer-term loans these banks also strengthen and encourage private agencies in meeting agricultural credit needs.

There was a marked increase in the number of agricultural-credit corporations during the year, the number of such corporations rising from 300 at the beginning of the year to about 400 at the close. These credit corporations have in general proved of decided benefit to their members by furnishing production credit at a reasonable cost and on terms in other respects fairly well adapted to the farmers' needs.

The cooperative marketing associations have been instrumental in organizing a number of credit corporations which are managed more or less as subsidiaries of the cooperatives. The latter are interested in having the production program of their members financed as economically as possible on a plan which tends to encourage the use of cooperative marketing organizations.

### Farm-Mortgage Credit

In the field of farm-mortgage credit the Federal farm loan system is an increasingly important factor. The net loans of the 12 Federal land banks oustanding at the close of 1926 exceeded a billion dollars, while the loans of the 54 joint-stock land banks was about two-thirds of a billion. This means that banks operating under the Federal farm loan act carried about one-fifth of the total farm-mortgage loans from all sources. Other important sources of such credit are local commercial banks, life insurance companies, farm-mortgage companies, and private individuals.

Seven of the Federal land banks reduced their interest rates during the year from 5½ to 5 per cent, and three others reduced their rates to 5¼ per cent. Two Federal land banks are retaining the old rate of 5½ per cent. The joint-stock land banks have also reduced their rates of interest. A few of these banks are now making loans at 5 per cent, but most of them charge 5½ per cent.

Many private loan agencies have also reduced their interest rates on farm-mortgage loans. In certain localities the farmer now has a choice as to source of loan on a 5 per cent basis. In most sections, however, the rates of private loan agencies continue relatively high and are apparently only slightly affected by the lower rates offered by the Federal and joint-stock land banks. Many farm-mortgage loans are of course made on security that would not be acceptable to the banks in the Federal farm loan system, and where the security is less ample, a higher rate is naturally to be expected. In general, however, there is apparent a tendency toward greater uniformity in interest rates as well as a reduction in such rates among all groups of loan agencies and for all parts of the country. The low and relatively uniform rates of the banks comprising the Federal farm loan system are undoubtedly a primary factor in bringing about this desirable change.

## CREDIT Through United States Warehouse Act

The serious condition in which the cotton grower found himself in 1914 resulted in the passage of the United States warehouse act in August, 1916. It was the opinion of many who had given serious thought to the cotton situation that if the farmers did not all try to sell their cotton within a few weeks following harvesting, but placed it in a warehouse and released it as the market could absorb it, that relief would follow.

Few growers of any products are in a position financially to do this. Besides, warehouse receipts covering agricultural products in the hands of the growers had little or no standing for credit purposes. Almost without exception the receipts conveyed no information as to the value of the products. Even the local banker who loaned to the farmer did so, not on the basis of the warehouse receipt, but on the basis of his opinion of the farmer or by virtue of a chattel mortgage against the products.

The framers of the warehouse act aimed to produce a warehouse receipt which would give specific information as to the quantity, grade, and condition of the product, and to have the warehouse receipt form a definite contract between the warehouseman and the holder of the receipt. Their big concern was to draft legislation so that the farmer might be furnished with a warehouse receipt that would make it possible for him to store some of his products at harvesting time and obtain a warehouse receipt on which he could borrow a fair amount of the value of the product. That meant that the law must be so worded as to put value into the receipts in such form that the banker could readily recognize it and to guard that value so long as the receipt was outstanding.

Ten years have elapsed since the warehouse act was passed. During those 10 years all has not been well with agriculture. In 1920 and 1921 agriculture passed through one of its greatest depressions. Has the warehouse act functioned in the meantime? Has it in any measure accomplished its purpose? Has it commanded the attention of bankers? Have they loaned their money on products represented by Federal warehouse receipts, and after having had experience, are they still willing to loan on such collateral? The acceptability of Federal warehouse receipts to bankers is a real test of the value of the warehouse act. Proof of the value of this law can best be demonstrated by accomplishment.

### Results in 1921 and 1922

The first several years following the passage of the law had to be devoted to investigational work, to drafting of proper regulations and to educational work with warehousemen, storers of agricultural products, and bankers. But when the agricultural depression of

1920 and 1921 came, then the warehouse act began to attract attention. It was first made use of in a big way by the Mississippi Staple Cotton Growers Cooperative Association. When officials of that Association approached the War Finance Corporation for a loan of $7,000,000 in 1921 and promised warehouse receipts issued under authority of the United States warehouse act as collateral for the loan, their application was almost immediately granted. A few weeks later the application of a tobacco growers' cooperative association for $30,000,000 was granted by the War Finance Corporation. Here again the Federal warehouse receipt was the collateral. Following these applications others were granted for large amounts.

By this time commercial bankers were becoming acquainted with the Federal warehouse receipt. Individual farmers were beginning to find the receipts of real value among their local bankers, while bankers in metropolitan centers were seeking this type of collateral. Other cotton and tobacco growers' cooperative associations, wool growers' associations, peanut growers' associations, and grain growers' associations were storing their products in warehouses operated under this law, and commercial bankers were loaning many millions annually on this collateral, and that, too, at unheard of rates.

Some of the Federal reserve banks early recognized the value of warehouse receipts issued under authority of the Federal warehouse act. The Atlanta Federal Reserve Bank in 1920 called attention of its member banks to the desirability of this type of collateral. The Federal Reserve Bank of St. Louis shortly after made attempts to impress upon its member banks the need for sounder warehousing practices in the agricultural field and shortly afterward adopted a policy that it would not accept as collateral warehouse receipts for agricultural products which were eligible for storage under the United States warehouse act unless such receipts were issued by a warehouse duly licensed under that act.

### Intermediate Credit Provided

In March, 1923, came the Federal intermediate credit act. After thorough study of the Federal warehouse act and regulations thereunder, the Federal Farm Loan Board, which administers the intermediate credit law, ruled:

> Intermediate credit banks will accept the receipt of any warehouse licensed and bonded under the United States warehouse act.

Early in 1922 the strictly commercial banks began to be actively interested in loans which would be supported by Federal warehouse receipts. The New Orleans Clearance House Association in June, 1923, expressed the attitude of the bankers of that city in this language:

> *Resolved*, That the New Orleans Clearing House Association, recognizing that Federal Bonded Warehouse Receipts are preferable for collateral purposes, and that the safeguards offered by the Federal Warehouse System, through its selection in admitting warehouses into the system, its supervision and inspection of warehouses, and the bonded responsibility of the warehousemen, are to the interest of financial institutions handling warehouse collateral as well as the patrons of such warehouses, including producers and merchants, hereby expresses itself as favoring the licensing of warehouses under the

> United States Warehouse Act, and urges upon warehousemen in the State of Louisiana to operate their warehouses under this statute.

This action was followed by similar or identical action by bankers' associations in other sections.

### Bankers Indorse Warehouse Act

In the Pacific Northwest the bankers manifested an interest in Federal warehouse receipts as early as 1920. In the State of Washington the interest was crystallized into action at the annual meeting of the bankers' association in June, 1926, in the following language:

> *Be it resolved by the bankers of Washington at Walla Walla in their thirty-first annual convention assembled,* That we commend all warehousemen in this state who are operating under the United States Warehouse Act and we urge upon warehousemen who are not doing so to qualify under the provisions of the Act. We recommend that in the interest of agriculture in the Northwest and as a means of protection to farmers who store their products with public warehousemen that our members discriminate between applications for loans supported by warehouse receipts issued under the United States Warehouse Act and applications supported by other forms of receipts, and that we each counsel with our farmer and dealer clients with a view of educating them in the advantages of the Federal Warehouse Act.

A large bank in New York City which has loaned many millions on agricultural products at low interest rates and which is ready to loan many millions more, in acknowledging a list of licensed warehousemen which is sent to certain bankers at regular intervals, recently wrote:

> In actual practice in this institution, when we find the name of a warehouse on your list we feel it unnecessary to make any further inquiry into its standing, and this fact is of great value to us in our commodity financing operations.

Accurate figures are not available as to the amounts that may be loaned annually on Federal warehouse receipts but a conservative estimate places the total amount well above $500,000,000. Not only are large sums loaned to growers and their cooperative organizations and others handling agricultural products, but frequently because of the character of collateral the loans are made at very decidedly better interest rates than have been offered when other than Federal warehouse receipts constituted the security. A concrete instance of the effect of Federal warehouse receipts on interest rates is the case of a dried-fruit growers' organization which advised that through this type of collateral it was able to get money for 2 per cent less than it could on its former type of collateral. In addition, the interest of banks in metropolitan centers in these Federal warehouse receipts has had a stabilizing influence on local bankers who were sometimes disposed to charge high rates.

### Unlimited Reservoir of Credit

The reservoir of credit that is available to agriculture for orderly marketing through the warehouse act seems unlimited, granting that the applicant is entitled to credit. Scarcely a week passes that those who administer the warehouse act do not receive an inquiry from some large banking institution wanting to learn of parties who may be seeking loans and who can offer Federal warehouse receipts.

The Federal warehouse act has already accomplished the purposes of the framers of the law. It has made sound, orderly marketing possible. It has opened new avenues of sound credit to the farmer and others handling agricultural products. It has a record of accomplishment. It is a reality.

H. S. YOHE.

## CROP Acreage by Actual Measuring

Evidence of the extent of the yearly changes in the acreages of crops is now being obtained by actual measurements. A simple machine devised by the Government crop reporting service, measures in feet the frontage of fields devoted to each crop along thousands of miles of roads in each important agricultural State.

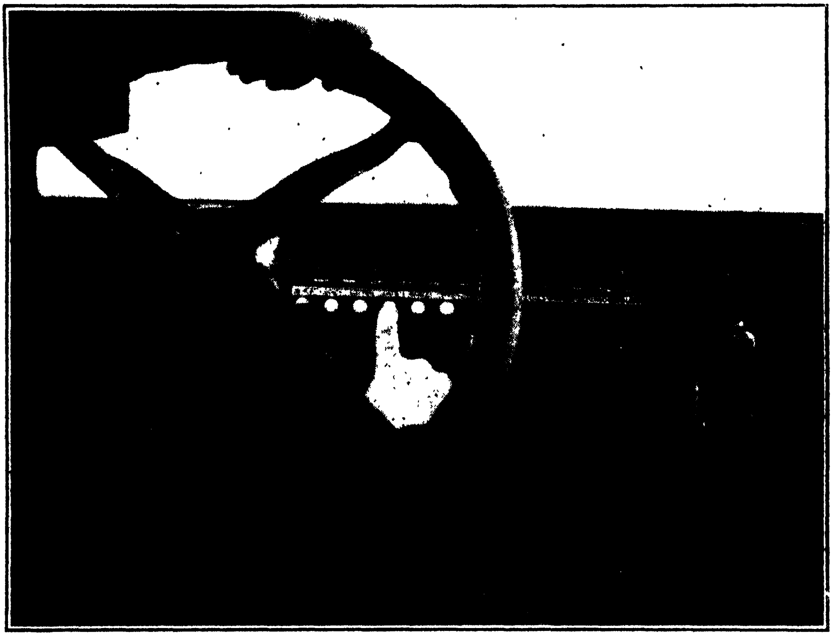

FIG. 64.– The cropmeter is attached to the dash of the automobile and the speedometer. Keys are provided to record principal crops

The new device is installed in an automobile in the same manner as a speedometer and has a dozen or more dials with buttons for throwing them into gear. By pressing the proper button at the corner of each field the frontages of the different crops along the road traversed are separately recorded. Permanent routes selected to give proper samples of each agricultural section are followed year after year. Measurements are made under uniform rules so that all records may be comparable.

The measurements along identical routes in successive years are compared to determine annual changes. If, for example, it were found that the total measured frontage of fields of oats in a particular district on identical routes was 500,000 feet in 1925 and 475,000 feet in 1926, a decrease of 5 per cent in the oats acreage would be indicated.

This method gives results unaffected by personal interest, public propaganda for acreage changes, momentary enthusiasm or discouragement, and other psychological factors that interfere with the accuracy and comparability of figures based upon the judgment or opinion of even those best informed.

Other objective methods for determining acreage changes have been used for many years by field estimators of the crop reporting service. Counting the number of fields devoted to each crop, or of the number of telegraph or telephone poles in front of fields of different crops, along the same route in successive years has been done for about 15 years. These earlier methods were very useful, although they involved more difficulties and were less accurate than the present plan.

S. A. JONES.

---

## CROP Yields per Acre Show Gain

Despite common belief to the contrary, crop yields per acre have been rising slowly in the United States during the past 40 years. In fact. a considerable part of the increase in the volume of production of the important food and feed crops during that period has been due to the gradual increase in yields per acre. This increase has been most notable in the long-settled northeastern section of the United States, where some of the land has been supposed by many to be wearing out.

Since the population is growing steadily and the lands of good quality which are easily available for use without reclamation are already largely employed for crop production, the problem of agricultural productivity and soil fertility in their relation to our future food supply will become a more and more important phase of the problem of land utilization.

The future trend of acre yields can be estimated best on the basis of past performances. The average yield per acre of corn in the United States has increased from 23.4 bushels for the 5-year period 1883–1887 to 27.7 bushels for the 5-year period 1921–1925, or about 18 per cent; wheat from 11.9 to 13.9 bushels or 17 per cent; oats from 27 to 30.9 bushels or 14 per cent; and potatoes from 76.9 to 107.4 or 40 per cent (fig. 65). During the past four decades the combined acreage of corn, wheat, oats, and potatoes has been expanded about 52 per cent, whereas the total production of these crops has increased 77 per cent. It is evident, therefore, that nearly one-third of the increase in the production of these four crops can be assigned to increase in yield per acre, while two-thirds is owing to expansion of the acreage (fig. 66.)

The rise in the yield per acre of these crops during the past 40 years has made available, on the average, during the half decade, 1920–1924, about 440,000,000 bushels more of corn, 120,000,000 of wheat, 165,000,000 of oats, and 115,000,000 bushels of potatoes, or in all over 800,000,000 bushels of the four feed crops more than would have been realized under the yield level prevailing at the beginning of the period.

Most of the increases in acre yields have occurred in the older farming regions east of the Mississippi River, thus disproving an-

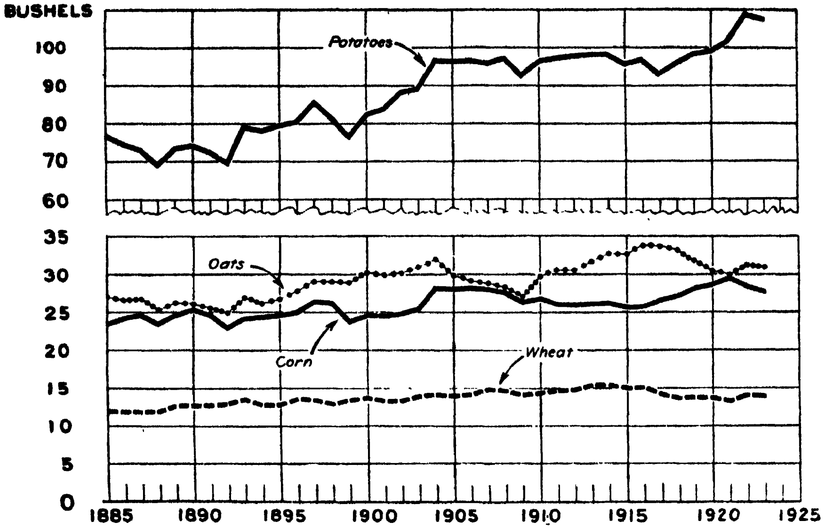

FIG. 65.—Yield per acre of corn, wheat, oats, and potatoes for United States, five-year moving average, 1885–1923

other erroneous impression that farms in the older areas of the United States in general have become worn out. The record of the past four decades indicates that the outstanding increases in yields have been in the North and South Atlantic States, with lesser increases in the eastern North Central States. In a general way these sections comprise the oldest farming regions in the United States. The soils in these regions have already entered or are now entering the period of permanent use, the pioneer methods of the past century having largely passed away. Similar changes have occurred in many portions of the western North Central States where pioneer agricultural methods have disappeared.

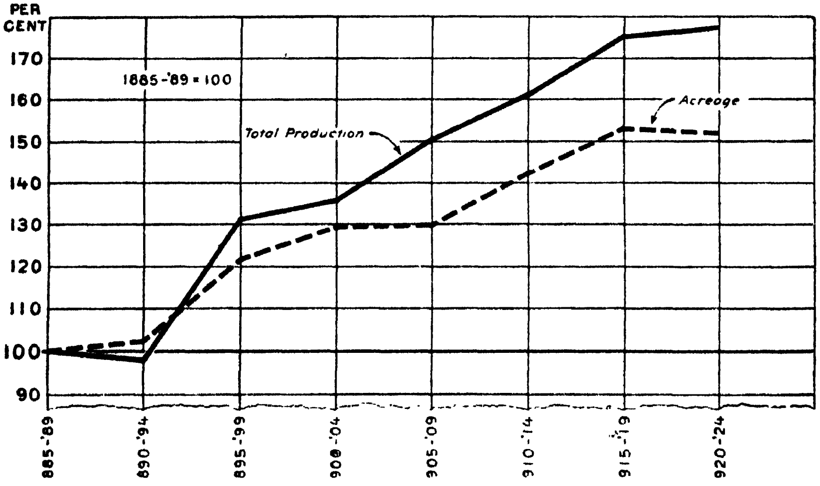

FIG. 66.—Trend of combined acreage and total production of corn, wheat, oats, and potatoes in the United States, 1885–1889 to 1920–1924

In the case of corn yields especially, a marked rise has taken place in the northern portion of the South Atlantic States. Virginia and North Carolina corn yields have increased 10 and 12 bushels per acre, respectively, during the past 40 years, and Maryland yields over 14 bushels. In New England the increase is over 10 bushels, and in the other North Atlantic States the increase has been from 6 to 10 bushels per acre according to the State, while Iowa and Minnesota show, respectively, increases of 8 bushels and 6 bushels per acre.

### Rise in Wheat Yields

The record of wheat yields for the several States shows a rise during the period of 5 to 6 bushels per acre in the northeastern portion of the United States, although in Ohio and other States in the Ohio Valley the general upward trend was interrupted by a marked decrease in the average wheat yields for the period 1920–1924, largely the result of unfavorable weather during the first three years of that period.

Despite the expansion of the wheat area in Kansas into the semiarid portions of the State, yields have remained practically stationary for the entire 40 years, because the lower yields of the newer semiarid areas have been offset by increased yields in the older humid portion of the State. Yields in Missouri on a considerably expanded wheat area have remained low, notwithstanding a temporary increase in the 5-year period just before the war. They are now about where they were 40 years ago. Statistics of yield per acre seem to suggest that the southern part of the Corn Belt, as represented by Missouri and eastern Kansas, has lagged behind the northern portion, as represented by Iowa and Illinois, in the development of agricultural practices and soil-management methods that tend to raise the acre yields of important crops.

### Pioneer Methods Delay Progress

In the spring wheat region the persistence of pioneer methods and the continued expansion of wheat production into drier areas have prevented a rise in the State averages. Moreover, since moisture is commonly the limiting factor in crop production in the semiarid portions of the Plains States, it appears probable that this part of the United States will not experience, at least in equal degree, the tendency toward rising acre yields which is shown by the statistics for the Northeastern States.

It seems safe to presume that developments in the coming years with regard to acre yields will depend, as in the past, to a great extent on the prices of agricultural products. Rising values of food products normally would result in increasing intensification and a higher level of soil productivity through the wider use of better cultivation methods, development of suitable rotations, including the growth of legumes, more efficient use of crop residues and animal manures, greater use of commercial fertilizers, and the more common use of selected seed. It seems not unlikely that in the course of time acre yields in the humid, northeastern portions of the United States may approach the present standards in northwestern Europe, which are about a third higher than in our Northeastern and eastern North Central States in the case of wheat and oats, and fully 40 per cent higher for potatoes.

B. O. Weitz.

## CUCUMBER Mosaic and How to Control It

Cucumber mosaic is one of the most serious diseases affecting the cucumber in the Eastern, Central, and Southern States. Mosaic plants are dwarfed, the younger leaves are mottled with green and yellow, and the fruits are also mottled and misshapen; the darker areas forming warty projections on the surface. The cause of mosaic is unknown, but the juices of mosaic plants contain an infective principle or virus which produce the disease when introduced into wounds in healthy plants. The disease is disseminated chiefly by insects, particularly the melon aphis, *Aphis gossypii* and, to some extent, by the striped cucumber beetle, *Diabrotica vittata*, and the 12-spotted beetle, *D. 12-punctata*. It is also spread by the handling of mosiac and healthy plants. The most effective control for the disease consists in the elimination of the agencies by which it is carried over winter.

Mosaic does not live in the soil and is not carried in the seed of the cultivated cucurbits, but is known to live from year to year in certain wild plants, some of which occur in most of the cucumber growing sections. The known wild hosts are the wild cucumber, *Micrampelis (Echinocystis) lobata*, milkweed, *Asclepias syriaca*, two species of wild ground cherry, *Physalis subglabrata* and *P. heterophylla*, and catnip, *Nepeta cataria*. Unlike the cultivated cucurbits, the disease is carried in the seed of wild cucumber, but the other hosts are perennial, the roots of mosaic plants sending up mosaic shoots each year. The insects which carry mosaic in the field also feed on these wild hosts in the spring and the disease is thus transmitted to the cultivated cucumber.

In a number of fields where the average mosaic infection had been approximately 40 per cent, it was reduced to 3 per cent after the eradication of wild host plants. As a result of these experiments, the following methods are recommended for the control of cucumber mosaic: Cucumbers should not be planted continuously on the same land and the field should be some distance from the farm buildings. Mosaic perennials accumulate about land which is constantly planted to cucumbers and are often common about farm buildings. Before planting, the field itself and all land within 75 yards should be carefully inspected and all plants of the species listed above, whether healthy or mosaic, should be pulled out.

In the case of the pokeweed the large roots should be dug out or otherwise destroyed. This inspection should be repeated every 7 to 10 days during the season. If the cucumber field can be surrounded by other cultivated crops, the work of eradication will be simplified and insects are likely to be less prevalent. Where mosaic cucumber plants appear early in the season they should be removed immediately to prevent further infection and it is also advisable to use insecticides to reduce the number of insect carriers of the disease. If carefully followed, the above procedure should greatly reduce the losses from mosaic under ordinary conditions but, where several fields are adjacent to one another, it is essential that all growers cooperate in removing the wild hosts about their fields.

S. P. DOOLITTLE.

## CYANIDES and Hydrocyanic Acid in Farm Operations

If you ate an orange for your breakfast this morning and it came from California, the chances are very good that that orange was protected from insect pests in the early stages of its growth by the use of hydrocyanic-acid gas. Thousands of tons of this interesting substance are now used annually for that purpose. The usual method of application is to cover the tree to be treated with a tent under which the hydrocyanic-acid gas is liberated either by (1) simply opening a can of liquid hydrocyanic acid, which vaporizes to give the gas at ordinary temperature, (2) treating sodium cyanide with sulphuric acid, or (3) exposing a quantity of solid calcium cyanide, a comparatively new substance on the market, which is acted upon by the moisture of the air, to give hydrocyanic-acid gas.

The value of hydrocyanic acid as an insecticide and fumigant is by no means limited to citrus fruits, although that outlet is doubtless the most important. It has also been extensively used in the fumigation of greenhouses, flour mills, warehouses, the holds of ships, and residences, as well as for the extermination of rats and mice. The chief drawback to the use of hydrocyanic-acid gas is its deadly poisonous character, which necessitates extreme care to thoroughly ventilate before reentering a room after fumigation.

This versatile class of substances, the cyanides, has found extensive use in still other directions. Sodium cyanide has the property of dissolving gold and silver from their ores and it has been possible by making use of this principle to recover values from ores which could not have been economically worked under the older methods. Considerable quantities are also required as an essential constituent of the solutions from which gold, silver, and other metals are plated onto metal surfaces.

### Sodium Cyanide Obtained

In the manufacture of these substances, sodium cyanide is practically always obtained either as the final product or as an intermediate step in the preparation of hydrocyanic acid or calcium cyanide. Sodium cyanide contains the chemical elements, sodium, one of the constituents of common salt, carbon, and nitrogen. The older method of manufacture consisted in treating sodium at a high temperature with powdered coke and ammonia gas obtained as a by-product in the making of coke from coal. It has long been known that sodium cyanide is one of the comparatively few nitrogen compounds which may be made directly from the nitrogen of the air. This has been accomplished commercially in recent years by heating a mixture of soda ash and coke (with a small proportion of iron) in the presence of nitrogen gas. A third method for the manufacture of sodium cyanide consists in melting lime-nitrogen—the primary product which United States Nitrate Plant No. 2 at Muscle Shoals, Ala., was designed to produce—with common salt.

If hydrocyanic acid is desired, sodium cyanide is treated with an acid, usually carbonic acid, and the hydrocyanic-acid gas resulting is condensed to a liquid, for convenience in handling, by refrigeration. Calcium cyanide is obtained by treating calcium carbide, such as used in acetylene-lighting plants, with liquid hydrocyanic acid.

E. W. GUERNSEY.

---

### DAIRY By-Products and Methods of Utilizing Them

In the manufacture of butter, cheese, and casein very large quantities of skim milk, buttermilk, and whey are produced. The total quantity of these by-products produced in the United States in 1924 was 22,724,340,000 pounds of skim milk from butter making, 1,356,080,000 pounds of buttermilk, and 4,320,223,000 pounds of whey; a total of 28,400,643,000 pounds. Some of this is delivered at factories where it is available for manufacturing purposes; but the greater part, particularly the skim milk, is retained on the farms and fed to animals. Although it may at times be used inefficiently it can not be considered a waste product. In city milk plants the skim milk, for lack of any market, is sometimes run into the sewer. This is also true of buttermilk in some of the creameries located in cities. Whey is usually carried back to the farms from the smaller cheese factories. In some cases, however, it is not only a waste product but a nuisance, on account of the difficulty of disposing of sewage containing so much putrescible material.

Skim milk, buttermilk, and whey contain material entirely suitable for human food. These include protein in an easily digestible and assimilable form; milk sugar, which is valuable not only for its food content but also for certain physiological effects; a relatively small quantity of fat; and salts in a combination especially suited for human nutrition. Table 6 gives the quantity of food material in each of the dairy by-products, the total of which is over 2,500,000,000 pounds. Of this nearly 900,000,000 pounds is protein, the most expensive of our food constituents.

TABLE 6.—*Quantity of dairy by-products produced annually in the United States*

| | Skim milk | | Buttermilk | | Whey | | Total |
|---|---|---|---|---|---|---|---|
| | *Per cent* | *Pounds* | *Per cent* | *Pounds* | *Per cent* | *Pounds* | *Pounds* |
| Casein | 2.75 | 624,919,000 | 2.8 | 37,970,000 | 0.10 | 4,320,000 | 667,209,000 |
| Albumin | .80 | 181,794,000 | .8 | 10,840,000 | 0.75 | 32,400,000 | 225,034,000 |
| Total protein | ...... | 806,713,000 | ...... | 48,810,000 | ...... | 36,720,000 | 892,243,000 |
| Lactose | 5.25 | 1,193,025,000 | 4.4 | 59,667,000 | 4.80 | 207,370,000 | 1,460,062,000 |
| Ash | 0.80 | 181,796,000 | 0.7 | 9,492,000 | 0.60 | 25,921,000 | 217,209,000 |
| Fat | 0.10 | 22,724,000 | 0.1 | 1,356,000 | 0.35 | 4,320,000 | 28,400,000 |
| Total solids | ...... | 2,204,258,000 | ...... | 119,325,000 | ...... | 274,331,000 | 2,597,914,000 |

This immense quantity of food material may be better comprehended by considering that 7,400,000 prime steers, which is only a little less than the total number of cattle slaughtered in Federally inspected plants in 1924, would be required to produce the protein contained in our 28,000,000,000 pounds of dairy by-products. The desirability of utilizing the greatest possible quantity of this material as human food is too obvious to need discussion. It is true that the greater part is now converted into human food by feeding it to calves, pigs, and poultry. In utilizing it in this way it should be kept in mind that milk, which is eminently suited for human nutrition, has been made from roughage which can not be utilized by man. In feeding milk to farm animals we are merely converting it into food in a new form and using for this purpose animals capable of making human food from material unavailable to us. Moreover the changing of skim milk to pork or poultry results in a decided loss in food value.

Table 7 is obtained by assuming that 6.4 pounds of digestible nutrients is required to produce 1 pound of edible pork, and 23.4 pounds to produce 1 pound of edible fowl.[4]

TABLE 7.—*Available quantity of food produced if all skim milk, buttermilk, and whey were fed to hogs or chickens*

| | In by-products | In pork | In fowl |
|---|---|---|---|
| Protein ........ pounds.. | 892, 243, 000 | 52, 557, 000 | 21, 427, 000 |
| Carbohydrates ........ do.... | 1, 460, 062, 000 | | |
| Fat ........ do.... | 28, 400, 000 | 139, 028, 000 | 18, 096, 000 |
| Ash ........ do.... | 217, 209, 000 | 9, 133, 000 | 1, 110, 000 |
| Total dry edible matter ........ do.... | 2, 597, 914, 000 | 200, 718, 000 | 40, 453, 000 |

### Feeding to Animals Unavoidable

Notwithstanding the inefficiency of this method it will probably be necessary for many years to come to utilize a large proportion of dairy by-products by feeding them to animals. In the meantime it is highly desirable that means be perfected and put into practice for converting as much as possible of these by-products into forms suitable for human use. Since it is difficult to make products from skim milk, buttermilk, or whey which appeal to the human palate, it will be necessary to resort to methods by which they may be incorporated into staple articles of food.

When a satisfactory market can be developed cottage cheese is one of the most profitable outlets for skim milk. A yield of 14 to 17 pounds per 100 pounds of skim milk is obtained, and this may be sold in bulk at from 3 to 6½ cents per pound. The equipment required is simple and inexpensive, and no great technical skill is required in its preparation. Its disadvantages lie in the seasonal variation in the demand and in the short life of the product, which must be marketed within a few days after it is made.

Casein is like cottage cheese in that the equipment required is comparatively simple, and the cost of manufacture is low. Vats for curdling the milk, draining racks with cloths, presses, a curd mill, and a tunnel drier with drying trays are essential. Most of this equipment may be homemade. A yield of 3 to 3½ pounds of casein per 100 pounds of skim milk is obtained, and the cost of manufacture is estimated at 2 to 3 cents per pound. The price, which varies from 7 to 15 cents per pound, does not make this a profitable means of disposing of skim milk, but it has the advantage of being a stable product which can be made whenever milk is available and can be marketed when convenient. From 85 to 90 pounds of whey is obtained from each 100 pounds of skim milk. This may be used in making milk sugar or other products.

---

[4] JORDAN, W. H. THE FEEDING OF ANIMALS, p. 422.

Casein is used principally in making coated paper, adhesives, fungicides and insecticides, and other minor products. Recently the manufacture of casein plastics has been developed in this country, and this industry may in time make casein a more profitable product.

### Condensed and Evaporated Skim Milk

Ice-cream makers and bakers use milk solids not fat in the form of sweetened condensed skim milk or evaporated skim milk. The former product is made by adding 18 pounds of sugar to each 100 pounds of skim milk and concentrating it in a vacuum pan to about 72 per cent solids. A yield of 37 to 38 pounds per 100 pounds of skim milk is obtained which usually sells at 4 to 6 cents per pound. When properly made this product keeps indefinitely. The evaporated milk is concentrated without the addition of sugar until it contains from 26 to 30 per cent milk solids. This is usually sold in 10-gallon milk cans. Since it is not sterilized it will not keep longer than Pasteurized milk or cream. When a large volume of skim milk is available and the market is favorable these products offer a satisfactory outlet for skim milk; but the investment in equipment, which includes a vacuum pan, coolers, and boilers, is large. If the sweetened product is made a considerable investment in sugar is also necessary.

Ordinary sour milk can not be concentrated satisfactorily because of its tendency to lump when heated and to burn onto the coils of the pan. If the acidity is increased by special cultures to 1.8 or 2 per cent lactic acid it may be condensed to one-third of its volume in a vacuum pan. This gives a smooth, pasty product with sufficient acid to inhibit completely the growth of bacteria and yeasts. When packed in tight barrels or other suitable containers it may be held indefinitely. This product sells readily to poultry raisers at 3¼ to 4 cents per pound. From 30 to 33 pounds per 100 pounds of skim milk is obtained. In addition to the vacuum pan the necessary equipment includes vats for Pasteurizing and souring the milk and an incubator to carry the starter.

### Milk Powder

From 8½ to 9½ pounds of dry skim milk can be made from 100 pounds of skim milk. This product sells from 7 to 14 cents per pound. The variation in yield is due to the composition in the milk, the amount of water retained, and the efficiency of the process in recovering the powder. Among the processes now available for making milk powder are the following:

The spray process. The fluid milk, sometimes partially condensed, is sprayed into a current of heated air, which removes the water and leaves the milk solids as a finely divided powder. Various devices are used to separate the powder from the moist air.

The roller or drum process. Steam-heated drums are so arranged that partially condensed skim milk is spread in a very thin layer on the outer surface of the drum. During the revolution of the drum the adhering film of milk dries and is scraped off. This dry film is reduced to a powder by revolving brushes or other grinding devices.

The vacuum drum process. This is really the roller process with the roller or drum inclosed in a vacuum chamber, thus making it possible to dry the milk at temperatures below the normal boiling point.

The flake process. Partially condensed whipped skim milk is spread on a wire belt which passes through a heated chamber where currents of hot air are directed against it. The dried product is removed from the belt in the form of flakes.

In selecting the type of drier to be installed, creameries should consider the quality of the powder to be made, the labor involved in operation, the recovery of the powder, and the efficiency of the process in utilizing the heat of the drying medium. The cost of drying will vary with the efficiency of the process, the cost of fuel, and various local conditions. It is estimated at from 2½ to 4½ cents per pound exclusive of royalties.

It is usually considered that a milk-drying plant can not be operated efficiently on less than 30,000 pounds of milk daily.

### Methods of Utilizing Buttermilk

Buttermilk has a composition nearly identical to that of skim milk, but the chemical effect of the acid developed in ripening the cream and the physical effect of churning have so changed its properties that its possible uses are very limited.

Casein can be made from buttermilk, but it is very difficult to obtain a satisfactory quality even from the best grade.

The acid flavor of any product made from buttermilk makes it difficult to use in any type of cheese. Even buttermilk from sweet-cream butter has a deleterious effect when mixed with skim milk to make cottage cheese.

The most satisfactory outlet for buttermilk at the present time is the concentrated or dried form for poultry and pig feeding. Concentrated to about one-third of its volume in a vacuum pan, it is sold extensively as semisolid buttermilk.[5]

There is a stable market for dried buttermilk through jobbers of feeding stuffs and manufacturers of proprietary feeds. The drying is usually done on steam-heated drums operated at atmospheric pressure. This equipment is less expensive than that ordinarily used in making milk powder.

### Methods of Utilizing Whey

Whey contains about 5 per cent of lactose, a sugar found only in milk and possessing certain physiological properties which make it of especial value in nutrition, nearly 1 per cent of completely digestible and assimilable protein, and the greater part of the salts of the milk. Thus the solids of whey have a high food value but are in such a dilute form that it is difficult to utilize them efficiently. Moreover, the sugar is relatively insoluble and low in sweetening power.

---

[5] The name "semisolid buttermilk" is a copyrighted trade name, and the process of concentrating buttermilk is covered by patents.

Whey from casein, cottage cheese, or other skim-milk products is low in butterfat; but cheese whey has an appreciable amount of butterfat which in some varieties is as high as 1 per cent. This can be recovered by separation and with reasonable care makes a satisfactory grade of butter.

Certain "appetite" cheeses can be made from whey. These include Mysost or Primost, made by evaporating the whey in an open pan until the sugar crystallizes, and cheese of the Ricotte type, made by coagulating the albumin with heat and drying it in molds.

The market for this kind of cheese is limited and at best offers an outlet for only a small quantity of whey. Aside from its use in feeding, the principal means of utilizing whey is in the manufacture of milk sugar. This requires vats for precipitating and filters for removing the albumin, a vacuum pan for concentrating, crystallizing vats, and a centrifuge for separating the crystals from the mother liquor. Additional equipment is necessary if the sugar is refined. The precipitated albumin is dried in a tunnel drier and sold as poultry feed. About 3 to 3½ pounds of crude sugar is obtained per 100 pounds of whey. It may be sold in this form to refiners at from 8 to 12 cents per pound, depending on the lactose content. The present consumption of milk sugar in this country is only about 4,000,000 pounds per year, and it is very easy to depress the price by overproduction.

It has recently been demonstrated that milk sugar is of great value in combating coccidiosis and other intestinal diseases of chickens. Poultrymen are now buying milk powder to obtain sufficient quantities of milk sugar, and it should be possible to use whey, which has a high milk-sugar content, for this purpose.

In plants where concentrated sour milk is made it is practicable to sour whey and mix it with sour milk before concentration. In this way a concentrated sour poultry feed is obtained with a high milk-sugar content.

L. A. Rogers.

## DAIRY Industry in Process of Change

There have been a number of important changes in the production of dairy products during the period from 1917 to 1925, inclusive, and while the changes have affected all products, the effect on the industry is more noticeable and far-reaching in those products of largest production, such as butter, cheese, condensed and evaporated milk, and ice cream.

The total quantity of milk produced in the United States has been increased from 87,609,400,000 pounds in 1917 to 116,505,395,000 pounds in 1925, or 33 per cent.

A few changes have been noted in the production of creamery butter, and all are important, for in each change the quantity of milk necessary to make the change has been very large. The production of creamery butter has increased during the period from an average monthly production of 63,293,000 pounds in 1917 to 113,460,000 pounds in 1925. That is, the production has increased 79.2 per cent in nine years. A part of this increase offsets the decrease in the production of farm-made butter, but the exact decrease in the farm-made butter is not of record. The average output per factory in 1917 was 193.036 pounds and in 1925 it was 366,494 pounds. That is, the production per factory increased 89.9 per cent, due partly to operating more nearly to capacity, but also due to the consolidation of factories.

The proportion of the total milk production of the country used in the manufacture of creamery butter was 17.8 per cent in 1917 and 24.54 per cent in 1925, an increase of 6.7 per cent.

### Seasonal Trend of Production

The seasonal trend of creamery-butter production has varied during the period. If the year is divided into two parts, namely, the feeding season (November to April, inclusive) and the grass season (May to October, inclusive), it appears that the trend has been toward an increased production during the feeding season. The increase in proportion of butter made in the feeding season was rapid for the years 1917 to 1920 or 1921. Afterward while the trend continued upward, it was less rapid. In 1917 the proportion of creamery butter made in the feeding season was 36.1 per cent and in the grass season 63.9 per cent. In 1925 the production in the feeding season had increased to 39.9 per cent of the total output, leaving 60.1 per cent for the grass season. These figures indicate that winter dairying for butter production is increasing. There was a sound reason for this change in the production of creamery butter during the period from 1917 to 1925. In Minnesota, for example, the average price of a balanced ration sufficient to produce a pound of butter in 1917, was 24.96 cents, and in 1925, 21.6 cents. The average price of 92 score butter in New York market in 1917 was 42.7 cents per pound. In 1925 it was 45.3 cents. The feed cost had decreased 13.5 per cent while the price of butter increased 6.1 per cent for these two years.

TABLE 8.—*Seasonal production of creamery butter in the United States*

| Year | Feeding season, November to April | Grass season, May to October |
|---|---|---|
| | *Per cent* | *Per cent* |
| 1917 | 36.14 | 63.86 |
| 1919 | 36.53 | 63.47 |
| 1923 | 39.84 | 60.16 |
| 1925 | 39.90 | 60.10 |

TABLE 9.—*Cost of feed and price of butter compared*

| Year | Feed (balanced ration necessary to produce a pound of butter) | Price of butter (92-score), on New York market | Difference |
|---|---|---|---|
| | *Cents* | *Cents* | *Cents* |
| 1917 | 24.96 | 42.7 | 17.74 |
| 1919 | 33.22 | 61.0 | 27.78 |
| 1923 | 20.97 | 46.9 | 25.93 |
| 1925 | 21.60 | 45.3 | 23.70 |

Increased production in the feeding season was to be expected, as the acreage of grassland has been decreasing for years and as during the period mentioned the price of feeds was at a comparatively low level; the economy of home feeding was taken advantage of by the dairyman in the butter-producing sections. The increase accrued to butter rather than to some other product largely because butter is the natural reservoir for all surplus milk of other branches of the industry.

### Increase During Feeding Season

Some of the other branches of the industry have had changes in production trends. In 1917 the cheese made in the country utilized only 4.3 per cent of the total milk and in 1925 the percentage had been reduced to 3.8 per cent of the total milk, though more cheese was made in 1925 than in 1917.

The percentage of the total milk produced used in the manufacture of condensed and evaporated milk in 1917 was 3.9, for 1925, 3.8. The output of these two products was greater in 1925 than in 1917.

The ice-cream industry has made very rapid increases in the past few years but still uses only a small percentage of the total milk of the United States. In 1917 the percentage of milk used was 3.3 and in 1925 it was 3.8, while the actual increase in total production of ice cream was 53.7 per cent. As there are practically no imports or exports of this product, production is equivalent to consumption. This branch of the industry is particularly subject to the effects of wide and rapid variations in weather conditions.

Milk used for household purposes, including consumption by bakeries and in public eating houses, affords the largest market of the dairy industry. In 1917 household milk was 41.7 per cent of the total milk produced in the United States; in 1925, it was 46.6 per cent. This increase in consumption was mostly in the cities, where many milk campaigns were carried on and where the health officials stressed the value of clean, safe milk. The per capita consumption of milk increased from 42.2 gallons in 1917 to 54.8 gallons in 1925.

T. R. PIRTLE.

---

## DATE Growing: A New Industry for Southwest States

The date palm, *Phoenix dactylifera*, was introduced into Florida and California, when these territories belonged to Spain, by Spanish explorers and missionaries nearly two centuries ago. Date palms are still growing in the San Diego Mission at San Diego, Calif., which were planted more than 150 years ago.

Choice varieties of dates can be propagated only by means of offshoots which sprout from the base of the trunk. The first successful importation of offshoots of standard date varieties was made in the summer of 1900 by the United States Department of Agriculture in cooperation with the University of Arizona. These offshoots were planted at the cooperative date garden at Tempe, Ariz., and more than 60 per cent of them lived and are still growing in this garden. They are now splendid palms, 25 to 30 feet high.

Date palms can be grown successfully only in hot irrigated valleys in the southwestern United States. Dates are now grown commercially on a large scale in the Coachella Valley lying just north of the Imperial Valley about 100 miles east of Los Angeles, Calif. They are being planted on a large scale in the Salt River Valley in Arizona, and on a somewhat smaller scale near Yuma. Ariz., and in the Imperial Valley in extreme southeastern California. Perhaps 25,000 or 30,000 date palms are now planted in California and Arizona in orchard form, and plantings are being extended very rapidly, especially in the Coachella Valley of California and in the Salt River Valley of Arizona.

### Setting Offshoots in Orchard Form

Good-sized offshoots properly rooted while still attached to the mother tree can be set out in orchard form in the late spring or early summer and if handled carefully take root within a few weeks and make some growth the first year. They grow rapidly the second or third year and begin to bear the fourth or fifth year, although they do not come into full bearing until the sixth or seventh years; sometimes even later. The young date palms produce abundant offshoots, the number depending upon the variety, ranging usually from 10 to 20 to the palm, but as the palm reaches the age of 10 or 12 years offshoot production ceases. As the date palm is propagated only from offshoots, the slow rate of offshoot production constitutes a natural bar to any sudden expansion of date plantings, for only home-grown offshoots are available for new plantings as the importation of date offshoots from abroad is now impossible under the present quarantine laws except when made by the Federal Government itself for experimental purposes.

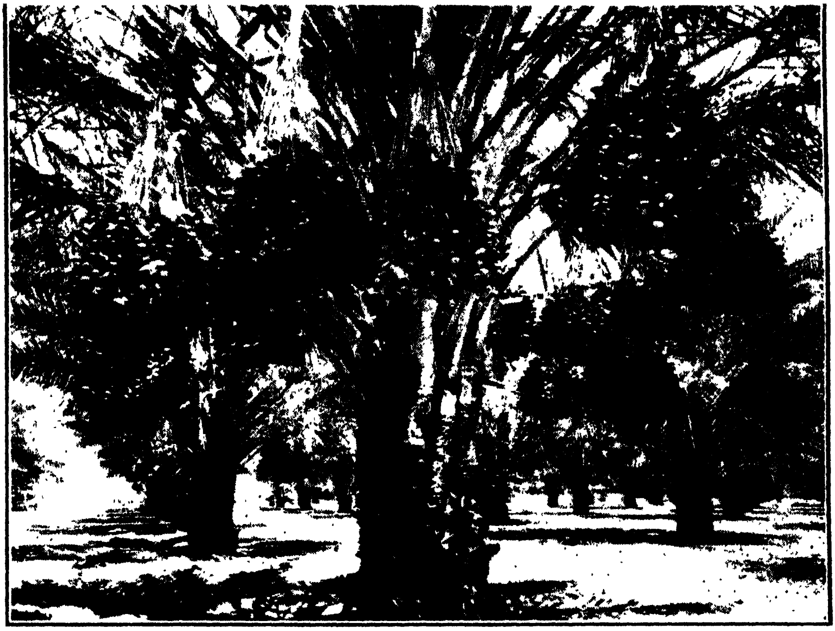

FIG. 67.—Eight-year-old Deglet Noor date palms in full fruit in private garden near Indio, Calif., October, 1924. Some of these palms yielded more than 200 pounds of fruit

It is highly important for anyone proposing to grow dates to realize that the date palm, unlike commonly grown fruit trees, can not be budded or grafted and consequently it is very important that varieties set out be suitable for commercial culture in the region where they are to be grown. Offshoots of good varieties are scarce and expensive, the price ranging from $10 to $25 an offshoot, and if 50 are planted to the acre, as is commonly done, the cost of nursery stock alone amounts to from $500 to $1,250 an acre. If such an expensive planting is brought into bearing and found to be of a variety unsuited to the region, there is nothing to do but dig up the palms at great cost and plant some other variety. It is therefore necessary to test out carefully date varieties in all regions where it is proposed to make date plantings, in order to determine which varieties are most likely to succeed on a commercial scale.

### Seedling Dates Inferior

Dates can be grown from seed but seedling dates are usually inferior to the mother variety and probably not more than 1 per cent of the seedlings are of sufficiently high quality to justify planting their offshoots on a commercial scale. Even where a choice new variety is originated in this way it is not possible to get enough offshoots to make any sizeable plantation until 20 to 30 years after the variety is originated. Large plantations of seedlings are hard to manage, too, since each palm is in effect a different variety and it is very difficult to market such a mixed production.

It should be remembered that the date palm is a diœcious plant, the male and female flowers being borne on different palms. Two or three male palms are usually planted to an acre of bearing dates, and the flowers of the female palm are pollinated by hand in the spring. Date palms bloom in January, February, March, and April, but mostly from the middle of February to the middle of April; and ripen in the United States from the middle of August to the middle of December, usually from the middle of September to the middle of November.

Great progress has been made in working out methods for picking, curing, packing, and storing dates, and the American-grown dates are of a much superior quality and appearance to those grown abroad. The quantity of dates now produced in the United States is about 1,000,000 pounds annually, but probably less than one-half of the crop is packed for long-distance shipment. The choice dates produced in this country meet with a ready sale at good prices.

### Not Thrifty in Salty Soil

Palms can be grown in salty soil, but do not thrive in such situations unless the roots have access to a layer of soil containing less than 1 per cent of soluble salts. In view of the present high cost of offshoots and the heavy expense of starting a date plantation, it is desirable to set out date palms in the very best fruit land and not attempt to grow them in alkali soil even though the date palm can stand more alkali than any other commonly cultivated fruit tree.

It is probable that date culture will be the leading fruit industry in many of the hot irrigated valleys of the southwestern United

States. It is believed that at least 11 counties lying in southeastern California, southwestern Arizona, and southern Nevada have larger or smaller areas where dates can be grown successfully on a commercial scale. In addition to these 11 counties there is a large area in southern Texas where date palms grow well and where they often ripen fruit. Rains are likely to occur during late summer and fall in most parts of southern Texas and such rains are usually very injurious to ripening dates. It is nevertheless believed that certain date varieties which are resistant to rain and moisture may be grown on a commercial scale in Texas and an experimental trial of the most promising imported varieties is now being undertaken by the Department of Agriculture in cooperation with the Texas experiment station.

FIG. 68.—Oldest date palms of standard varieties growing in California. Two of Rhaar's variety date palms planted at Indio, Calif., in July, 1900. Photographed October, 1924

The climatic hazards of the date are much less than of oranges, lemons, and other citrus fruits. Young date palms are injured by severe cold weather in winter but after the palms are well established they can stand temperatures as low as 15° F. without serious injury beyond the freezing of a few leaves. Dates are much injured by rain and many varieties are badly injured even by dew or excessive humidity during the ripening season. In general, rains and moist weather are the chief climatic hazards of the date grower.

### Yields Large Crops of Fruit

The date palm under favorable conditions yields a large crop of fruit, usually from 100 to 200 pounds, when the palms have reached full size, say 10 years after planting. The cost of picking is low, the curing in the packing house is easily done, and dates can be graded and packed as cheaply as any other dried fruit. The profits from date culture vary greatly according to the skill of the grower and market conditions, and range at the present time from $250 to $750 or even more an acre for plantations in full bearing. Probably the average net annual return is about $500 an acre.

There are many kinds of dates known to the Arabs, probably more than 1,000 in all. More than 100 varieties have been tested in the United States and of these not more than 10 or 15 have proved suitable for commercial culture in this country and only 4 or 5 are being planted on any considerable scale. Among the varieties which are now being grown on a commercial scale are the Deglet Noor from North Africa, the Saidy from Egypt, the Halawy, Khadrawy, and Zaheedy from Mesopotamia, and a few other special varieties grown on a small scale in commercial orchards. Among the latter is the Thoory from Algeria, which is sold as a dry date, and the Hayany from Egypt, which is likely to be sold soft, just as it is picked from the palm, without drying and curing. More than nine-tenths of the date palms planted in the United States belong to the seven varieties mentioned, and more than half are of the Deglet Noor variety. Other varieties, some of them very valuable, exist only in limited numbers as yet in this country and are still under trial, though doubtless some of them will some day become commercially important.

WALTER T. SWINGLE.

## DAYLIGHT a Factor in Flowering

The flowering of plants is a familiar observation to the flower lover and gardener. Within recent years it has been found that the flowering time of many plants can be controlled in a very simple manner. It has been found that the number of the hours of daylight which is in normal operation in nature can be made a controlling factor. It has been learned that the seasonal flowering of many plants is not as fixed, not as uncontrollable, as the rising and setting of the sun. To be sure, the rising and setting of the sun itself can never be controlled. In nature this regulates the number of hours of daylight over the earth throughout the seasons, thereby fixing more or less definitely the seasonal flowering of many of our plants. Knowing, however, that in nature the hours of daylight may control the flowering period of many plants, it is a simple matter to cut off daylight from experimental plants by placing them in dark houses or dark cases for definite periods each day.

If this is done in summer when the day is long, one can subject the plants to only 8 or 10 or 12 hours of daylight as he pleases. What happens? Some plants flower; some do not. Such plants as Klondyke cosmos, poinsettia, late varieties of chrysanthemums, dahlias, Jerusalem artichoke, African marigold, Orange Prince, the Maryland Mammoth variety of tobacco, and late soy-bean varieties (Biloxi and others) flower long before their normal time in late summer or fall when this is done. Many of our wild late-flowering asters and goldenrods respond in the same manner. While these fall-blooming plants flower, such plants as bee balm or Oswego tea, coneflower (*Rudbeckia bicolor superba*), the coneflower variety Autumn Sun (*R. nitida*), the garden stonecrop (*Sedum spectabile*), hollyhocks, garden beets, and others do not flower if the day is shortened. They behave otherwise because they require the long days of midsummer in which to flower; and if short daylight periods of 12 hours or less are given them, they grow rosettes of leaves only, just as they do in fall and winter in the field when the days are normally short.

### Electric-Light Experiments

We have shortened the daylight artificially; now how can we lengthen it artificially when the wintertime brings us short days, less than 12 hours in length? Electric light has been used, and in many instances it works when the proper intensity has been given. It keeps from blooming the plants that want short days for flowering, and it hastens into flowering the long-day plants, beets, spinach, radish, Oswego tea, and the coneflowers mentioned above. No matter how warm and favorable other conditions for growth in the greenhouse may be in wintertime, adding electric light from sunset to midnight to obtain long periods of light each day, will make Klondyke cosmos, poinsettias, and many other fall-flowering plants simply grow on and on with no signs of flowering.

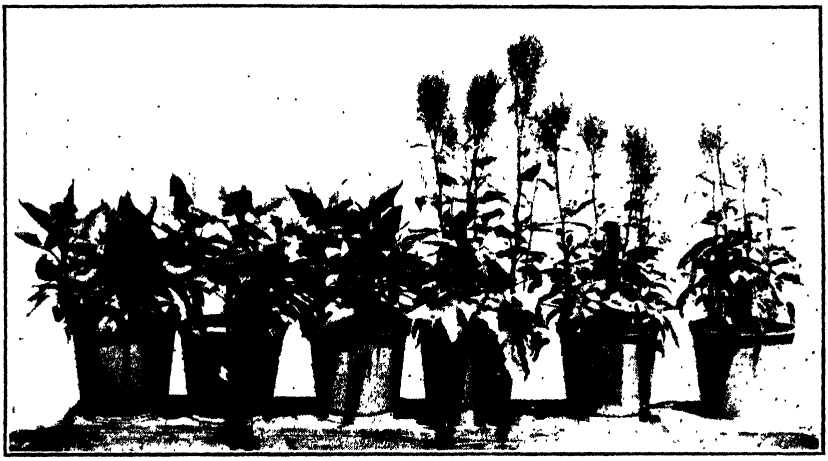

FIG. 69.—Rumex species, related to sorrel, showing the behavior of plants which require artificially shortened daily light exposures for flowering in the summertime. From left to right the plants were given full daylight, 4 hours of darkening in the middle of the day, and daily exposures, beginning at 5.30 a. m., of 12, 10, 8, and 5 hours of summer daylight. Only the 5, 8, and 10 hour treatments were short enough to induce flowering, which occurred promptly in June. The plants darkened in the middle of the day behaved as if receiving full daylight. The plants receiving 12 hours of light and full daylight did not flower until late fall, when the days were less than 12 hours in length

Some plants are not so sensitive as these to changes in the duration of daylight. They simply flower whether the day is long or short. The ordinary lengths of day do not affect them. Such are buckwheat, the commercial varieties of common tobacco, and the Mandarin variety of soy beans. It has not only been found that the flowering of many plants may be artificially hastened or hindered by the proper length of daylight exposures, but it has been found that this response may be localized in particular buds or branches experimentally. In other words, one may give a portion of a plant, a single branch or the top or the bottom of a plant, a daylight exposure of 10 hours, and the rest of the plant a long exposure of 14 to 15 hours or more, such as obtains in midsummer in middle and northern latitudes, and if it is a short-day type of plant, such as poinsettia or Klondyke cosmos, that portion given the short daylight exposures of 10 hours will hasten into flower, while the remaining portions will not flower until the shorter days of fall or winter have arrived.

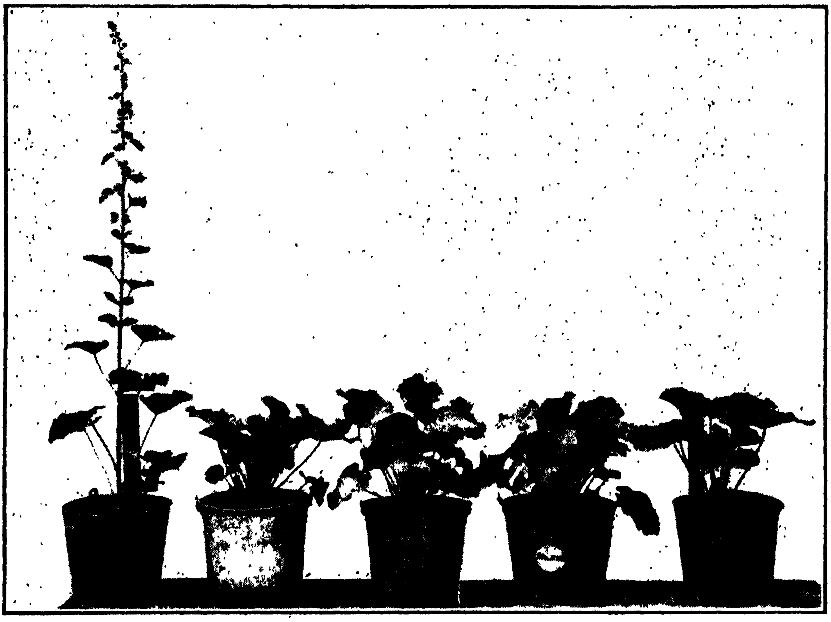

FIG. 70.—Hollyhock, double yellow variety. From right to left the plants were given 5, 8, 10, 12 hours, and the full daylight of summer. The latter alone flowered. To flower, a daily light exposure of more than 12 hours is required by the hollyhock, as well as many other plants, this being the characteristic behavior of plants which require long days for prompt flowering

This is a very convincing experiment, and shows how wonderful the artificial control of the flowering of some plants has become. How much more is known now than in the beginning. More is known than the mere fact that plants flower somehow. It is known that some plants flower in response to certain rather definite lengths of day, for they have been made to respond to an artificial, experimental short day or long day, just as they do in nature when the seasons in their swing afford them approximately these same daylight periods. The nature of the plant has not been changed in the least, and no reason is known why it should flower when given long or short days. The plants have not been fooled so much as one would believe. If they flower out of season, the poinsettia in June, for instance, it is because some dominant condition of June no longer affects them. The internal behavior of the plant has not been changed one bit, but a dominant factor of the normal season has been changed—the length of the daylight. So far as known the plant has to respond, and it does respond in one way or another.

### Home Demonstrations Possible

If anyone wishes to demonstrate these facts to his own satisfaction, let him obtain some small plants of poinsettia, or grow some plants of Klondyke cosmos in spring and keep them in a very dark, ventilated room or warm, dark cellar, giving them the sunlight each day from 6 a. m. till 3 p. m. Darkening the plants in the middle of the day several hours will not produce these effects. In about a month they will flower quite out of season and prove of no little interest to all who see them and learn the methods which made them flower. In this simple experiment one has worked out a fundamental relation in the behavior of plants, i. e., their growth and flowering responses to the factor of length of day, whether it be a natural seasonal relation or an artificial control of the daylight.

H. A. Allard.

## DRAINAGE Ditch Clearing

The function of a drainage ditch is to remove excess water from the soil and ground surface. Injury to growing crops after a rain is often averted by the rapid removal of this superfluous water. Any obstruction in a ditch retards the velocity of the moving water and thereby partly defeats the object for which the ditch was intended.

Vegetation is the most common form of obstruction in ditches. Drainage ditches badly choked up with growth are a very common sight in every section of the country. This growth consists most generally of weeds, tall grasses, vines, bushes, and small trees. The generally bad condition of ditches throughout the country would naturally lead one to conclude that very few landowners realize that there is a great difference in the discharge or water-carrying capacity of a cleared and an uncleared ditch.

The presence of vegetation in a ditch indicates either that the landowner is not deriving the full benefit from drainage for which the ditch was intended or if he is receiving this benefit that he has invested his money in a ditch which is larger than would be required if the vegetation were kept out. Apparently the truth of the above statement is not generally accepted by the farmer, so for the purpose of showing definitely to what extent the capacity of a ditch is affected by the growth of vegetation a large number of measurements of the flow of water in ditches before and after clearing and before and after the growth of vegetation were made by the writer and his associates in the Department of Agriculture.

### Drainage Good After Clearing

In Figures 71 and 72 are two views of the Lake Fork special ditch near Bement, Ill. One of these views was taken looking upstream and the other downstream over the same portion of the channel.

The view in Figure 71 was taken during July, 1924, when the vegetation in the channel consisted principally of bushy willows which were in full leaf. The view in Figure 72 was taken during May, 1926, after the growth had been cut out. Measurements of the flow in this ditch were made before and after clearing and it was found

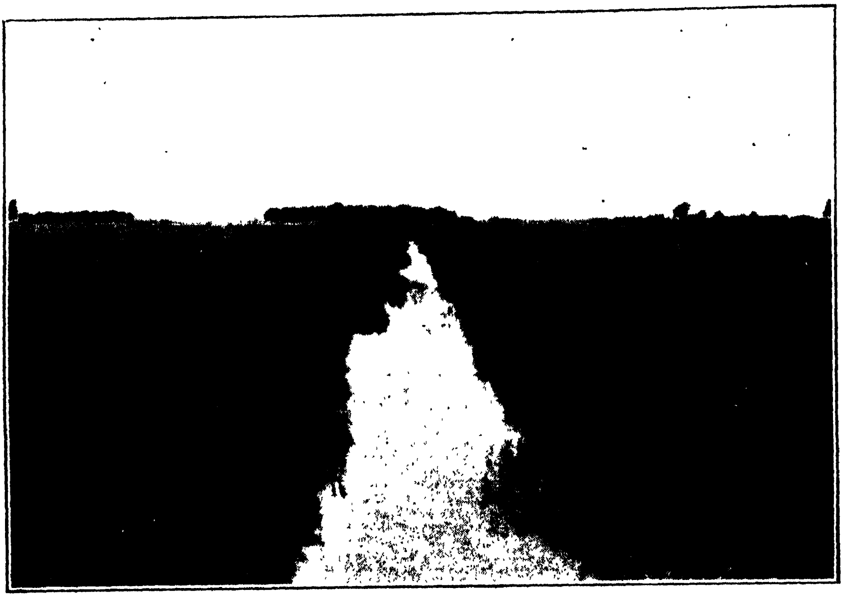

FIG. 71.—Lake Fork special ditch near Bement, Ill., before clearing, July, 1924

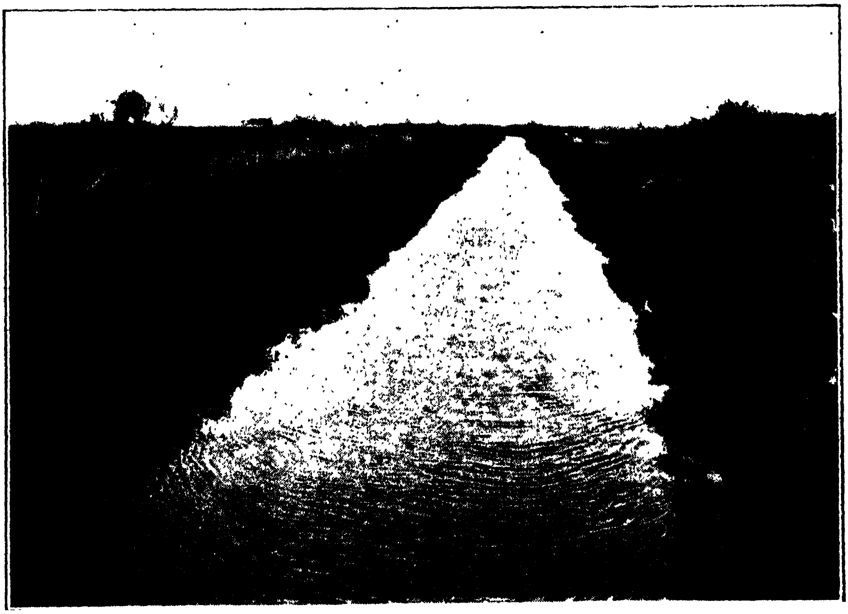

FIG. 72.—Lake Fork special ditch near Bement, Ill., after clearing, May, 1926

that the channel carried about 75 per cent more water after it was cleared. The cost of clearing out this channel was insignificant as compared with the losses sustained by the farmers owing to the tardy removal of the excess water after a rain. Since clearing the channel satisfactory drainage prevails.

The Kaskaskia mutual ditch near Bondville, Ill., has never been cleared since it was dug, as one might suppose, judging from the large size of the trees in the channel. A view of this ditch taken when the trees were in full leaf is shown in Figure 73. The thick foliage practically obstructs the view of the channel and the capacity of the ditch in this condition is only about one-third of what it would be if it were cleared out. Ditches of this sort afford extremely poor drainage. Not realizing the cause, landowners will often have such ditches dredged larger at great expense when if the growth were simply removed at a comparatively small expense adequate drainage would be provided.

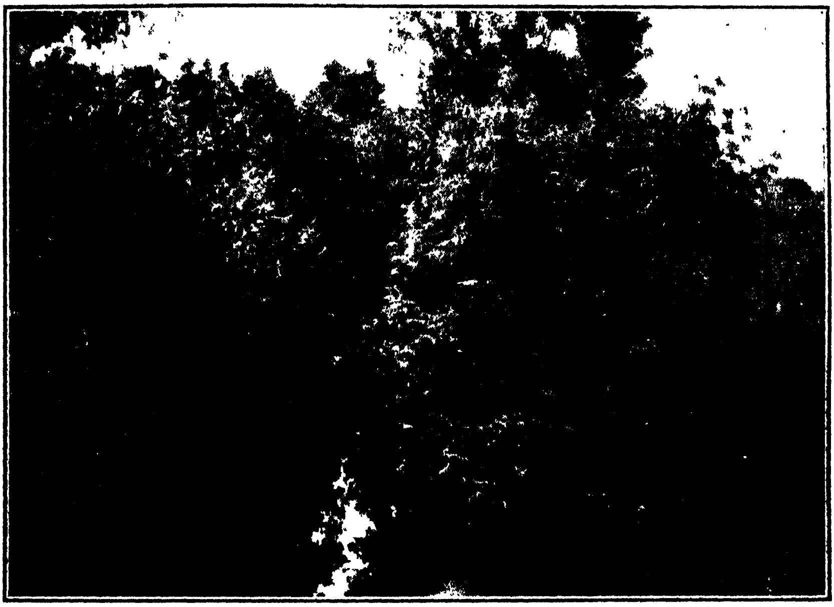

FIG. 73.—Kaskaskia mutual ditch near Bondville, Ill., July, 1924

### Willow Growth Reduces Ditch Capacity

Measurements of the flow in the Cummins Lake ditch near Gould, Ark., were made to determine what effect a comparatively short-time growth produces. It was found that the capacity of this ditch before the appearance of the willow growth was about 50 per cent greater than it was after they had grown a year or two, and twice as great as when the willows were in full leaf. These measurements apparently indicate that drainage ditches should be cleared out every year in order that they be maintained in a state of high efficiency. An examination of the bottom of this ditch showed that a certain amount of silting has taken place, which is due no doubt largely to the presence of vegetation. It is a generally established fact that where vegetation remains in a ditch over a long period of years the cross section of the ditch is greatly reduced in size by the accumulation of silt, and it becomes necessary to redredge the ditch at great expense. This, of course, is especialy true where the ditch drains a somewhat rolling and hilly watershed.

### Enlarging Ditches Often Unnecessary

The Cypress Creek drainage district near McGehee, Ark., has never been cleared since it was dredged. The trees in the channel are about 8 years old. Measurements of the flow in this channel were made when there was a heavy growth of foliage on the trees and it was impossible to see any appreciable distance along the channel. It was found that the capacity of this ditch is only about one-fourth of what it would be if it were cleared out, and that a clear ditch about one-third its size would have the same water-carrying capacity. The capacity of the ditch in its present condition is entirely too small to provide satisfactory drainage for the land in its watershed. Overflows generally occur after every heavy rain.

The results of the measurements described in the foregoing tend to show:

That the usefulness of a ditch is greatly impaired by the growth of vegetation.

That the clearing out of a long-neglected ditch will often provide satisfactory drainage and prevent injurious overflows.

That the costly mistake of enlarging a ditch is sometimes made when simply clearing the ditch would have produced the desired result.

That in most localities drainage ditches should be cleared out once a year if maintained in a state of high efficiency.

That the expense of clearing out a channel is in most cases much less than the crop losses suffered from one moderate overflow.

That vegetation in a ditch causes appreciable silting which often requires the redredging of the ditch at great expense as compared with the much smaller expense of systematic maintenance.

C. E. Ramser.

## DRAINING Marshlands Unwisely

Marsh areas produce a greater income in many cases than do adjacent farmlands and also are indirectly valuable to the surrounding country. Through ignorance of this, there is much needless destruction of the homes of birds, fur animals, and other kinds of wild life amid such surroundings as conservationists seek to perpetuate. They do not, however, oppose the drainage of lands that will be less valuable as wild-life refuges than for agriculture or any other economic use.

The Department of Agriculture is in position to assist both the agriculturist and the conservationist in solving conflicting drainage problems. In recent years the Biological Survey has made many investigations for associations and individuals, and, as a result, a number of proposed drainage projects that were found to be unwise have been abandoned or the areas under consideration were, when suitable, made into wild-life refuges. The upper Mississippi River wild life and fish refuge furnishes an outstanding example of a marsh and water area which was recently seriously contemplated for drainage, but which, after careful consideration, was preserved for its wild life. An investigation by the Biological Survey of this wonderful breeding ground more than 300 miles in extent, assisted materially in its perpetuation.

### Study of Projects Urged

Careful study of proposed drainage projects is recommended by the Biological Survey with the view of preventing the unrestricted and indiscriminate destruction of marshlands and obtaining definite information as to their worth before drainage as compared with their possible utility afterward. When no effort is made in advance to determine the probable results of drainage, frequently the land uncovered is found useless for agriculture, and, in fact, only a small proportion is ever successfully cultivated. The files of the department contain particulars of the disastrous results following ill-considered drainage projects.

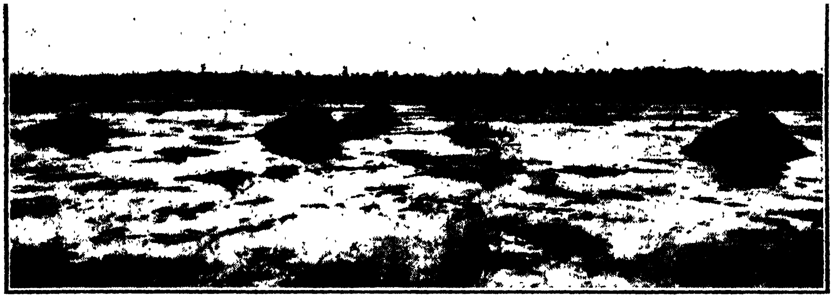

FIG. 74.—Bird haven ruined by drainage. Lower Klamath Lake, Oreg., drained, but with mud 8 feet deep, which makes it useless for agriculture

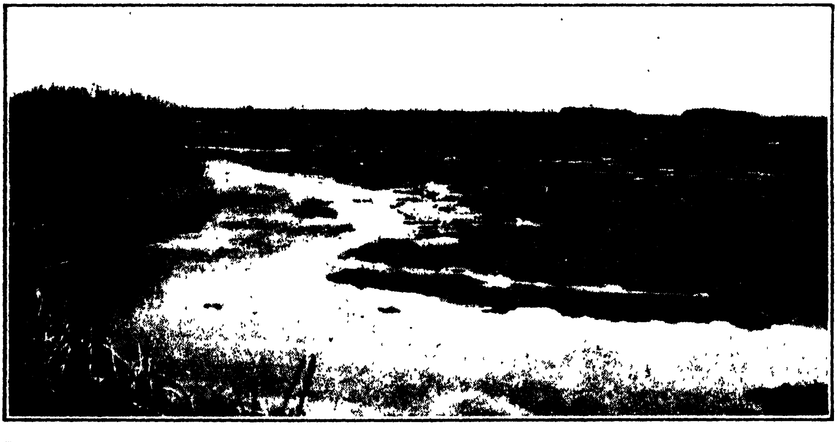

FIG. 75.—Productive undrained marsh. More valuable for muskrat farming and as a breeding and feeding ground for ducks than for agriculture. Dorchester County, Md.

In addition to providing breeding, feeding, and resting places for thousands of birds, fur animals, and other forms of wild life, the principal value of marshlands may be briefly summarized as follows: They can add to the nation's food supply a great variety of fishes; they may produce a natural ice supply and grasses and other growths useful for forage and for making bedding, rugs, and baskets; in maintaining the underground water level they promote forest growth, insure the flow for springs and wells, and hold back the run-off of floods, thereby more evenly distributing the water over a longer period and preventing excessive erosion and other flood damage; furthermore, populated with interesting wild life, such areas can furnish millions of people with natural playgrounds, thus encouraging the beneficial study of nature and the greater enjoyment of outdoor life.

TALBOTT DENMEAD.

## DROUGHT and Its Effects in United States

On account of the widely diversified climate of the United States, the great variety of agricultural products, and the different requirements of these in the matter of moisture, the term drought, as applied to a lack of moisture in the soil for proper plant growth, embraces a multitude of conditions differing with each particular type of agriculture; hence no certain deficiency in precipitation can be defined as constituting a drought.

In the more eastern districts, where precipitation is usually well distributed and mainly sufficient for agricultural needs, a period of 30 days without beneficial precipitation constitutes a drought, and damage might be serious and even disastrous if the subsoil were not well supplied with moisture at the beginning of the drought period.

In our central valleys and Great Plains, where the bulk of the precipitation comes in the warmer months, drought during the early spring months will greatly diminish the wheat yield, and drought in midsummer will spell disaster to the corn crop.

Over the Pacific Coast States possible drought is confined mainly to the colder half of the year. Here precipitation may be decidedly scanty for a month or even a considerably longer period during the rainy season without serious inconvenience, but a generally dry winter season may be disastrous to nonirrigated crops through lack of sufficient soil moisture for crops that mature after the cessation of the winter rains.

A short period of drought in the eastern part of the country during the early spring months will frequently greatly curtail the hay crop, but it may not seriously injure wheat; in fact it may be beneficial in preventing excessive straw growth.

As to corn in its early growth, a period of drought may even be beneficial, forcing the roots to greater depths, a result which may prove beneficial later in the season if the surface soil becomes depleted of moisture.

Drought of short duration may be quite disastrous to corn when it follows a wet period immediately preceding the early formation of the ear, when abundant moisture is required, and if previous wet weather has caused the root system to develop near the surface the supply of moisture still available in the subsoil may not be reached in time to prevent loss.

Moderate drought is not always associated with scanty production. It may even prove beneficial to cotton by hindering activity of insect pests which do not multiply in dry weather. Further, the cotton plant remains somewhat dormant during drought, only to resume growth promptly when moisture is finally supplied, thereby at times enabling the development of a crop after the season of worst insect infestation.

Early droughts are particularly detrimental to most truck and small-fruit crops, as growth and development of these are usually rapid, and any material interruption is decidedly harmful.

### Losses by Drought

Probably no part of the country is free from occasional heavy losses in agricultural products from deficient moisture, but improved methods of tillage and increase in the amount of vegetable matter in the soil tend to retain considerable moisture that would otherwise be evaporated or lost through seepage, thus affording a partial source of supply when rainfall is deficient. The amount of moisture conservable in this way is limited, and extended drought periods finally exhaust the whole supply and agricultural losses are in proportion to the time drought continues or to the actual possibilities of damage, this depending largely on the stage of crop development.

During the period of crop growth there is seldom a time when more or less drought does not exist in some portion of the country. In the Atlantic coast districts droughts more or less severe for a period of 30 days or more from March to September occur in nearly half the years, while in the lower Ohio and middle and lower Mississippi Valleys drought is liable during the same period in more than half the years. Over much of Texas and the western Great Plains drought is liable in 70 to 90 per cent of the years or even more.

This does not indicate that all crops necessarily suffer, as the drought may occur too late to injure winter wheat or too early to harm spring wheat; it may come before the corn is susceptible to severe injury or after it has largely matured, and it may happen during the various stages of cotton growth, when lack of moisture, though retarding growth, encourages fruiting and lessens insect depredations.

In portions of the eastern plains and upper Mississippi Valley, notably in much of Missouri and Iowa and portions of near-by States, on account of the preponderance of the yearly precipitation in the late spring and early summer months, the percentage of years with drought during the crop-growing season is the lowest in the entire country, being only from 30 to 40 per cent.

### Dates of the Greatest Droughts

In 1901 lack of precipitation during the latter part of June and the greater part of July over the principal corn-producing States, associated with intense heat, threatened an almost total loss of the corn crop in some States. Fortunately, good rains near the end of July partly revived the crop, but the average yield of corn that year for the entire country was reduced to 16.7 bushels per acre. In Kansas the average yield was 7.8 bushels per acre; Arkansas had 8 bushels; Oklahoma and Missouri, 10; Texas, 12; Nebraska, 14; and in other near-by States yields were reduced to a less extent.

A severe drought, affecting corn particularly, centered over Kansas in 1913. Intense heat persisted for long periods, and conditions were worse than in 1901, reducing the average yield of corn in the State to slightly more than 3 bushels per acre. but in this instance drought was not so extensive in area as in 1901.

A notable drought occurred over the southeastern part of the country in 1925. Precipitation was greatly deficient during the entire growing season, most late crops were practically failures over the southern Appalachian region, and more or less loss was sustained in all near-by localities and over much of the eastern and central Cotton Belt as well.

With increasing hydroelectric development, drought losses are not so fully confined to agriculture as formerly. Now great interests are associated with water-power plants, and any lessening of the stream flow through drought is reflected in reduction of output and consequent loss.

With the development of large irrigation systems in the far West, the occurrence of drought in the winter months is of much greater concern than formerly. A deficiency in the winter's snow in the mountains now means a reduced flow of water into the irrigation ditches during the summer, and serious loss to crops depending on water from melting snow may result.

At present no basis for foretelling the occurrence of drought exists, but the damaging effects on crops of all kinds may be greatly ameliorated by recognizing the possibility of its occurrence and planning such a system of soil preparation and cultivation as will minimize its damaging effects.

Much information on soil preparation and types of cultivation most effective in conserving soil moisture is available in the publications of the Department of Agriculture.

P. C. Day.

**EATING to Keep Body in Health** The idea of selecting food primarily to build and maintain a standard of health belongs to the present day. It is beginning to supplement materially in the popular mind the age-old idea of eating simply to appease the pangs of hunger and gratify the appetite. The causes that are contributing to the popular acceptance of this idea are the high cost of living. the growing scarcity of household labor, advances made in the science of human nutrition, and the many avenues afforded to-day for popular education along this and other lines.

The principles of eating for health have been outlined in a food-habits score card, which has proved to be one of the most effective devices for the modern teaching of food habits that make for health. This score card was first developed at conferences of the nutrition specialists of the cooperative extension service of the United States Department of Agriculture and the State agricultural colleges and was later amplified and approved by the extension nutrition committee of the American Home Economics Association.

The score card is not intended to represent a complete diet, but rather to focus attention and interest on the food habits most in need of improvement. The nucleus of building, regulating, and protective foods which it specifies needs to be supplemented by moderate quantities of fats, sweets, and such other desirable foods as are necessary to keep the individual within the zone of normal weight for his age, height, and type of body build.

The score card itself is as follows:

*Food-selection score card*

[For the average person over 6 years of age]

| Perfect score | Credits | |
|---|---|---|
| 20 | Milk: | |
| | Adults, ½ pint 10, ¾ pint 15, 1 pint | 20 |
| | Children, ¾ pint 10, 1 pint 15, ¾ to 1 quart | 20 |
| 40 | Vegetables and fruits: | |
| | Vegetables— | |
| | 1 serving 5, 2 servings 10, 3 servings | 15 |
| | Potatoes may be included as one of the above servings. | |
| | If leafy vegetable is included, extra credit | 5 |
| | Fruits— | |
| | 1 serving 10, 2 servings | 15 |
| | If raw fruit or vegetable or canned tomato is included, extra credit | 5 |
| 15 | Whole-grain products: | |
| | 1 serving 10, 2 servings | 15 |
| 15 | Cheese, eggs, meat, dried beans or peas: | |
| | 1 serving of any one of above | 10 |
| | 1 serving of any two of above | 15 |
| 10 | Water (total liquid): | |
| | Adults, 1½ quarts 5, 2 quarts | 10 |
| | Children, 1 quart 5, 1½ quarts | 10 |
| 100 | Total credits | |
| | DEDUCTIONS | |
| | Use of tea or coffee for children | 10 |
| | Use of over 2 cups of tea or coffee or both for adults | 10 |
| | Eating sweets between meals | 10 |
| | Total deductions | |
| | Total score | |
| | Weekly average (for daily checking type) | |
| | Average score for family (for estimate type) | |

The size of the serving should vary according to the need of the person; for adults and older children an average serving of vegetables, fruits, or cereals is one-half cup. Servings will be smaller for children under 10 years.

The score card is now in general use in extension work as a part of the food-selection teaching. State nutrition specialists, county home demonstration agents, and trained local leaders have helped thousands of families to check their food habits against it. By checking also on such signs of physical fitness as freedom from constipation, colds, headaches, and indigestion, and proper weight for height and type, families have realized perhaps for the first time that a diet consistently low in any of the essential food groups results eventually in a poorly running body machine. This has led to a gradual improvement of food habits which has been rewarded by corresponding improvement in physical condition.

The score card is an excellent guide to the diet of the expectant mother, when the milk is raised to 1 quart a day and correspondingly less is taken of other forms of protein, and for the nursing mother when the quantity of milk is increased to satisfy the demands of lactation. By the end of his first year the baby will be getting small quantities of all the groups of food included in the score card except dried legumes and possibly meat.

The attempt to live up to the food habits recommended in the score card immediately shows up any shortcomings in the farm or community food supply. The score card guides the farmer in the planning of the family garden and warns the housewife that she must can and store a goodly supply of fruits and vegetables for use during the winter or see to it that these are available, fresh or canned, in near-by markets. It calls attention to too small milk consumption and to the need for obtaining clean, safe, and palatable milk the year round for both drinking and cooking purposes. It shows the value of a supply of eggs, chickens, and meat, and the wisdom of canning, preserving, and storing these products throughout the year. In this respect it leads to good form as well as home management, for in days of descending price curves and disparity in prices between raw foodstuffs and manufactured products, the farm should produce as much as possible of the food for both the farm family and the livestock. Substantial cuts in bills for sickness and for medicines and substantial savings in cash outlay for essential foods that can be grown on the farm mark the trail of the food-selection score card as a guide to eating for health.

The adoption of a standard for food selection must be supplemented by the foods selected so that they tempt the appetite and at the same time keep the greatest food values. Good quality of protein, especially milk, plenty of roughage, succulent foods during the winter, leafy foods at all seasons, and an abundance of fresh, pure water are the essentials in eating for health.

MIRIAM BIRDSEYE.

## EFFICIENCY of U. S. Agriculture is Increasing

Efficiency in agricultural production in the United States as measured by the physical volume of production per worker has shown a constant upward trend since data on production first became available. Production per agricultural worker was twice as great in 1919 as it was in 1879, 40 years earlier (fig. 76). In this period, output per worker in agriculture has been increasing at approximately the same rate as in manufacturing, but not so rapidly as in the transportation industry.

Production per worker is only an imperfect measure of efficiency. Many things other than labor are used in farming. From the standpoint of a particular line of production on the individual farm efficiency would be measured by the relation between the volume of product and all of the different inputs used. For example, in milk production several different kinds of food are used, as well as labor and equipment.

From the standpoint of the organization and operation of the entire farm as a business unit, efficiency may be defined as the ratio of the returns from the entire farm to the labor, land, capital, and other resources that are put into the business. If one is to obtain the greatest return from the resources he uses, i. e., if he is to be most efficient considering his entire operation as a unit, he must not only conduct each line of production efficiently, but must also choose and adjust his different lines of production so that they all have the right relation to each other.

### Variations in Individual Efficiency

Many examples could be cited to show how efficiency in the different lines of production has increased; many examples of opportunities for further increases. All the farm-management and cost studies that have been made show wide variations in the effectiveness with which the farmers in a particular locality at a particular time are carrying on their different lines of production. The results in cow-testing associations invariably show great variations in the efficiency of milk production. The various production contests sponsored by the extension services show similar variations. It is evident that there are abundant opportunities for farmers to attain higher standards of efficiency in their different lines of production than those now prevailing.

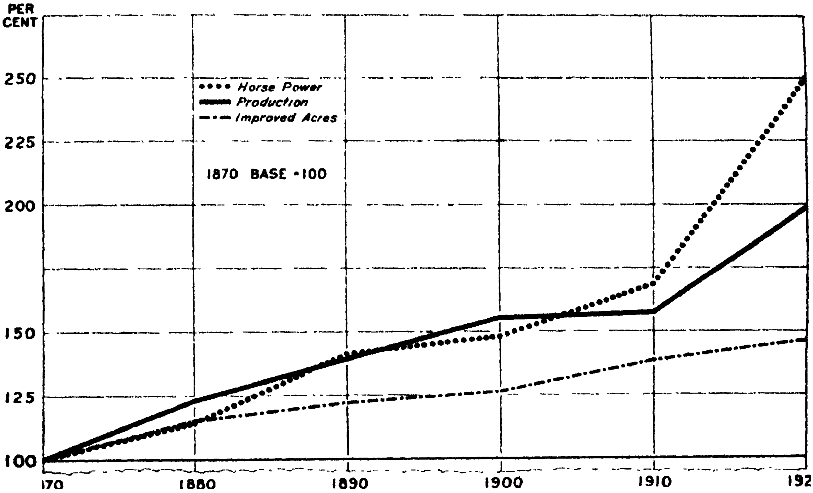

FIG. 76.— Indices of agricultural horsepower production, and improved acres per agricultural worker

Evidence that many farmers are improving their efficiency by modifying the organization of their farms is found in practically every region. Even in old sections shifts toward larger units which give opportunity to increase gross returns without a corresponding increase in the outlay for labor and equipment are found. In every region, farmers are found who are introducing minor enterprises or giving more attention to them in order to round out the labor program and to utilize nonmarketable feeds and other resources which otherwise have no value. For instance, throughout the Northeastern States an increasing number of farmers are growing a few acres of potatoes as a side line to dairy farming. In the South an increasing number are growing a few acres of truck crops as a side line to cotton production. In the Great Plains more farmers are keeping a few milk cows as a supplementary enterprise on grain farms.

### Requisites for Continued Gain

If farmers continue to improve the organization of their farm businesses and to adopt better cultural and feeding practices, if plant and animal breeders continue to develop more productive varieties and strains, and if manufacturers continue to make new and better machines, continued increases in efficiency may be expected.

Turning now to the effect of increased efficiency on the returns from farming, what opportunities are there for farmers to increase their returns through greater efficiency? When considered from the standpoint of an individual farmer at a particular time and in a particular place, it is apparent that increased efficiency in carrying on the major lines of production will always be desirable. The grain grower who consistently obtains high yields by using good seed, by planting it at the right time, and by using good husbandry throughout, will, other things being equal, obtain a better income from his farm than will the man who is lacking in these respects. Similarly, the hog producer who manages to save a goodly portion of the pigs that are farrowed and who has adopted a good system of feeding, will, other things being equal, always make more money than the producer who has high losses and who is not a good feeder.

In considering the problem from the standpoint of farmers as a class, one must take into account the effect of increasing efficiency upon supply, and the effect of supply on price and returns. The farmer who increases his crop yields without a proportional increase in the use of labor, power, and materials, and he who increases the production of his livestock without a proportional increase in the quantity of feed usually increases the total output of his farm. A general increase in efficiency would thus tend to increase the total supply of farm products.

### Effect on Volume of Production

As an example, let us examine the possible effect of a general increase in the efficiency of pork production on the incomes of pork producers. Records on more than 350 hog farms in Iowa, Illinois, and Indiana, covering the period from 1920 to 1926, show that over one-third of the pigs farrowed died before weaning time. Some of the farmers were able to avoid these losses almost entirely and it seems that through good management this loss can readily be reduced one-half. Assuming that the losses on these farms were typical of the losses on all hog farms, what would have been the effect on the number of hogs coming to market in 1926 and on the incomes of hog producers if half of these losses had been avoided?

If 85 pigs out of every 100 farrowed had been saved and sent to market, instead of the 67 which actually were saved, market receipts and slaughter would have been one-fourth greater than they actually were.

The usual relation between the price of hogs and the number slaughtered per month under Federal inspection is shown in Figure 77. The slaughter during the year was such that prices ranged from about $12 to $14, with the average for the year not far from $13. According to this chart, if slaughter had been 25 per cent larger than it actually was, prices would have been about 15 per cent lower, or only about $11. The total value of the hogs sold would, therefore, have been only slightly larger—about 6 per cent. The result would have been equivalent to selling those actually saved at $13, as before, and then selling the additional hogs at $3. And, of course, it would take 25 per cent more corn to feed the additional hogs—so they would be returning about 30 cents a bushel for the corn they received.

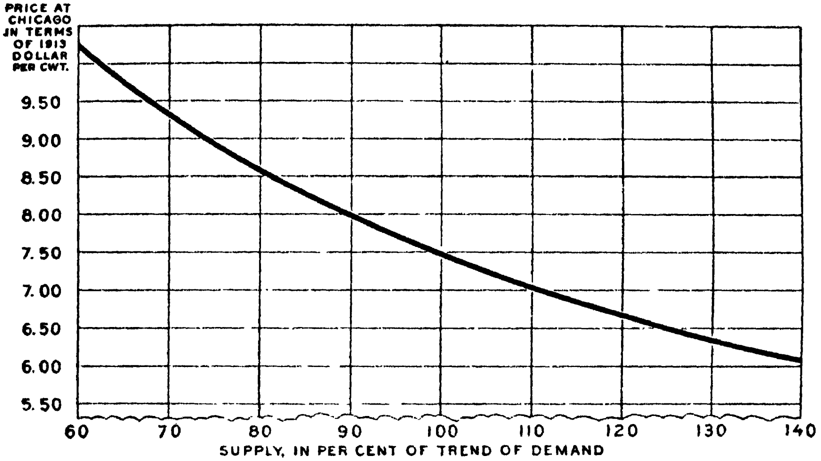

FIG. 77.—The price of hogs declines as the supply coming to market increases. When supplies are low, as they were in 1926, a given change in the supply causes a greater change in the price than is the case when supplies are plentiful

### How Efficiency Can Be Made to Pay

Adding 25 per cent to the number of hogs would have increased the demand for corn, raising its price, as well as lowering the price of hogs; and the corn-hog ratio. instead of being highly favorable to hog producers, might have become even unfavorable. So the increase in efficiency by farmers who grow hogs to sell would finally result mainly in increasing the incomes of farmers who grow corn to sell.

But if hog producers should cut down the number of sows enough to offset the increase in pigs saved, they would receive the same price for their hogs, and reduce the expense of producing them. One-third of all expenses in producing hogs are incurred before the pigs are weaned, so the saving by cutting down the number of sows enough to offset the increase in pigs saved per sow would make a substantial reduction in the total expense of producing the hogs, without in any way reducing their selling price.

Many other examples could be given but they would all point toward the same conclusion: Increased efficiency can not have a favorable effect on the returns that farmers as a group will receive if production is increased so much that the advantage is lost through a decline in prices.

It is generally accepted as a fact that at present the incomes of many farmers are not sufficient to afford a satisfactory standard of living. A summarization of income statements for 1925 from over 15,000 farmers well distributed over the entire country showed that the "net result" (the difference between cash receipts and cash expenses plus or minus the change in the value of farm property other than real estate) for about 10 per cent of the farmers in the sample

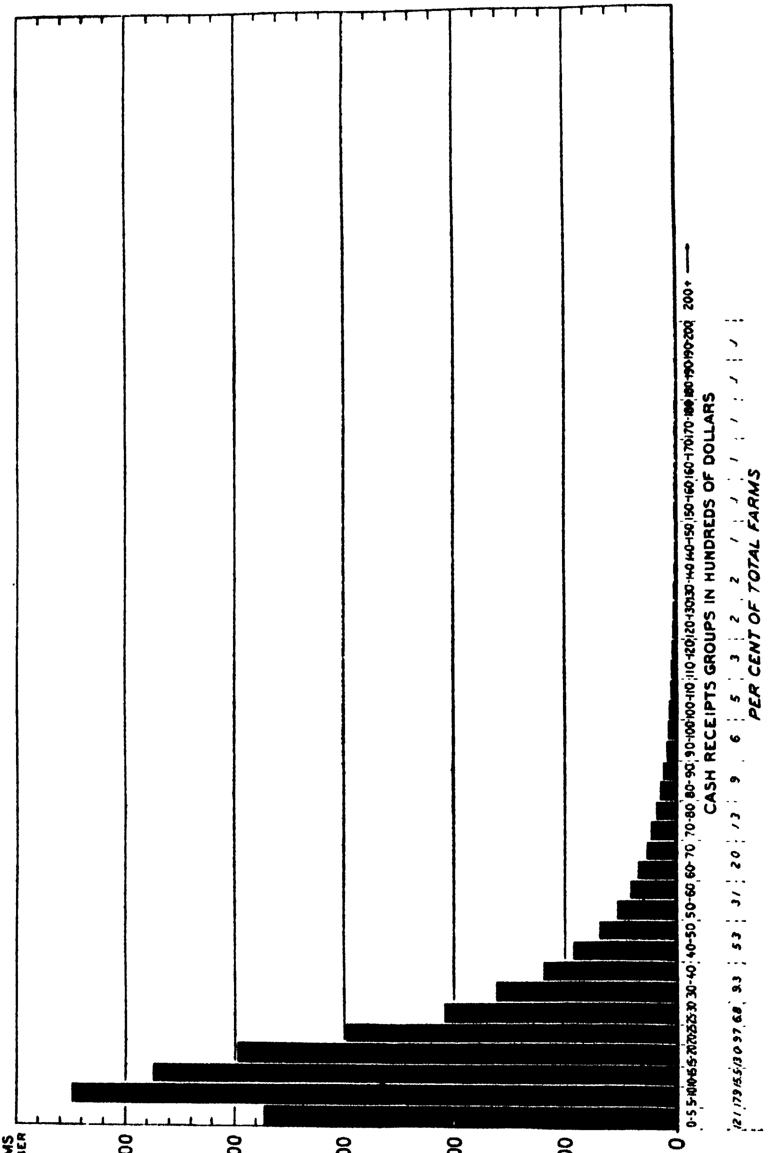

FIG 78.—Variation in cash receipts of farmers in 1925. Number and percentage of farms with cash receipts of indicated size as reported by owner-operators in the farm-returns inquiry

was a minus quantity, for 45 per cent it was less than $1,000, and it was between $1,000 and $2,000 for 25 per cent.

### Reducing Costs but not Increasing Output

A great many farmers could reduce their costs without increasing the output of their farms and thus increase their net incomes without increasing the total supply of farm products. But 30 per cent of the farmers reporting had gross receipts (without any deductions whatever for operating costs) of less than $1,000, and 28 per cent had gross receipts of $1,000 to $2,000. (Fig. 78.) If all of these farmers succeeded in lowering their costs to the absolute minimum a great many of them would still not have satisfactory net incomes. If they could all expand their operations to the point where their incomes would be satisfactory on the basis of present prices, the total supply of many commodities would be so large that, actually, prices would drop to a point that would be ruinously low for most producers. On the other hand, if a part of the farmers with small businesses moved into other occupations, those who remained could combine the land thus released with their own and increase their incomes without increasing the total volume of production.

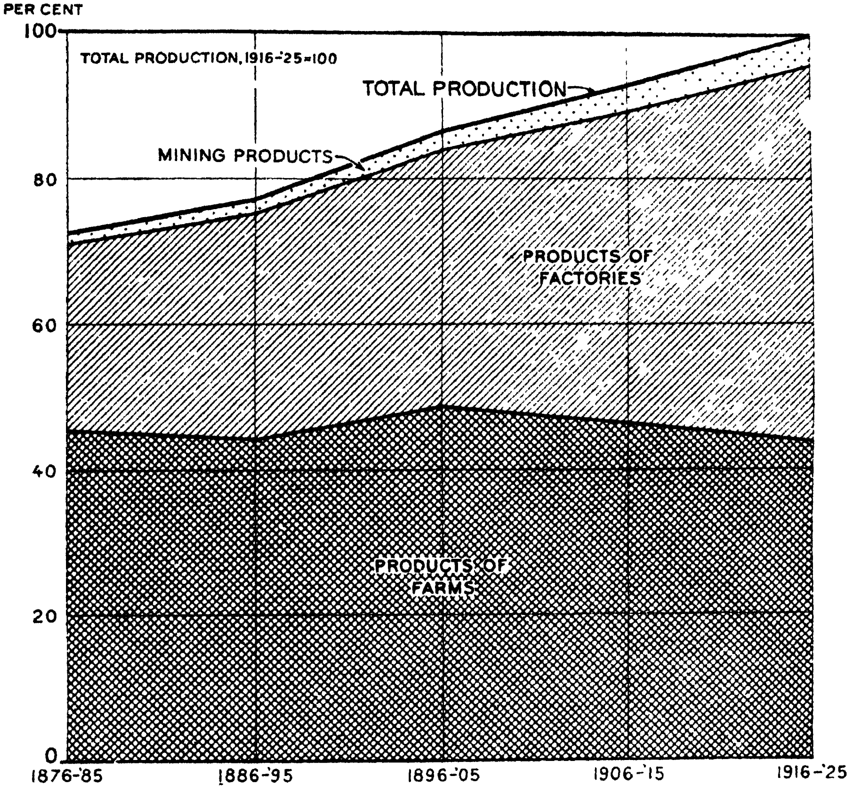

FIG. 79.— Changes in goods produced per capita of population, 1876–1885 to 1916–1925

It seems that unless many new and important outlets for farm products can be found, so that much larger quantities will be taken without serious decline in prices, many of those now engaged in farming can not reasonably expect to obtain returns comparable to those available to them in alternative occupations.

The consumption of food products is definitely limited, however, and increased consumption of some products is offset by decreased consumption of others. The production of farm commodities per capita of total population in the United States is no greater now than it was 50 years ago. On the other hand, the per capita production of manufactured commodities has doubled, and per capita production of mining trebled. (Fig. 79.) A large part of the increased production in manufacturing has been in the form of new kinds of products satisfying new wants. In 1850, 65 per cent of the workers in the United States were employed in agriculture. By 1920, the proportion had declined to 26 per cent. Further decline is to be expected, and the movement of some farmers into alternative occupations should be encouraged. The unfortunate thing is that the need for fewer farmers, which grows out of increased output per man has never been clearly recognized until prices have dropped, making incomes from farming relatively lower than incomes in other occupations.

H. R. Tolley.

## EGG Standardization is Put in Effect

The basic step in egg standardization, the establishment of standards of quality applicable to individual eggs, is an accomplished fact. After careful investigation and consultation with the various groups in the egg industry, the department separated the range of egg quality into seven divisions and formulated quality specifications for each, known as the United States standards of quality, by use of which it is possible to place definitely any individual egg in its proper quality division. These standards of quality were submitted to the egg industry for its approval, and at a meeting held in Chicago in January, 1925, under the auspices of the National Poultry, Butter, and Egg Association, were adopted as adequately differentiating and describing individual egg quality.

With the quality standards as a basis, the department next promulgated United States grades for eggs. At present these are still in tentative form, although their use under a rather wide range of conditions and over a considerable period of time indicates that they are practical grades. There are three distinct sets of United States grades, the make-up of each being varied in accordance with the point at which it is applied to eggs during the process of marketing. The first set is known as United States buying grades and is intended for use at primary country-buying points. The second set is known as United States wholesale grades and is intended for application to lots of eggs, car lots or less, in the wholesale trade, or from the time they are packed by the concentrator or shipper until they are sold to the jobber. The third set is intended for use in retail trade after the eggs have been finally prepared for consumer use. All these sets of grades, both in nomenclature and actual make-up, have been prepared with due respect to uniformity and to relationship to each other.

While these various sets of grades are still in tentative form, they are all in actual use. The buying grades are being used in a number of places in different parts of the country as a basis for grading eggs as they are purchased from producers and as a basis for a graduated scale of payment according to quality. In some instances these buying grades are not used in their entirety but in a form modified to meet the particular local conditions.

### Grades in Extensive Use

The United States wholesale grades are in extensive use in certain markets as a basis of inspection. Egg-inspection services have been established at San Francisco and Petaluma, Calif., New York City, Philadelphia, and Sedalia and Medill, Mo. The work in California is carried on in cooperation with the State department of agriculture. At Petaluma the work is shipping-point inspection, while at San Francisco, both the United States wholesale grades and the Federal-State inspection service are official and required in connection with exchange trading in eggs. In Missouri the work is carried on in cooperation with the State marketing bureau and consists of shipping-point inspections. In New York City the work is entirely Federal in character but is mostly inspection for contract purchases and does not, therefore, deal so much with the United States wholesale grades. In Philadelphia the greater part of the work also consists of contract inspections which are entirely Federal, but, in addition, through a cooperative arrangement with the Philadelphia Produce Exchange, the Federal inspector is also the exchange inspector and makes any inspection required by the exchange on the basis of United States standards of quality, which are then translated into terms of exchange grades. Arrangements are pending with other agencies by means of which it is expected that there will be established in a considerable number of other important market and storage centers, inspection services using United States wholesale grades.

Various Government agencies, such as the Navy, are the principal users of the United States retail grades at the present time, all their contract purchases specifying certain of these grades. Some other agencies, such as public institutions and shipping lines, are also beginning to specify United States retail grades as embodying more definite quality requirements than the purchase specifications previously in use.

Egg standardization as a country-wide program still has far to go before it is a general practice. The first step, however, is an accomplished fact and the present status of egg standardization is characterized by rapid advance and constantly increasing application.

R. R. SLOCUM.

---

**EGG Supplies in Winter** Chickens do not ordinarily produce eggs during the fall and winter months unless they have been carefully raised and managed toward that end. It is not surprising, therefore, to find that our winter supply of fresh eggs must come from those sections of the country where large numbers of chickens are raised and managed for the primary purpose of producing eggs when most chickens are not laying.

The most highly specialized egg-producing sections of the country are located on the Atlantic and on the Pacific coasts, and the great majority of ordinary farm flocks are located in the grain and livestock producing regions of the Middle West. In these latter regions the bulk of the Nation's egg supply is produced.

Even in the highly specialized egg-producing sections of the country there are large numbers of small flocks (fig. 80), but these are of small importance in the total annual egg production of the section, and especially in the winter production. In Cumberland County, N. J., in which Vineland is located, 72 per cent of the egg production comes from flocks having more than 450 chickens. This represents 15 per cent of all the chicken flocks in the county.

In Sonoma County, Calif., where Petaluma, the most intensive egg producing section in the world is located, 30 per cent of the flocks have more than 450 chickens and these flocks produce 91 per cent of all the eggs in the county. In the two Iowa counties, which are representative of ordinary farm flock conditions in the Middle West, less than 2 per cent of the flocks have over 450 chickens and less than 5 per cent of the total egg production comes from flocks of this size.

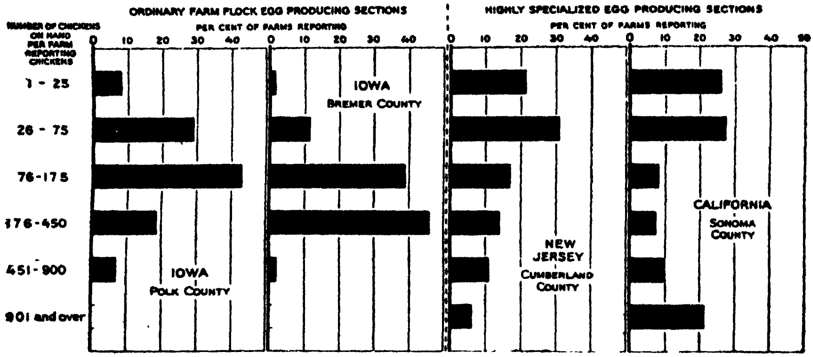

FIG. 80.—Number of farms reporting chicken flocks of various sizes in commercial and noncommercial poultry sections, January 1, 1925

### Specialized Egg Farms Get Winter Trade

States that have large numbers of commercial chicken flocks naturally send to market a much larger proportion of their total egg production during the fall and winter months. Iowa sends to the four leading markets about twelve times as many eggs during the spring month of highest production as it does during the winter month of lowest production; New Jersey four times as many, and California only twice as many.

Climate has much to do with the potential supply of winter fresh eggs. It is not likely that the middle West will ever specialize in winter egg production to the same extent as certain sections on the Atlantic and Pacific coasts where climatic conditions are more favorable to winter egg production. Petaluma, Calif., has an ideal climate for specialized egg production. The comparatively mild and open winters make it possible to provide green feed and to care for the chickens with comparatively little effort, and it is not necessary to keep chickens confined to houses on account of inclement weather. The cooler summers are not only desirable from the standpoint of the comfort of the birds, but help to maintain high quality in market eggs.

We must look for our supply of fresh winter eggs principally from those sections of the country which have large numbers of specialized egg farms and where climatic and economic conditions are such that large-scale poultry farming is one of the most profitable enterprises in which farmers in the locality may engage.

E. R. JOHNSON.

**ELECTROCULTURE Experiments Not Yet Conclusive** Electrical phenomena are intimately associated with plant development. The nature of the relationship is not yet understood, but the possibility that electricity may be an essential factor in plant development constitutes the underlying reason for electrocultural research.

In some manner as yet unexplained the earth maintains a negative charge in relation to its upper atmosphere, so that in the intervening air an electrical tension of the order of 100 volts per meter is usually present. This lower air contains about 1,000 free ions per cubic centimeter, the greater portion of which carry positive charges and move earthward at the rate of about 1 centimeter a second, giving up their charges on contact. The current density occasioned by such a transfer of electrical charges is of the very low order of $5\times10^{-8}$ amperes per acre.

Growing plants assume the earth potential and readily take these downflowing charges, so that under natural growth conditions a minute electrical current flows through them. The intensity of this current may vary greatly, particularly during storms, when the air locally may become negative and reverse the direction of current flow.

The earth itself, on the other hand, is traversed by minute electrical currents of varying intensity and direction. These currents are quite possibly adjustments to the unequal absorption of air charges occasioned by differences in soil conductivity, in which case they might be classed as secondary currents. It was at one time thought that soil-conducted currents might influence plant growth, but the experimental results have not been promising and this method has been discontinued for the most part.

### Evidence is Negative

The majority of electrocultural experiments have sought to relate increased growth with the passage of an electric current through air and plants from an overhead system of wires discharging at high voltages. Such a set of experiments were conducted by the department (1907 to 1918), but no satisfactory evidence of a favorable influence for the treatment was obtained.[6] The British Ministry of Agriculture and Fisheries has recently been conducting similar experiments, and while their results as a whole have not given any definite proof of an increased plant development, certain trials indicated appreciable differences between treated and untreated plants. Because of these significant differences obtained in England the department in 1923 again began electrocultural investigations.

---

[6] Reported in U. S. Dept. Agr. Bul. 1379, January, 1926.

In the present series of trials apparatus is employed which permits of the passage of fairly constant and measurable currents of electricity from an overhead network to boxes of plants on insulated platforms below. A control series, similar in every way except for the treatment, is used for a comparison, and the average increases in growth under these conditions are used as measures of plant response to the different environments. This apparatus is shown in Figure 81.

Although significant differences have been obtained in a number of experiments, the variability of the controls has as yet prevented any satisfactory association of these differences with the current.

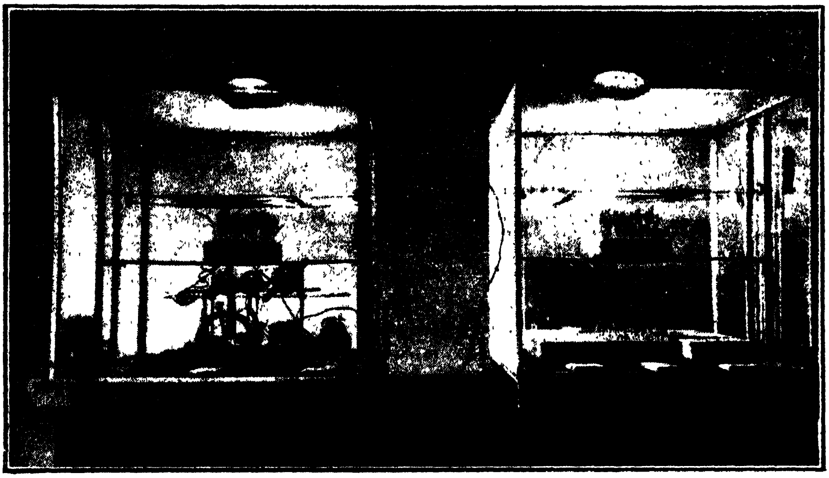

FIG. 81.—Methods used in electrocultural experiments. In the cage on the left a measured current of electricity was passed from the overhead network through the plants on the insulated supports below

It seems clear that at the present time no practical method of electrical stimulation has been developed.

L. H. FLINT.

### EXHIBITS in Farm Education

The next time you go to your State fair or to one of the big livestock shows, ask the man at the gate where you can find the Government exhibit. He will probably direct you to one of the main buildings. You can easily find the exhibit, because it will have a large sign over it, "United States Department of Agriculture." This is the department's traveling school of agriculture.

This particular school may include such subjects as farm management, livestock raising, better roads, forestry, and home economics. Again, it may be limited to a special course on one subject such as dairying, giving the latest information on methods of feeding, breeding, and management. Whatever the course happens to be there is usually much to interest every visitor. This may be called a silent school of agriculture because the information is presented by means of educational exhibits. There will probably be from 10 to 20 of these exhibits, each one of which has a message so presented that it may be easily and quickly grasped.

The department is a storehouse of valuable information on agricultural subjects and new information is being added all the time. This information is valuable only when it is put into use. Millions of people attend the State fairs every year, a large proportion of whom are interested in farming. These offer a selected audience to which to present this information.

Many people learn more quickly and retain information longer when it is received through the eye than through any other means. One authority has stated that 80 per cent of retained knowledge is that which comes through the eye. Whether or not this figure is correct, the educational exhibit, presenting information visually, is very effective. It yields its message quickly so that he who runs may read, and it yields it without conscious effort on the part of those who receive it.

### Reached 5,000,000 Persons

During the fiscal year ended June 30, 1926, the department showed exhibits at about 60 fairs and expositions with a total attendance estimated at 5,000,000 people. These fairs and expositions were widely distributed throughout the United States, and as many of them were held at the same time, it was necessary to make up 18 complete units of exhibits, each consisting of about a carload of material. It is a task to build these exhibits, start them on circuits on time, have them installed by the opening date, demonstrate them during fair week, answer many questions, and finally pack them in their crates, reship them to the next point of showing, and then repeat all this at the next fair. The men who travel with these circuits and the men who arrange the circuit movements are a busy lot.

One of the temporary Government buildings used by the Department of Agriculture in Washington houses a section of the Extension Service known as the office of exhibits. All through the year specialists in exhibit planning are building new exhibits and improving old ones. Designers are constantly searching for more interesting and effective ways of presenting information. Each year finds new diversions to take the attention of the State fair visitor and each year, therefore, the department's exhibit must be more attractive, more interesting, and more effective to gain and hold the attention of those it wishes to reach. Other workers are busy painting backgrounds, coloring bromide enlargements, lettering and making representations of various objects and scenes in wax, papier mâché, and other types of plastic material. To these folks, a thing isn't impossible simply because it hasn't been done that way before. This is the spirit that constantly works out new types of exhibits.

### Spectators Are Critical

Because exhibits are examined critically by people in groups it is specially necessary that they be free from errors in statement or illustration. An error in a press article or bulletin is less likely to be noticed and ridiculed because only one person sees it at a time and there is no opportunity for mass discussion and expression of opinion. Not so with the exhibit. The slightest error is seized on by some one in the crowd who wishes to show his wisdom or his wit. Much of the comment, however, is offered in good faith. For example, at the National Dairy Show two or three years ago, different kinds of silage were shown in large glass jars fitted with wooden tops like silo roofs. A woman stepped up to the attendant in a perturbed manner and said, "Don't you think it's dangerous for the Government to advocate glass silos? They would break so easily!"

### Made for Quick Setting Up

The department's exhibits are made as light in weight as possible and are so constructed that they may be easily and quickly set up and taken apart. The various pieces of the framework often hook together with bed hooks similar to those formerly used in wooden bedsteads. Where canvas or curtains are used they are equipped with snap fasteners. Every device which tends to shorten the time and labor of handling the exhibits is adopted. Crates are constructed so that the various parts of the exhibits can be placed in them quickly.

FIG. 82.—The average American is always on the lookout for new information. Information in exhibit form is "easy to take" and the crowds make the most of it

Where does the information or subject matter for all of these exhibits come from? The Department of Agriculture has a great number of facts it wishes to make available to those who need it. Each year the various bureaus of the department submit subjects which they believe are particularly important at that time and which they wish portrayed in exhibit form. Plans are then made to present the information clearly and effectively and in a manner so that it will first attract and then hold attention. When these matters have been determined and the exhibit produced, the next question is to route it during the exhibit season where it can accomplish the most good.

The different sections of the United States have different methods and types of agriculture and naturally have different problems. An exhibit on how to trap and poison coyotes and wolves would not be of interest in any section except the West, where the problem of predatory animals is of great importance. An exhibit on the best ways to pack apples for market should be sent only where apples are grown commercially. Of course, some subjects are of general interest, and exhibits portraying information on these offer no difficulties to the men who arrange the routing.

### Description of Material

The nature of a general course in the silent school of agriculture is best illustrated by a brief description of the material which actually made up the department exhibit on a fair circuit. This unit consisted of 12 exhibits, as follows:

Cooperative marketing.—A portrayal of the fundamental principles of successful cooperative marketing.

Farm woodlands.—How the farm woodland should be managed to supply fence posts, poles, and firewood, and yield a substantial profit each year.

Farm sanitation.—The value of sanitation on the livestock farm, proper types of buildings, yards, etc., and proper management.

Horses for power.—Types of horses and the uses for which they are best suited.

Milk for health.—How each member of the family may use dairy products in the diet as an aid to health.

Publications-information.—Showing the more popular Farmers' Bulletins and how bulletins may be obtained.

Selecting meats.—How to tell well-flavored, tender meat from meat of inferior quality, the different cuts of meat, their relative value and how to use each cut to advantage.

The neglected camp fire.—Urges caution in the forests with matches, cigarettes, camp fires, etc., as a means of preventing the 33,000 forest fires each year.

Tuberculosis of dairy cattle.—Shows the progress of the tuberculosis eradication campaign, how the disease attacks the cow and the desirability of getting rid of diseased cattle.

What cow testing revealed.—How one good cow, the average producer in a cow-testing association herd, produced more income above her feed cost than 91 cows in a herd on an adjoining farm.

When lightning strikes.—A flash and a roar attract visitors to this exhibit, which shows them the value of lightning rods to protect their farm buildings, and how to install the rods.

Contrasted with such general and diverse exhibits are those which deal with a single subject. At some of the fairs during the 1926 season a special show on dairying contained the following features:

Care of dairy bulls.
Dairy products for the family.
Dairy-herd management.
Dairy-farm organization.
Dairy-herd improvement.
Milk for children.
Sanitary milk house properly located.
Soy beans for the dairy farm.
Use of dairy products on farms.
Value of pasteurization.
Publications-information.

Associated with the department in making available these traveling schools of agriculture are the fair boards, colleges, and other State agencies. This cooperation makes wide distribution possible. Space for the exhibits is furnished by fairs without cost. They also pay for the transportation of the exhibits and supply labor for installation and maintenance. Each "school" has a corps of men who answer questions and give advice on agricultural problems to those desiring it. These advisers are drawn from the department, the State extension services, and other agencies.

### Holding the Visitor's Attention

Light, color, motion, contrast, and sometimes noise are brought into play to attract attention. Once the visitor stops to look, his attention must be held by the effectiveness and attractiveness of the exhibit. Modern art, mechanical devices, and advertising psychology and methods are largely used to make these "silent schools" efficient carriers of agricultural information.

C. A. Lindstrom.
H. T. Baldwin.

## EXPENDITURES of Farm Home Need Planning

How much should our food cost? What should we spend for clothes? Ought we to spend more on household equipment? What could we afford to do about books, recreation, membership dues to organizations, and other such expenditures?

Why bother ourselves with such questions? Most of us have no great surplus to expend. True, but we do have some choice, and if we remember that home makers as a group are directing the spending of many millions of dollars annually, we will each want to put our family finances on a business basis, for in this way we can both do our part in increasing national prosperity, and also improve our own manner of living.

Fortunately, the thoughtful home maker and her family can themselves work out a plan for expenditures better than can any outsider. How? The family must know five things: (1) What are its absolute necessities; (2) what, in addition, it most wants out of life; (3) the size of its money income; (4) how it now spends that income; and (5) what changes in expenditures would better provide its necessities and more nearly attain its other aims of life.

Planning the expenditure of the farm family is made unusually difficult by the fact that the cash income varies so much from year to year, and comes in at such irregular intervals. But this very situation makes it especially important that the family plan well ahead if it is to get the most for its money.

The first step is to figure out what total amount of money the family is fairly sure of receiving during the next 12 months, from the farm business and not to be put back into the farm, from earnings by work outside the farm, from interest on money in savings banks or invested in mortgages or elsewhere, and from rent coming in.

### List Things Required

The next step is to list, in order of need and real usefulness, all the things the family will require or desire during the coming year, beginning with the most absolute necessities and going on down to the things desirable but not essential.

What will have to be spent on food not provided by the farm? This can be estimated from previous weekly or monthly food purchases, if known; otherwise, from trial weekly or monthly accounts kept for the purpose. What will new clothes and repairs to old ones cost for each member of the family?

Fuel, light, telephone, laundry and other domestic services, soap, blueing, and other household supplies, must be considered. Will any of the furnishings have to be replaced? Visits to the dentist, doctor, and oculist, eyeglasses and medicine, are difficult to foretell, but the future cost of such health services can be estimated by looking back over past experience. Life insurance premiums are definitely known; income and other taxes may be estimated from the past year. Unless a separate farm account is kept, all taxes on the property, water costs, fire insurance, and interest on any mortgage on the farm and payments on the principal, would probably be cared for in the household record. Where an automobile is run, there will be expenditures for gasoline, oil, repairs and replacements, insurance, tax, license, and perhaps new equipment and a replacement fund to provide for a new machine.

Every family needs some recreation; is interested in helping to maintain some organization; wants to buy books, newspapers, music; has expenses in connection with the children's schooling. There are many small personal expenditures such as those for tobacco, candy, barber, and special toilet supplies. The simplest way to handle these latter is to give each member of the family an allowance to cover such items.

After all the necessities are cared for, the family may consider whether it will spend any surplus on new furniture, on equipment, on repairs and enlargement of the house, or increase its savings. The total list of planned expenditures should then be compared with the estimated income. In a well-planned budget the income will be a little larger than the total of all the estimated expenditures, so that any emergency which arises may be, in part at least, taken care of without cutting too deeply into the savings.

It will be found helpful to plan expenditures for each month and to write down what income will be received and what it is planned to spend on each class of items, as food, clothes, and so on during each month of the year.

### A Record of Spending

In order to know how well the plan for expenditures is working, it is necessary to keep a record of the family's spending. A special account book is not necessary. An ordinary blank book will do very well. On one page could be written down all the food bought and its cost. There would be other pages upon which to record the clothing expenditures of each member of the family. All other expenditures could be written on another page; or, if it were thought desirable to keep separate any items, as savings and insurance, furniture and equipment, and so forth, a special page could be reserved for recording on each expenditures group. In most cases except that of food, one page would be sufficient to record all the expenditures on one special class of items during the year.

At the end of each month a line would be drawn across each page and the amounts which have been spent on each class of items, as food, clothes for each member of the family, and so on, be added up. These totals for the month should then be written on a summary page so that one could see at a glance what had been spent on each class of items and what was the total expenditure for January, what for February, and so on for each month in the year.

This summary sheet should be compared with the sheet on which has been written the plan of expenditures for each month. By studying the two sheets, one could see where the plan for expenditures needed to be changed when planning for the next year, and also where one could do somewhat better in the actual spending.

CHASE G. WOODHOUSE.

**EXPERIMENT Stations Promote Soil Betterment** Efficient use of the soil is the basis of successful agriculture. Inquiries into the relations of the soil to the growth of crops have therefore formed an important part of work of the Department of Agriculture and of the agricultural experiment stations in the different States since they were first established. They now comprise approximately 10 per cent of the entire station work and cover almost every feature of soil improvement and use, including drainage and irrigation; correction of alkali, acidity, and other unfavorable conditions; use of fertilizers, green manures, and soil amendments; and crop and soil adaptions.

Much of the earlier work was very elementary, but later it began to go more deeply into correlations of cause and effect, explanations of the phenomena observed, and in furnishing a scientific basis for improved practices.

The series of systematic soil surveys inaugurated by the Bureau of Soils of the department and participated in by the experiment stations have served to increase the exact knowledge of the types, distribution, and general agricultural adaptations of the soils of the United States. The stations have added to the usefulness of these general surveys by supplementing them, especially with more detailed studies of the various soil types. This has made possible a more discriminating choice of soils, crops, and cropping systems and the more effective use of fertilizers and other methods of soil improvement.

It became evident early in the work that something must be done to stabilize the manufacture and sale, as well as the selection and use, of commercial fertilizers, since these were rapidly coming into use as means of improving the productive capacity of soils.

### Results from Fertilizer Inspection and Experiments

To meet this need, fertilizer inspection and testing were inaugurated at many of the experiment stations. This resulted in considerable general improvement in the quality of commercial fertilizers and in their more intelligent and economical use. However, the need of more intimate studies of plant nutrition, of the conditions and transformations of plant food in the soil, and of the best means of fitting the soil to the needs of crops soon became evident. Out of the study of such questions has grown a great volume of practical knowledge as to the best methods of soil management and use of fertilizers and other soil improvers.

Much has been done, for example, to show how the requirements of individual crops for nitrogen, the most needed and expensive plant-food constitutent, may be effectively and economically met, and how soils may be managed to maintain an adequate supply of this element by making better use of the cheaper natural supplies of nitrogen in stable manure and green manures. An important practical result has been the establishment of crop-rotation systems including green manures and cover crops, especially leguminous crops, which take nitrogen from the air through the medium of bacteria.

Similar investigations have been made with reference to potash, phosphoric acid, lime, and sulphur. These have yielded useful information on the requirements of crops for the different plant-food constituents, on the forms in which they are most readily utilized by crops, and on the total and available amounts of them in various soil types. They have also thrown light on the condition in which these materials exist in soils, which in turn has provided a basis for the development of rational soil-management practices to insure the conservation and most effective and economical use of the available supplies.

Unfavorable soil conditions, such as acidity, alkalinity, impermeability, and the like, are widespread and have received much attention by the stations. The work of the stations on soil acidity, for example, has had an important bearing on soil improvement. It has shown not only the nature and extent of acidity in soils but also the amount of acidity which different crops can endure and the factors which influence its adjustment and control.

As a result, the correction of soil acidity by liming is now fairly well understood and extensively practiced. Similarly the nature, cause, and manner of occurrence of alkali conditions in soils have been explained, and effective and economical methods of preventing or controlling the unfavorable conditions have been found. Much has also been learned as to the tolerance of individual crops for different alkali salts and combinations in soils, as well as methods of cropping and management which will overcome the injurious effects of excessive alkalinity. As a general result, profitable use is now being made of many soils which formerly were alkaline, water-logged, or impervious, and therefore worthless for agricultural purposes.

### Basis for Improved Tillage

Studies of the physical properties of soils have provided the basis for improved methods of tillage and moisture control and of liming and manuring. Methods have thus been developed for maintaining soils in the friable, well-aerated condition required by crops, and a basis has been laid for the improvement of tillage operations and machinery.

Much has been done to determine the moisture requirements of different crop plants and, with this as a basis, to determine the movement, distribution, and conservation of moisture in soils of different kinds and the ability of the soils to make water available to crops. As a result, methods of tillage, manuring, cropping, drainage, and irrigation have been developed which aid in maintaining the optimum moisture conditions for growing crops on different types of soils. It has also been made possible, largely as a result of such work, to do much in the way of adapting crops to prevailing conditions of precipitation and soil and thus make most efficient use of the available moisture supply.

Two other lines of scientific endeavor which promise to aid eventually in the improvement of soils are the studies of colloids and replaceable bases. It has been shown that colloids exist in considerable amounts in soils and have a marked influence on those physical and chemical properties which largely govern soil productivity. The work with replaceable bases promises to provide a more reliable basis than is now available for the adjustment of soil reaction to the needs of different crops.

The above are some examples of ways in which the experiment stations have been able to contribute to the improvement of agricultural soils. Many other examples might be cited showing the wide range of soil problems to which the stations have given attention. The broad scope of these activities and the closeness of contact of the stations with local or regional soil problems undoubtedly accounts for a large measure of their usefulness in solving problems of soil improvement.

R. W. TRULLINGER.

## EXPERIMENT Station Work on Animal Disease Control

Animal diseases exact a heavy toll of the farmer and at times result in enormous and overwhelming losses. Naturally the subject of their control demands and receives much attention from those concerned in maintaining efficient and profitable production and safeguarding the food supply and the public health.

Of the approximately 6,500 projects of investigation of the agricultural experiment stations, 216 deal with animal diseases and their control. This work of the stations supplements and in many cases is closely associated with that of the department. The combined efforts of these and other agencies have made possible a high degree of protection of the health of man and beast and advancement of the livestock industry of the country. Certain destructive diseases, such as contagious pleuropneumonia, have been actually eradicated; others, like Texas fever and tuberculosis are in the process of eradication; and with many others, as, for example, hog cholera and bacillary white diarrhea of chicks, a high degree of control has been attained.

The list of diseases to which the stations have given attention is a long one, including most of the important diseases which seriously affect livestock.

Tuberculosis of cattle was one of the first diseases investigated. This disease has been studied from many angles and the knowledge thus gained has paved the way for the campaign of eradication now being successfully conducted throughout the country. A marked recent increase of tuberculosis in swine noted in certain regions has been attributed by the Nebraska station in large part to infection from tuberculous fowls. The avian form is apparently not so virulent in swine as that transmitted from cattle, and its diagnosis appears to be somewhat more difficult.

### Means of Disease Control

The Nebraska station finds that tuberculin of mammalian origin often fails to detect avian tuberculosis, and vice versa. The station, therefore, recommends that both avian and mammalian tuberculin be used in diagnosis. The station recommends as the best means of controlling the disease the selection of safe quarters and feed, the rejection of diseased carcasses as food for swine, and, above all, the practice of hog-lot sanitation such as is now generally advocated for the prevention of filth-borne pig diseases. The Minnesota station found that less than 1 per cent of the eggs from tuberculous fowls actually contained living tubercle bacilli. No tubercle bacilli were found in or on the eggshell.

Investigations of Texas fever were also undertaken at an early date, but little progress was made until the causative organism was discovered and its transmission by the cattle tick, demonstrated by Theobald Smith and F. L. Kilborne of the department in 1889, and methods of dipping infested cattle and of immunization were successfully worked out. This has made it possible to introduce improved breeding stock and thus build up the beef and dairy industry of the South. The stations have assisted in furthering the tick eradication campaign, which has resulted in the release from quarantine of large areas of formerly tick-infested country.

Hog cholera has been one of the most destructive diseases with which the American farmer has had to deal, particularly in those regions where hogs are raised in large numbers. Following the discovery by Marion Dorset of the department that the disease is caused by a filterable virus and the perfection of the serum method of treatment, the stations have taken an active part with the department in the application of such knowledge in prevention of the disease and in assuring a sufficient supply of dependable serum for the purpose.

### Infectious Abortion a Menace

Infectious abortion has become a serious menace to the livestock industry, especially to the business of the breeder of cattle, horses, and swine. The loss of young and the sterility which may follow has led to investigation by a number of the experiment stations of the means of transmission, diagnosis, possibility of immunization, and control measures. Elimination of the disease by isolation of reactors appears to be a possible practical solution of the problem. The Washington experiment station found it possible to control abortion in a Holstein herd, 65 per cent of which was infected, by dividing the herd into two groups on the basis of the agglutination reaction and keeping the two groups separated when they were at liberty. This necessitated having separate pastures in the summer and two open sheds in the winter. All of the cows were milked at the same barn by the same attendants. The negative cows were brought in first and stanchioned, after which the positive cows were brought in. After milking, the positive group was turned loose first. The cows were brought into the barn for the purpose of milking only and while there were fed their grain. No hay was handled, stored, or fed in the milking barn. After milking, the manure was removed and the floors washed and scrubbed.

A striking illustration of the practical value of the scientific work of the stations on animal diseases is the result of investigations on bacillary white diarrhea of chickens in which a number of the stations, notably those of Connecticut and Massachusetts, have engaged. This disease spread so rapidly as to threaten the day-old chick business. The losses were so large that many hesitated to buy baby chicks under any circumstances. Investigation led to the discovery that the organism causing the disease passes from the ovary of the infected hen through the egg to the chick. This discovery was followed by the adaptation of the blood test to the detection of the infected hen, thus making it possible to eliminate the carrier fowls from the flock in much the same way that the tuberculous cow is detected by means of tuberculin and removed from the herd. This furnishes a means of eradicating the disease and makes practicable the accreditation of disease-free flocks.

W. A. HOOKER.

## EXPERIMENT Station Results in Food Crop Improvement

Production of the highest yields of high-quality products appears essential to the financial success of the farmer. The pioneer efforts in experimentation with crops aimed toward increased acre production and the cultivation of greater areas. The recent excess production of certain crops, with consequent reduction in profits, has given impetus to development or search for better crops or those possessing particular outstanding qualities. The plant-breeding sections of the agricultural colleges and experiment stations have been constantly engaged in endeavors to develop better varieties of cereals, root crops, and vegetables, and to make them available to the farmers.

The numerous varieties obtained either as the results of definite attempts or as by-products of investigations have been variously characterized by their earliness, disease resistance, adaptation to specific environmental conditions, commercial value, or culinary qualities. Enhanced protein content of wheat, variation in the oil or protein content of corn and soy beans, better brewing quality in barley, increased sugar content of sugar beets, improvement of quality and length of fiber in the fiber crops, better seed quality of potatoes, and improved quality in tobacco have resulted from the extensive efforts of the plant breeders.

Food grains have naturally received first attention in view of their prime importance in the home, on the farm, in manufactures, and in commerce. The principal aim in wheat improvement has been the production of high-yielding varieties, but milling and baking quality and resistance to drought and disease are important considerations.

### New Varieties of Wheat

Among the noteworthy varieties of wheat is Kanred, a pure-line selection from Crimea (Turkey) contributed by the Kansas experiment station, which has proved more resistant to rust, somewhat more winter hardy, and slightly earlier than the more commonly grown Turkey and is now grown extensively. Denton, a pure-line selected from Mediterranean wheat by the Texas station, is rust resistant and outstanding in yield and has a wide distribution in the wheat-growing region of northern Texas. Fulhio wheat, developed by the Ohio station as a pure-line selection from Fultz, has exhibited high yields, good tillering capacity, winter hardiness, fairly stiff straw, and a somewhat greater resistance to loose smut than Fultz. Redrock, an awned, soft, red, winter type selected by the Michigan station, is suitable to well-drained, fertile loams and heavy soils and is of excellent milling quality. Inbred, developed from Banat wheat by the Iowa station and the United States Department of Agriculture, has given excellent results, showing winter hardiness, excellent quality, stiffness of straw, and a good yield. Michikoff, developed from a hybrid by the Indiana station, is known for its winter hardiness and a hard, glutinous kernel of high-test weight, producing flour of superior quality for bread.

Marquillo, a new awnless wheat originated at the Minnesota station by crossing Marquis and the rust-resistant durum Iumillo, has a stiff straw, matures somewhat earlier, yields slightly better than Marquis, and compares favorably with' Marquis in baking quality. Mindum, a bearded, white-kerneled durum wheat selected by the Minnesota station, has fair rust resistance, yields high under Minnesota conditions, and is of good quality for macaroni and other durum-wheat products. Minturki, a bearded, white-chaffed winter wheat with kernels of the Turkey type, resulted from attempts by the Minnesota station to produce a hardy winter wheat with other desirable qualities. Mosida, developed by the Idaho station, has given high yields, has a better than average resistance to bunt, good strength of straw, and is adapted to the cut-over sections of northern Idaho. Ridit wheat, developed by the Washington station from a hybrid, is an awnletted hard winter wheat and has resistance to bunt and to shattering and superior milling qualities as outstanding characters.

### Corn Investigations

Investigations with corn have been so extensive and diverse that only significant current trends may be discussed. Practically every station has compared local and introduced varieties and has endeavored to produce better strains by selection, hybridization, or other breeding methods. The wide variation according to the type or variety of corn and also within the variety renders it possible to select for ear or plant characters, e. g., the high and low protein and the high and low oil strains produced by the Illinois station and the cold-resistant strain by the Wisconsin station, as well as the characteristic kernels and other features of certain types. The widespread use of improved varieties such as Leaming, Reid Yellow Dent, and Boone County White has greatly increased the value of the corn crop.

Considering that corn is highly cross pollinated, that the grower naturally tends to select certain of the several types in the variety, and that the several types may react differently to the environment, it is not surprising that the improved variety may be decidedly modified in relatively short periods. Systems of breeding depending on mass selection, i. e., ear-to-row or score card, generally have not been found advantageous, since these are based on ear or plant type and consider only the female parent.

The method of breeding known as selection in self-fertilized lines recently in vogue at many of the experiment stations controls the male parent by self-pollination. Inbred lines so derived are differently characterized by their vigor, weakness, tendency to lodging, and resistance to diseases. Chlorophyll variations, dwarfing, and other aberrant tendencies may appear during the several years of selfing and can be eliminated. The most vigorous and promising of such inbred strains may be combined in single, double, and multiple crosses, even to the extent of producing " synthetic " or " re-created " varieties. Current results suggest that the standard corn varieties may be decidedly improved by this means.

### New Strains of Oats Profitable

Oats, a cereal ranking high in acreage and crop value and very important in American agriculture, has also received considerable attention from plant breeders. The claim has been made that the improved oats varieties developed and distributed by the Iowa station return to the State each year more than the total annual appropriation made by the State for the support of the State college and the experiment station combined. A survey indicated that over 46 per cent of the total oats acreage of Iowa in 1924 was planted to Albion, Richland, Iowar, and Iogren oats, varieties developed cooperatively by the Iowa station and this department. The total production gained by growing station varieties that year was about 11,000,000 bushels.

Gopher, an early maturing oats with white grain, selected by the Minnesota station, is characterized by a stiff straw, high yielding ability, and heavy weight per bushel. Kanota oats, distributed by the Kansas station, excels the commonly grown Red Rustproof (Red Texas) in yield, test weight, and earliness, and can endure heavy spring frosts better than Red Rustproof. The New York (Cornell) station cooperating with this department has brought forth six pure-line selections of oats—Cornellian, Ithacan, Comewell, Empire, Standwell, and Upright. Wolverine, a very productive oats for the lighter loams and upland soils, and Worthy, a stiff-strawed variety adapted to very heavy soils, resulted from breeding work by the Michigan station. The superior characters of Markton oats, developed by the Oregon station and this department, include early maturity, high yield, immunity from covered smut, thin hull, and excellent milling quality. Tech oats, originated by the Virginia station, combines high yield, early maturity, and winter resistance. The Wisconsin station has produced several high-yielding oats, including State Pride, characterized by earliness and adaptation to fertile soil; White Cross, identified by earliness, tall straw, and adaptation to light soil; Forward, having plump kernels and relative freedom from rust; and Wisconsin Wonder, known for its stiff straw.

### Other Cereals

Among the cereals used to a lesser extent for food may be mentioned Tennessee Winter a six-rowed awned hulled barley developed by the Tennessee station, and Colsess, a six-rowed hulled barley derived by the Colorado station, which stands up under irrigation, does not shatter much, is early, high yielding, and adapted to mountain agriculture. Michigan Black Barbless is a short, stiff-strawed, smooth-awned barley brought forward by the Michigan station and indicated for heavy fertile soils. Minsturdi, a six-rowed barley produced by the Minnesota station cooperating with this department, has a stiff straw, yields well, and is particularly adapted to rich or heavy soils where other varieties often lodge badly. In similar cooperation, resistance to spot blotch and the smooth-awned character were combined in Velvet, a six-rowed high yielding barley. This department cooperating with the Idaho station developed Trebi, a six-rowed awned, stiff-strawed barley for irrigated land, and with the New York (Cornell) station produced Alpha, a two-rowed hybrid yielding well in New York.

Grain sorghums improved by the Texas station include Spur feterita, a variety apparently well suited for growing under irrigation and surpassing the original feterita for both grain and forage; Dwarf feterita, selected from common feterita, being very early and drought resistant and valuable for extreme western Texas where rainfall averages below 20 inches; and high-yielding strains of Blackhull kafir. Resulting from crosses between kafir and feterita in cooperation with this department, Primo excels the common sorghums in both grain and forage qualities, and Chiltex, considerably earlier than Primo, is better adapted to the dry regions of western Texas.

Several new varieties of rice, Fortuna, Acadia, Delitus, Tokalon, Evangeline, Vintula, and Salvo, characterized by their agronomic and culinary qualities, were developed cooperatively by the Louisiana station and this department. Texas Fortuna rice, developed by the Texas station, resembles the Fortuna selected in Louisiana.

### Vegetable Breeding

Vegetables make up a considerable and important portion of the diet of the family, and, naturally, have been the subject of extensive breeding work at the experiment stations. The Robust white navy bean, a vigorous, disease-resistant, and productive variety has been selected by the Michigan station. Iowa 5 cabbage, developed at the Iowa station, proved resistant to yellows and growers reported it a very good type. Several types of cabbage resistant to yellows have been developed by the Wisconsin station cooperating with this department. Penn State Ballhead, a late cabbage notable for uniformity in size, shape, and weight, and high yields, was brought forth by the Pennsylvania station. Sunshine sweet corn, a yellow sort considerably earlier and with much larger ears than Golden Bantam, resulted from breeding work at the North Dakota station. A high quality and evenly maturing type of Country Gentleman sweet corn, developed at the Indiana station, outyielded its nearest competitor by from one-half to three-fourths ton per acre. Selection in self-fertilized lines has given rise to superior sweet corn at the Maine station.

The Everbearing pea, developed by the Idaho station, is a good market garden pea, combining high yield with exceptional flavor.

The V. P. I. Green Mountain potato, a hill selection outyielding the ordinary Green Mountain, has excellent cooking qualities and is in great demand and widely grown in western Virginia. Kitchenette Hubbard, a small Hubbard squash developed at the Minnesota station, averages about 5 pounds per squash but yields as heavy a tonnage as any of the Hubbards and is considered the ideal squash for the family. The Virginia Truck station originated a variety of spinach, Virginia Savoy, resistant to the mosaic disease and possessing good quality. The Red River tomato, an extra early red variety which is rounder, smoother, and more solid than Earliana, and the Agassiz, a medium early purple tomato of good size and heavy yielding ability, were developed at the North Dakota station. Tomato strains selected at the Missouri station for resistance to wilt (*Fusarium lycopersici*) gave acre yields as much as 8 tons in excess of those by nonresistant commercial sorts.

Examples like the above, showing how the experiment stations have contributed to the improvement in yield and quality of food crops and thereby increased the potential food producing capacity of the country, might readily be multiplied.

HENRY M. STEECE.

## EXTENSION Education Making Great Progress in U. S.

A new leaven is at work in country life. The farmers, the agricultural colleges, and the United States Department of Agriculture are cooperating in a great teaching program that has for its object a more efficient and profitable agriculture, an adequate supply of food and clothing for the Nation, and a larger social, recreational, and educational rural life.

There are directly engaged in the new work about 5,000 Federal and State employees giving full time to the work, 200,000 volunteer farm men and farm women acting as chairmen of committees or sponsors of local improvement work, and about 1,500,000 farm and home demonstrators. The Federal Government is spending about $7,000,000 annually in support of the work, and the States and counties about $12,000,000 more, making a total of around $19,000,000.

As a part of this work, 565,000 rural boys and girls 10 to 18 years of age have been organized into 45,000 clubs for the purpose of learning better agricultural and home economics practices, how to do things, acquire property, develop character, and achieve. In all, about 3,000,000 farms and homes are changing some practice for the better annually as a result of this work with juniors and adults.

The partnership of Government and people in a rural teaching program is something new. The agricultural colleges, through their experiment stations, and the Federal Government, through its Department of Agriculture, have a research force of more than 5,000 trained men and women giving their whole time to finding out new things in agriculture and home economics. They are constantly discovering matters of fundamental importance to agriculture and significance to farmers.

### Farmers Who Are Experimenters

Then there are farmers in every community who are essentially experimenters. They have tried out new crops, new ways of doing things, have managed differently and have made a success where many others have failed. They know local conditions; what is likely to succeed and what is not.

When, therefore, the agents of the agricultural colleges and the Department of Agriculture, with their technical background of research, and the farmers with their knowledge of local conditions and background of experience in any community form a partnership, as they have in over 45,000 rural communities of the United States, for the purpose of improving the economic, educational, and social conditions in those communities, progress in those communities is inevitable.

In this new teaching work agents of the Government and the farmers and farm women, sitting around a common council table, first go over together the facts of the community—what crops and stock they are growing, the yields and products they are getting, cost of production, facilities for marketing, profits and losses, hindrances to success, and like matters, and together agree upon a plan of betterment. (Fig. 83.)

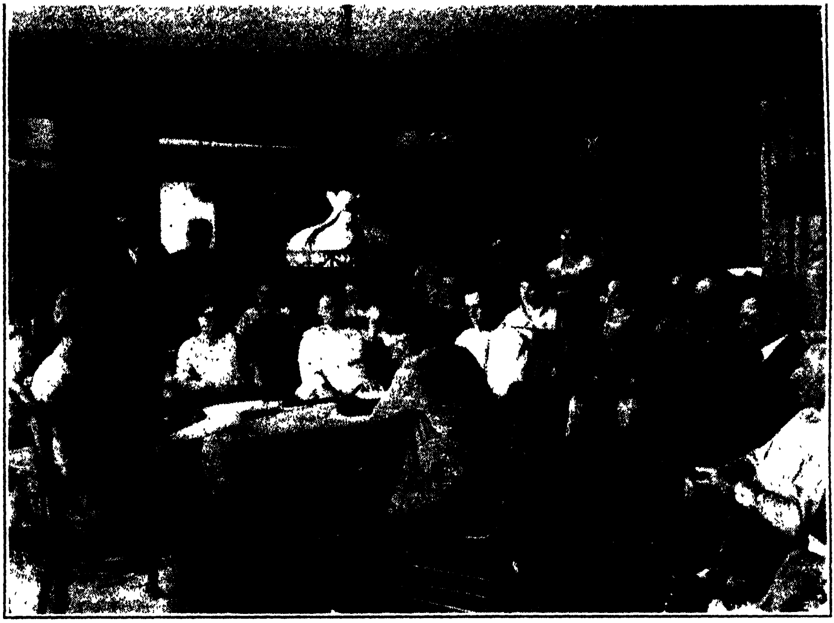

Fig. 83.—Developing a community program for extension work with the county extension agents

They determine whether they will employ a technically trained counselor to be stationed permanently in the county to aid them in their work, whether such counselor will be a man or woman county agent or home demonstration agent, who he or she shall be, what wages shall be paid, what program shall be put on the first year, what demonstrations made, what farmers will make them, what assistance shall be given the farmer demonstrators by the county agent or home demonstration agent, what field meetings shall be held, what exhibits and reports made by the demonstrators, what short courses they want held, what instruction given, and like matters. When people begin to think systematically and critically about their business, they take the first great forward step in progress.

### Learning by Doing

The essential characteristic of extension education is learning by doing. When a farmer in eastern United States puts on a demonstration in alfalfa, for example, with the cooperation of the extension agents, he learns through his own experience the value of lime, the need of inoculation with the proper bacteria, and the necessity of using native northern-grown seed.

When a field meeting is held on the demonstration plot and the farmer explains to his neighbors what he has done, how he did it, and the results he is getting, he grows mentally. When that winter he reports to the farmers' institute or other farmers' organization his yields, costs, profits, and the results he is getting in feeding the new legume to his cows, he makes further progress; and when the next season he acts as a teacher in showing his neighbors how to grow and feed alfalfa on their own farms, he becomes a real teacher and man of importance in the neighborhood.

Extension work brings farmers and farm women together increasingly in groups for the consideration of matters involving group action. Thus, in shipping livestock, pooling of the stock of a number of farms is often necessary if the advantages of carload-lot freight rates are to be obtained or if feed is to be bought at wholesale prices. The farmers learn the benefits of cooperation. They reach the decision as to whether or not they will form a shipping association, elect their officers, tag the stock shipped, decide on the market they will ship to, get back the returns, and make the distribution of proceeds. This is all an educational work, and men and communities develop in the process.

Extension is doing much for farm women; through it farm women are increasingly getting out of the home and meeting together in clubs. They are studying the principles of nutrition, how to blend colors to match form and complexion, make hats, test fabrics, use patterns, and dress becomingly, how to earn money, plan the year's budget, and organize their labor. Moreover, they are learning parliamentary practice, how to play together, entertain, train children, care for the health, and like matters.

### Training of Boys and Girls

Probably the most significant phase of extension education is the training that is being given rural youth in the boys' and girls' club work.

In this work, boys and girls 10 to 18 years of age are taught the best way to grow corn, feed and care for poultry, can fruits, meats, and vegetables, bring up a litter of pigs, and such things. The young folks usually are organized into clubs of 10 to 15 members each. Each member must do a piece of farm or home work and put it on in such a way that it will be a demonstration of better ways in the neighborhood.

The club members make exhibits of what they grow, are taught how to judge quality and value. They are taught how to earn money, acquire property, the value of thrift, while in the process they are taught how to sing together, play together, put on a team demonstration. It is something done voluntarily. It is not out of books but out of life. They like it. They are learning efficiency and cooperation and sociability in their youth and the records show that the things taught boys and girls in their youth are carrying over into their adult life. This is probably the most important phase of present-day agricultural extension education.

The agricultural extension work is a National, State, and county government service, available to all and within the reach of all rural people. No one can come in contact with it and take part in it without growing in efficiency, enlarging his outlook, becoming a better neighbor and citizen. It is a service for the whole family. How it may be brought into any rural community anywhere can be learned by addressing the extension service of any State agricultural college or the Extension Service, United States Department of Agriculture, Washington, D. C.

FIG. 84.—A girls' club member in her demonstration garden

C. B. SMITH.

**FARM Accounts an Aid to Efficient Planning of Work** Many farmers in the past have kept some form of accounts but only a small percentage have kept them in the most useful form. Some keep an account of their receipts, others keep only the cash outlay, and still others keep only inventories. In any case the procedure in account keeping has not been sufficiently systematic to inspire the farmer with the value of his accounts or to enable him to make important practical use of them.

One reason why progress has been slow is that practical farm bookkeeping methods have had to be developed mainly by the trial-and-error route. Attempts to transfer the accounting systems of the industrial field to farming have not worked. They involved too many transactions and too much time for bookkeeping. To meet this deficiency, a practical type of farm accounting was developed by the cooperative extension service of the State agricultural colleges and the United States Department of Agriculture through the assistance and cooperation of practical farmers.

This type of farm accounting recognizes the principles of standard accounting, and lends itself to such modification in form from year to year as the needs of farmers using it demand. The Extension Service has been working on this problem of farm accounting with groups of farmers in over 30 States and in each State practically the same basis for the keeping of farm accounts has been adopted.

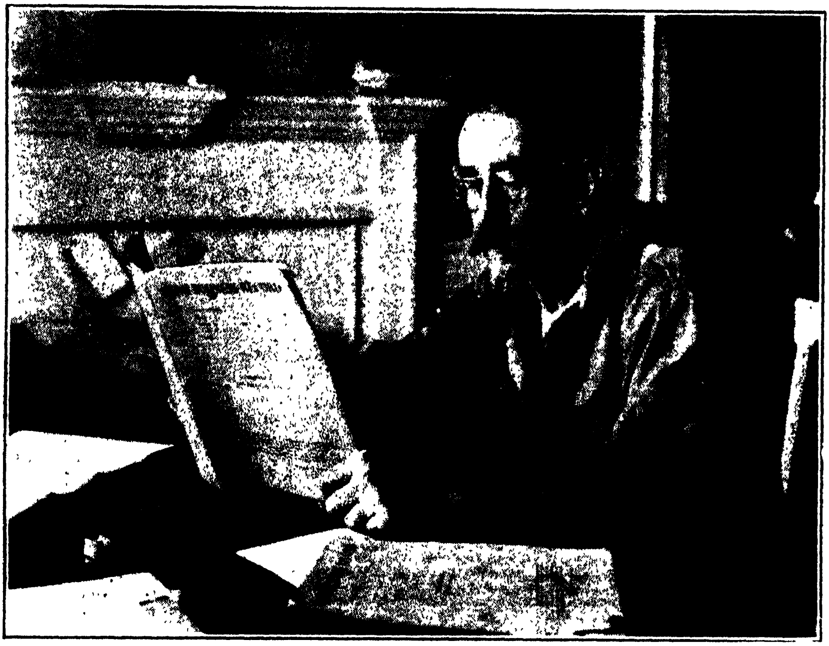

FIG. 85.—Farmers find properly kept accounts most helpful in planning the management and operations of the farm

### Extension Service Assists

More than 90,000 farmers procured copies of these simple farm account books for use in 1925. Although it is not possible to follow up all farmers receiving books and assist them with their accounts, 10,000 farmers were assisted by the county agents throughout the United States in 1925 in keeping and analyzing these accounts. The results were used by the individual farmers cooperating in improving their standing and by the Extension Service as demonstrations to larger groups of farmers of what can be accomplished by a better knowledge of the facts of a business. This work was done under the general supervision of the farm-management demonstrator and the department of farm management of the agricultural college.

Extension workers have supplemented the 10,000 demonstrations in farm accounting referred to above by inviting farmers to meet with them in groups to discuss the practical uses of their accounting records in the managing and operating of their farms. The point always emphasized in promoting this work is that the real value of the accounts to the farmer is in the final summary and analysis. It is pointed out that accounts enable the farmer to locate those parts of his business that are strong and those that are weak. Studies of the farm business show that very few farms are either high or low in all the factors of success. Each farmer has his own problems, must study his own facts and conditions with those outside his own business operations, and plan accordingly.

FIG. 86.—Extension workers meeting with a group of farmers to summarize and discuss their accounts

### Two Methods in Use

For those farmers who are keeping their accounts throughout the year, two methods are in use by the Extension Service to aid them in summarizing and analyzing these accounts. In some States, farm-account summarizing schools are held. Each farmer in the group summarizes his own account, works out the factors of success, and compares his practices with the average for the group. At the end of such a meeting, he knows how he stands and what factors to place stress upon for higher returns the following year.

Under the other plan, the books are obtained from the farmer and summarized and analyzed in the county extension office or at the State agricultural college. A combined summary of all the accounts in one county or similar agricultural area is prepared, showing the average standing of the group of farms in (1) rate earned on investment, (2) labor and management wage, (3) yield efficiency of crops raised, (4) returns of each kind of livestock kept, (5) labor efficiency, and (6) economy of production as measured by the net income per acre and the ratio of expenses to total receipts.

More light is also given the farmer in making comparisons of standing by showing not only the averages for the whole area, but the standing of the 10 best and 10 poorest farms as well. This analysis and summary is mimeographed and taken back to the farmers and discussed by some one fully qualified to explain it and aid in applying it to the individual farm. On the personal copy of these figures supplied, each farmer also has his own figures. These are set down alongside those of the average and the high and low groups. He is thus given a definite basis of measuring the success of his business as a whole and of the different parts making up the whole.

### Accounts Help Improve Farm Business

Farm accounts properly kept may aid the farmer in the following ways:

(1) They show what things pay best.
(2) Aid in adjusting crop and livestock enterprises.
(3) Help weed out poor livestock.
(4) Help in improving feeding methods.
(5) Help in procuring better equipment.
(6) Help in getting higher production or returns per man.
(7) Help in selling farms or in purchasing farms that are adapted to efficient operation practices.
(8) Furnish information for credit statements when funds are borrowed.
(9) Supply the facts for income-tax returns.
(10) Aid the tenant and landlord in keeping their accounts straight and in a fair distribution of the returns.
(11) Aid in obtaining adjustments in land appraisals for tax purposes.
(12) Supply facts for use on public policy or legislative matters.

On the other hand, more of these complete records are being made available each year to the Extension Service. These records in the past have proved invaluable as guides to sound programs of work and as an aid in showing the best combinations of enterprises in a county, region, or State.

H. M. DIXON.

## FARM Returns From 1922 to 1925 Studied

When the agricultural situation became recognized as a problem in which all were immediately concerned diligent search was made for facts on which to base solutions. Available data of different types were very numerous, and capable of interpretation in the new uses to which they were put to suit the purposes of persons stating their views.

Acceptable data on incomes of farmers were, however, conspicuous for their absence, though attention centered rather naturally on income as the one satisfactory measure of the net result of many economic forces more or less conflicting. Such income data as there were included the farm business analysis surveys of groups of farmers in scattered localities; the evidence offered in connection with collective bargaining for prices during the war period; and statements made by and for farmers in the press. These were local in character, or "special cases," and for specified short periods, whereas need was felt for a broad view of the industry as a whole, year after year, for comparisons. Analyses of mass statistics were begun by public and private agencies to overcome these deficiencies of the more limited data.

In 1922, a plan to obtain each year direct from farmers statements of the financial results of their own operations was approved. Sufficient numbers of such statements well distributed over the country were expected to yield data from farm sources adequate for the purpose of summarizing changes in incomes of farmers from year to year for the country as a whole and for selected sections, States and divisions, and for farmers producing different classes of products. The first inquiry was for the year 1922, and was sent out in January, 1923. In April, 1923, the averages for the 6,094 farms reporting were published in some detail for the main geographic divisions.

### 1922 Data Lacked Comparisons

The farm returns for 1922 stood by themselves without means of direct comparison—no other data from the same source and no other statements with quite the same classes of items were available. They were therefore subjected to critical examination by many persons before and after publication. The limitations of the data and of the method were pointed out and an effort was made to overcome the effects of these limitations in the inquiries for subsequent years.

Analysis of the reports for four years shows a consistency in the averages that is remarkable under the circumstances. Average cash receipts of the farms reporting have increased each year, reflecting the combination of good crops and improving prices for products Cash expenses, similarly, increased instead of decreased, but not quite so much, leaving an increase each year in the net results for the farm, and, by inference, in the income of the farmer, also. Yet these increases in the averages for all farmers reporting were not shared equally in any year. The greatest improvement is shown by the reports from the Western States.

The best year for the farmers reporting from the North Atlantic States was 1925 and it was the poorest for those reporting from the South Atlantic States, 1923 appearing best in that division. In the South Central States 1925 appears to have been less profitable than 1924 (the best year there by far) or 1923, but still somewhat better than 1922. In the North Central States, the average for both 1924 and 1925 showed marked improvement over 1923 and 1922. In the East North Central States the gain shown by reports for 1924 over 1923 was less than in the West North Central States, but reports for 1925 showed a further gain in the East North Central States, while reports from the West North Central States showed practically no net improvement.

The averages for each section each year are analyzed in tables in the statistical sections of the Yearbooks. The chances are even that the average net result computed from the reports of the same number of other farmers in the list addressed would not differ more than 1 per cent from the averages there shown for 1923–1925 or 1.75 per cent for 1922. For other items in the tables and for subdivisions of the United States the accuracy is less. Part of the difference between averages for divisions is due to differences in size or value of farms, and part to type of farming. Differences between years are largely attributable to climatic and market conditions.

### Farm Income Highly Variable

Farm income is a highly variable figure, a complex combination of factors of production which themselves differ widely in quantity and in quality, and are variously affected by economic conditions. Even when differences of size of farm and type of product are eliminated by selection of reports alike in these respects the net results are very different. Thus the net result for 1924 computed from the reports for 17 general livestock farms of 200 acres each in a single State varied from $310 to $7,520, averaging $2,478. The average net result was $1,616 for 236 farms of the same type in the same State, ranging from —$2,780 on a 519-acre farm to $9,610 on a 400-acre farm. The net results in 1925 were distributed over a range running from —$29,240 to $85,750. Though a smaller percentage than in previous years showed net results less than zero, still more than 60 per cent of the net results were less than average. (Fig. 87.)

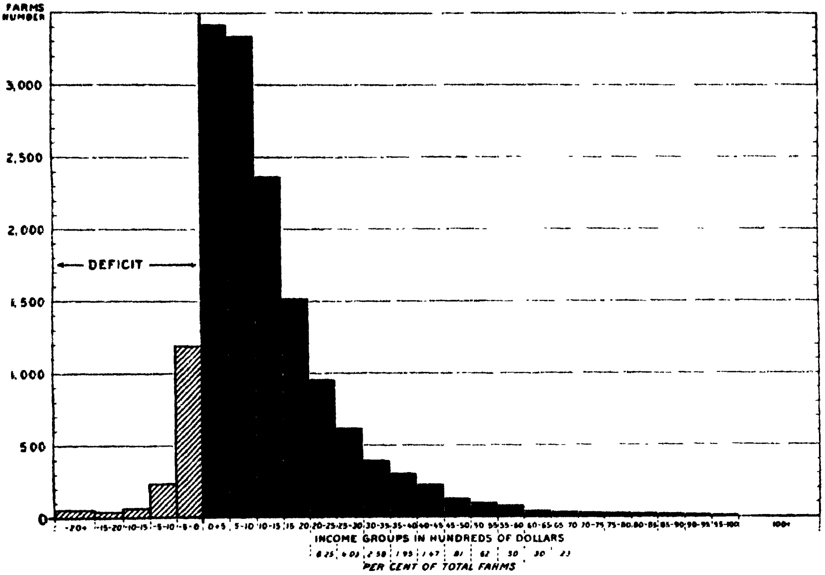

FIG. 87.—Variation in farm returns in 1925. Number and percentage of farms with net results of indicated size as reported by owner-operators in the farm-returns inquiry

The farmers reporting are voluntary correspondents of the department. Their reports are representative including as they do large and small farms, profitable and unprofitable, each of the dominant types of agriculture, from all parts of the country in about the same proportions as all owners of farms reported by the census. They are not "average" in a sense that would permit using the averages for the farms reporting as applying rigidly to all farms in any subdivision or in the United States, as may be done with census figures.

A number of factors need further analysis, with more years and greater volume of data, before the possibilities of the inquiry are completely exhausted.

S. W. MENDUM.

---

**FAMILY Living Level on the Farm** The question of the level of living which the farm family procures from the occupation of farming is becoming rapidly a major problem of American agriculture. The basic factors or elements of farm family living are being analyzed as never before. The cost at which these basic elements are provided is one of the chief concerns of the Nation.

Just what can be said of the farmer's present level of living? What variety and quantity of material and other goods does it contain? What is the cost or value of all the goods used annually by the farm family and how is this value distributed among the principal kinds of goods? What part of this value represents food, house rent, and fuel furnished by the farm not without cost but without the direct expenditure of money?

The most satisfactory answers to these questions are found in the combined results of a series of studies of family living among farmers of selected localities in 11 widely separated States. Almost 3,000 families are included in the studies which were conducted by the United States Department of Agriculture in cooperation with the State agricultural colleges or universities. Those States cooperating, with the number of families in each State were: New Hampshire, 40 families; Vermont, 86; Massachusetts, 81; Connecticut, 110; Kentucky, 370; South Carolina, 202; Alabama, 558; Missouri, 178; Kansas, 406; Iowa, 472; and Ohio, 383.

Data were gathered by the survey method. Typical homes within the localities studied were visited. The average size of family, not including relatives, hired helpers, and others, was 4.4 persons. Relatives and others housed and fed amounted to 0.4 of a person, on an average. Practically all of the schedules were filled between July 1, 1923, and December 31, 1924. Since price levels changed very little between the two dates the results are combined as representing the average value of goods used during one year by the 2,886 farm families, including 1,950 owners, 867 tenants, and 69 hired men.

### Food, House Rent, and Fuel

The average value of goods furnished by the farm, $684 worth per family, include foods, $441 per family, use of the farm house (10 per cent of the total value of the house), $200 per family, and fuel, $43 per family. Food constitutes the largest part of the $684 worth of goods furnished, the percentages being 64.5 for food, 29.2 for rent and 6.3 for fuel.

The value of family living furnished by the farm is 42.8 per cent of the total value of family living. Thus, approximately 57 per cent of the farm family living, $914 worth of goods, is provided by direct purchase.

Goods and services purchased include foods, clothing, furnishings, such as furniture, musical instruments, bedding, etc., operation goods, such as fuel and use of the automobile for family living purposes; health facilities, advancement goods and facilities, such as schooling and recreation; personal goods, such as barber's fees, candy, and tobacco; insurance goods, and goods not readily classified.

The average value of all family living is made up of the values of goods furnished and purchased. This amounts to $1,598 per family.

The distribution of the average value of all goods used among the principal kinds of goods grouped according to use is of interest. Food amounting to $659 per family comprises 41.2 per cent of the total. The costs for clothing amounting to $235 per family are 14.7 per cent and the average value of rent, $200 per family, is 12.5 per cent of the value of all goods used.

For all homes an average of 6.8 rooms per family, excluding bathroom, pantry, halls, and closets was reported. Slightly more than one-twentieth, or 5.7 per cent, of the homes were completely modern, that is, fitted with central heating and central lighting systems, running water, kitchen sink, bathroom (equipped with stationary tub and bowl), indoor toilet and sewage disposal. About one-fifth, or 20.8 per cent, of the homes were fitted with a part of the improvements named and almost three-fourths, 73.5 per cent, of the homes lacked all modern improvements.

The average value of furniture and household furnishings purchased during the year amounts to $40 per family, 2.5 per cent of the total value of all goods. The average value of operation goods, amounting to $213, comprises 13.3 per cent of the total. Expenditures for the maintenance of health amount to $61 per family, or 3.8 per cent of the value of all goods used. The average value of goods for advancement purposes amounts to $105 per family and constitutes 6.6 per cent of the value of the total value of all goods.

### Goods for Personal Uses

The average value of goods for personal uses amounting to $41 per family comprises 2.6 per cent of the total. The average expenditure for premiums on life and health insurance, life insurance primarily, was the same, $41 per family. The average amount of money spent per family for unclassified goods amounted to $3 per family.

The distribution of the average values of goods for ten $300 total-value groups ranging from less than $600 to $3,000 and over was determined. The proportion that the value of food is of the total value of goods decreases from 54.4 to 30.7 per cent as the total value of all goods rises from $486 to $3,779 per family. On the other hand, the proportion for clothing increases rather regularly from 11.6 to 16.4 per cent with the increased value of all goods. Similarly, the proportion devoted to advancement goods increases from 1.9 to 13.4 per cent. The proportions for the maintenance of health and for insurance increase somewhat irregularly. The proportions for the other groups of goods remain about the same or vary without regard to the rise in the average value of all goods used.

These statements give no indication of the amount of free time for the fullest use of available goods by the different members of the farm family. They take no account of the source of some of the major satisfactions of farm life, such as an ever-ready supply of fresh foods, sufficient space for children to play, contact with growing things and opportunity for apprenticeship. And they ignore those satisfactions which normally should accompany the successful operation of the farm, a cooperative enterprise involving all members of the family.

Further study of the level of living which the farmer and his family get from the occupation of farming will go far toward revealing the conditions which must be improved if American agriculture is to be stabilized.

E. L. KIRKPATRICK.

## FERTILIZERS in Concentrated Form Devised

At the close of the Civil War the rural population of the United States was about four times the city population. Since that time social and industrial conditions have greatly changed, and at present more than half the total population of the country is to be found in cities and towns having a population of 2,500 or more. The gradual drift of population from the country to the city has been the subject of much serious comment, and it has freely been predicted that this situation if continued must inevitably be followed by a serious shortage in our food supplies.

The proportion of people who live on farms is now only about one-fourth as great as 60 years ago; but instead of a shortage, there is now actually a surplus in many foodstuffs. It is probably true that food supplies are now available to the city dweller in larger quantities and of better quality than at any previous period in our history. The predictions of those who anticipated a shortage in our food supplies failed to materialize for the reason that they did not foresee the wonderful improvements which agricultural research has brought about within a comparatively few years in farm machinery, in the control of insects and plant diseases, and in methods for increasing the fertility of the soil and the productivity of crops. By the application of these various improvements the output per farmer has increased at a rate sufficient to offset the effect of the decrease in the number of people who work on farms.

One of the most important innovations which scientific research has introduced into agriculture is the use of chemical or commercial fertilizers for increasing the growth of crops. It is well known that barnyard manure makes an excellent fertilizer, but the necessity for greater crop production soon increased the demand for this material far beyond the available supply. The commercial-fertilizer industry was accordingly established to make fertilizers from minerals and various organic wastes, such as cottonseed meal, tankage, etc.

### Organic Wastes as Feed

It has recently been found, however, that these organic wastes are also suited for feed for livestock, and consequently the supply available for fertilizers is falling far short of the demand. The Bureau of Soils, foreseeing that this condition was likely to arise and that sooner or later the fertilizer industry would be required to make use of the air we breathe as a source of the nitrogen used in fertilizers, began to investigate the greater possibilities of chemical fertilizers, including the products resulting from "fixing" the nitrogen of the air into fertilizer materials.

The fixed-nitrogen products differ from the ordinary fertilizer materials in containing, as a rule, a high percentage of the plant-food constituents, whereas most fertilizer minerals and waste products are low-grade materials. The ordinary mixed fertilizers, as now manufactured from these low-grade materials, are also low grade, containing on an average only about 15 per cent of the plant-food constituents. If the materials prepared from the air were used in fertilizers, the alternate procedure would have to be adopted of either improving the grade of the fertilizer or of diluting the mixture with sufficient inert material to give the usual grade. The latter procedure would involve an additional expense in the manufacture of fertilizers, whereas an increase in the percentage composition of the fertilizer should decrease the cost to the farmer by reducing freight and handling charges.

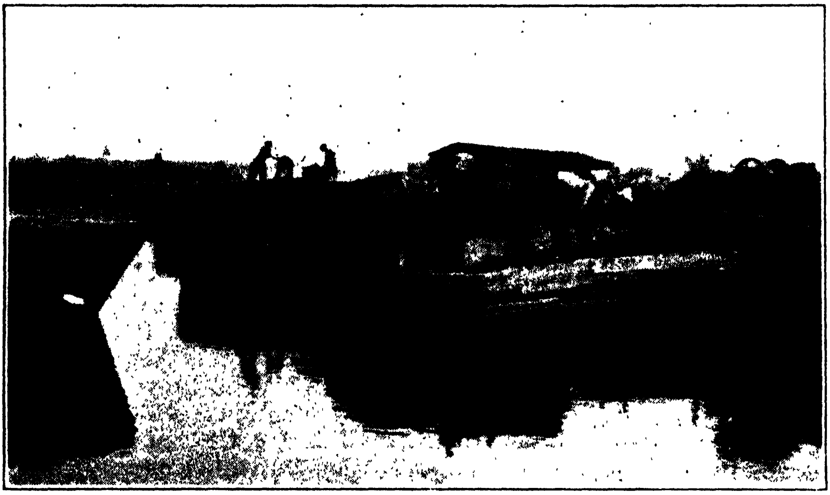

FIG. 88.—Unloading manure scows. A common scene in the trucking sections of the North Atlantic States when manure was plentiful and cheap

Unfortunately most of the materials, so far prepared from the air are disagreeable to handle or otherwise unsuited for use on the farm. Many have the property of absorbing such a quantity of moisture from the air that they cake or become sticky, and can be applied only with difficulty.

A study of these concentrated materials was accordingly undertaken by the Bureau of Soils several years ago to determine the best means of adapting them for use in fertilizers. It was found that their physical condition could be greatly improved at little or no expense by a slight modification in the process of their manufacture, resulting in a product having the form of small spherical grains.

It was also observed that the properties of these materials could be still further improved by combining them in the process of their manufacture with certain other fertilizer compounds of mineral origin. These materials do not absorb moisture from the air; they are easy to handle, and they can be readily drilled in the field with the greatest uniformity. They likewise have the further advantage of containing two of the three major plant-food constituents instead of one, as in the original materials prepared from the air. By proper selection of these new materials it is possible to prepare mixed fertilizers containing as much as 75 per cent of plant-food material, or five times as much as that carried by the average complete fertilizer.

### Cost Less to Farmer

The term "concentrated fertilizer" has been applied by the Bureau of Soils to mixtures which contain 30 per cent or more plant-food material. This term has now been adopted by the fertilizer industry, and during the past year most of the large fertilizer manufacturers have prepared for the first time one or more mixtures of this class. The labor of handling, hauling, and distributing these fertilizers is not only less than for the standard grades, but their actual cost to the farmer is also less per unit of plant food.

That the value of fertilizers in increasing plant growth is not diminished by increasing their concentration is shown by the field tests of the Bureau of Plant Industry and by such practical demonstrations as those recently made in California, where a new world's yield record of more than 1,000 bushels of potatoes was recently obtained with a concentrated fertilizer containing 47 per cent of the plant-food constituents.

The recommendations of the Bureau of Soils in favor of higher-analysis fertilizers are thus being adopted by the fertilizer industry; but many problems still remain to be solved. It is reasonable to conclude that further work on the subject will be followed by still greater improvements in the manufacture and use of concentrated fertilizers.

William H. Ross.

## FERTILIZER in Small Bulk Being Tested

The term "concentrated fertilizers" means the use of fairly pure fertilizer salts in combinations giving a very high-analysis plant food. There is no way to concentrate the ordinary fertilizer mixtures of commerce. The latter consist often of materials which carry a low plant-food content so that the mixtures may contain as little as 10 per cent of total phosphoric acid, potash, and nitrogen, though usually they contain 14 to 20 per cent. With the use of the ordinary materials of commerce, such as acid phosphate, bone phosphate, cottonseed meal, tankage, sodium nitrate, etc., fertilizers carrying a higher percentage of plant food than 20 per cent are rarely possible. The introduction of new fertilizer salts from the chemical industries, such as treble superphosphate, ammonium phosphate, ammonium nitrate, and a number of double salts carrying potash as well as nitrogen, urea, etc., are making possible the preparation of fertilizers of much higher plant-food content, two, three, and four times as much as the ordinary fertilizer mixtures of commerce. These new combinations produced by modern chemical research are known as concentrated fertilizers.

These concentrated fertilizer salts and their combinations have much to recommend them, but they also present many new and puzzling problems for solution before they can be generally used in American agriculture. In the first place their concentrated character means less labor in factory and in field, less bagging, less hauling and less freight, also greater purity of product and easier standardization. Instead of 10 bags to the ton of fertilizer, 2 or 3 bags only will have to be handled, shipped, and distributed on the farm to obtain the same quantity of plant food. This will mean cheaper plant food, pound for pound. In addition, fertilizer improvements in chemical manufacture, by nitrogen fixation from the atmosphere, cheaper methods of phosphoric acid manufacture, and new potash sources, will be stimulated by the increasing sales of these products, so that cheaper production is in evidence.

FIG. 89.—Experimental potato field in Maine on which concentrated fertilizers were used

### Has Some Bad Qualities

On the other hand the concentrated character of the chemicals involves some undesirable qualities. Many chemicals possess to a greater or less extent the property of becoming moist under humid conditions and on drying out again to become lumpy, hard, and "cake," as it is called. A drillable fertilizer is an absolute necessity under present American conditions of fertilizer practice and the present enormous fertilizer industry of approximately $250,000,000 annually is built upon this basis. Millions have been spent in practice and research to produce drillable fertilizer from the present materials of commerce. Further large sums must be spent in research before this problem is satisfactorily solved in connection with concentrated fertilizers so as to produce only salts or compounds which can withstand climates of widely varying humidity without becoming too moist or caking too hard.

The problem of distribution in the field is likewise great and new machines may have to be designed. Concentrated fertilizers are exceedingly strong in their action and must not come in contact with the seed or with delicate growing-plant tissue. Distribution in the soil at a uniform rate is therefore more imperative with the concentrated fertilizers than with the ordinary strengths to avoid injury to seed and to germination. Modern science is coping with these problems in this and other countries and considerable progress has already been made to make these new plant-food carriers safe and profitable in agriculture.

FIG. 90.—Farmers inspecting one of the department's concentrated fertilizer experiments

The importance of concentrated fertilizer salts and their mixtures is already well recognized in Europe, and considerable field experimentation is being conducted in England, France, Germany, Italy, and other countries to determine the value of such materials on their important crops and soils. It is obvious that while such results will be of interest to the American farmer and fertilizer manufacturer it will be only through experimental work in this country under our own conditions of climate, soil, and farm equipment that proper evidence can be obtained relative to the action and value of concentrated fertilizer salts on crop production.

When carefully and properly used excellent results have been obtained in Europe and in America. In the department's experiments cooperatively conducted with a number of State experiment stations on different crops and soils, there were obtained with such small quantities of concentrated fertilizers as good yields as were obtained with an equivalent larger quantity of the ordinary fertilizers. Some crops especially sensitive to one or the other of the concentrated plant foods have been slightly injured in germination and consequently in stand, but it is hoped that with further study of the methods of distributing the chemicals with improved machinery, safe results will ultimately be assured.

### Best for Intensive Cropping

The use of the more concentrated nitrogen materials from atmospheric nitrogen fixation, either combined chemically with other plant food elements such as phosphate or potash, or as a mixture of ammonia, phosphate, or potash salts in the form of concentrated mixed fertilizers, will naturally be greatest under crops like cotton, potatoes, and other truck and fruit crops where intensive agriculture is practiced, rather than under crops grown under extensive systems of agriculture, such as wheat and corn. That ultimately fertilizers will even be used with these crops is inevitable, but there are many problems yet to be solved before it can be done economically. The stabilizing influence which the production of highly concentrated nitrogen salts and other fertilizer salts will have on the fertilizer market will aid greatly in the extended use of fertilizers under all of our crops and will tend to lower the cost of production of our agricultural commodities.

OSWALD SCHREINER.

## FERTILIZER Nitrogen From Organic By-Products Valuable

Do you belong to the once numerous group of farmers who judged the potency and value of a commercial fertilizer by the robustness of its odor? If so, some of the materials that the department has recently pointed out as possible sources of organic fertilizer nitrogen, or ammonia, may not appeal to you, strongly.

There are by-products of the manufacture of cocoa and chocolate, for example, that carry the pleasing fragrance of a freshly opened can of breakfast cocoa, which have been produced in such quantities and held so cheaply that the Bureau of Soils has looked into the possibility of utilizing them for fertilizer purposes.

It was found that upwards of 20,000 tons of by-product cocoa cake is produced annually in the United States. This presscake is the residue from the manufacture of cocoa butter, of which enormous quantities are consumed in the confectionery industry. Like breakfast cocoa, much of the by-product cake results from the pressing of roasted and shelled cacao beans, but the cake is lower-grade material and usually contains less of the fat than beverage cocoa powders.

Viewed as fertilizer material, the by-product cocoa cake (or when ground, "cocoa meal") is somewhat like castor pomace in chemical composition. The cocoa, however, contains about 4 per cent of nitrogen (equal to 4.9 per cent of ammonia), whereas castor pomace will usually contain as much as 5 per cent of nitrogen, or about 6 per cent of ammonia.

Other by-products of the cocoa industry are the shells, known to the trade, after grinding, as "cocoa shell meal" and extracted press-cake, or defatted cocoa. The shells are produced wherever cacao beans are roasted for the manufacture of cocoa and chocolate. Production of the extracted or defatted cocoa, on the other hand, has been confined to a single locality.

### Nitrogen Content of Shell

Analyses show that the shells contain from 2.5 to 3 per cent of nitrogen (3 to 3.6 per cent of ammonia); and the dried defatted cocoa, about 4.4 per cent of nitrogen, or 5.3 per cent of ammonia. Cocoa by-products contain small quantities of phosphoric acid and upward of 2 per cent of potash. When applied to the soil, the cocoa by-products, like cottonseed meal and castor pomace, supply organic matter as well as fertilizing elements.

Fertilizer materials like these, known to the trade as "organic ammoniates," command comparatively high prices, as a rule. In view of this fact, the cocoa by-products seem to offer possibilities as economical sources of organic nitrogen, particularly in the vicinity of the centers of cocoa and chocolate manufacture—as New York, Philadelphia, and Boston, in the East, and San Francisco and Los Angeles, on the Pacific coast.

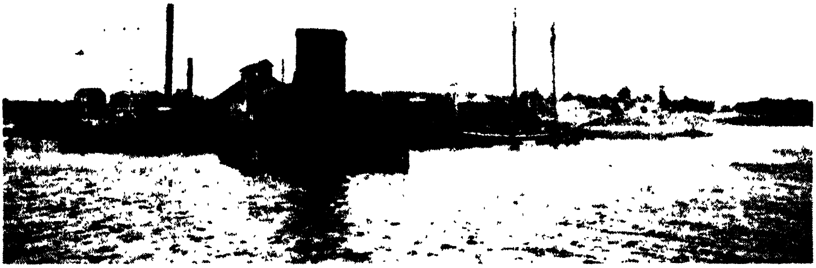

FIG. 91.—A source of nitrogen from shellfish waste

### Shellfish Wastes

There are other trade residues that have attracted attention and which more nearly satisfy the one-time requirements, namely, that a fertilizer should possess "an ancient fishlike smell." The refuse materials from the packing of crabs and shrimps, for example, are richer in plant-food elements, after drying, than the cocoa by-products.

Dried crab waste is a refuse from the crab-meat industry along the lower shores of Chesapeake Bay. A representative sample, after drying, was found to contain 5.2 per cent of nitrogen (6.3 per cent of ammonia) and quantities of phosphoric acid and lime equivalent to 7.4 per cent of bone phosphate, and over 30 per cent of carbonate of lime.

Shrimp waste and shrimp bran are by-products of different branches of the shrimp-packing industry located along the South

Atlantic and Gulf coasts. The so-called " waste " is the refuse of the canneries and is artificially dried. It contains about 8 per cent of nitrogen (9.7 per cent of ammonia), 10 per cent of bone phosphate, and 9 per cent of carbonate of lime. Shrimp bran consists of the air-dried heads and shell refuse separated from the meats, after the entire shellfish has been cooked in brine and then sun-dried.

As a result of the brine treatment, the bran may contain as much as 9 per cent of common salt, a substance not generally welcome in fertilizer materials. Less than 2 per cent of salt is normally present in the dried crab and shrimp wastes. The bran contains nearly 7.5 per cent of nitrogen, or about 9 per cent of ammonia, 8 per cent of bone-phosphate, and 7 per cent of carbonate of lime.

Such shellfish residues should prove valuable as organic-ammoniate fertilizers. With careful watchfulness of the salt content, they should also prove useful in the feeding of pigs or other livestock. And, in the districts in which they are produced, their use ought to be economically advantageous.

New trade wastes of similar character appear from time to time as the result of industrial developments. It is the aim of the Department of Agriculture to aid in all practicable ways in the conservation and utilization of waste products which give promise of agricultural usefulness.

G. P. WALTON.

---

## FERTILIZER Purchasing by Farmers

Fertilizers are bought largely by the eastern farmers, and specialists, such as the potato growers of Maine, tobacco growers, fruit growers, and cotton planters. It is believed that the buying of fertilizers should be very much extended, and that general farmers should purchase larger quantities, and that fertilizers could be used by dairy farmers and other agriculturists who now see little need of their use.

The purchase of fertilizers is only a part of a farm program to keep up the fertility of the soil, so that a proper balance should be established between the money spent for fertilizers, on the one hand, and for lime, feed for livestock, drainage, tile, irrigation, etc., on the other. For example, to get the best results with fertilizer it may be often necessary to purchase agricultural lime as well. It is somewhat difficult to give general rules for buying fertilizers, but other things being equal, the following suggestions are offered:

### Suggestions for Purchasing

(1) Buy complete fertilizers which carry nitrogen, phosphorus, and potassium—the three major crop nutrients.

(2) Buy high-analysis materials, mainly with a view to saving freight charges.

(3) Buy materials at the lowest cost per unit; for example, acid phosphate rather than bone meal.

(4) Buy materials carrying available fertilizer constituents; for example, water-soluble potash rather than ground feldspar; also, acid phosphate rather than raw phosphate rock.

(5) Buy standard, tried-out materials rather than materials that are unknown or untried. Standard materials are acid phosphate,

bone meal, basic slag, ammonium sulphate, nitrate of soda, fish scrap, cotton-seed meal, animal tankage, dried blood, sulphate of potash, and muriate of potash.

(6) Buy materials that are locally available rather than those on which high freight charges must be paid. Examples are, cotton-seed meal in the South, animal tankage near stockyards, and acid phosphate near factories which produce it.

(7) Buy from reliable firms rather than from firms having no business standing.

(8) In buying, do not allow simply the price of the fertilizer to govern its purchase. The main idea in buying fertilizers is to buy materials which will produce a profit. It may be unwise to use the wrong analysis or ratio in a fertilizer mixture even if it is cheaper per unit. (A unit is 20 pounds or 1 per cent of a ton. Example, 16 per cent acid phoshate has 16 units of phosphoric acid). It is not advisable to get, for example, a fertilizer high in potash and acid phosphate, such as a 0–10–10, for top-dressing truck crops even if it could be bought very cheaply, when a fertilizer like a 7–6–5 has been found by experience to produce the best results, even though the cost per unit of the first mixture is very much lower than that of the second. On the other hand, the first fertilizer may prove more satisfactory than the 7–6–5 mixture on certain muck soils even at a higher cost per unit. In the effort to sell high-analysis mixtures the suitability of the fertilizer to the soil and crop is often overlooked. An analysis of 0–10–10 means a fertilizer containing no ammonia or nitrogen, 10 per cent available phosphoric acid, and 10 per cent water-soluble potash. In the North the percentage content of nitrogen or ammonia is given first in a fertilizer analysis; and in the South the percentage of phosphoric acid is usually given first. The percentage composition of potash is always the last figure of a fertilizer analysis.

### Mixed Fertilizers in Demand

A decision often has to be made between the buying of simple materials like nitrate of soda and acid phosphate and complete mixtures. The common practice in this country is to buy mixed fertilizers rather than simple materials, and apparently this practice generally meets the American conditions of high labor and comparatively cheap land. Where a simple material is satisfactory, however, it will often give a larger return for the money invested than complete goods. The wide use of acid phosphate alone is apparently justified by economic conditions.

When complete mixtures are needed the farmer has a choice between factory-mixed and home-mixed goods. Factory-mixed goods sold by reliable fertilizer companies are fully satisfactory, and the main reason for home mixing is a desire to obtain fertilizer at a lower cost. Home-mixed fertilizers are sometimes cheaper, but the farmer should not try mixing his own fertilizers without making a real study of his soils, crops, and the fertilizer situation. He should get advice from Federal and State fertilizer experts, and read all the publications available on the subject. Home mixing is satisfactory when properly done, but it should not be attempted without adequate knowledge of the subject. (Fig. 92.)

When buying fertilizers it is well to get competitive prices from as many firms as possible, and it will pay also to deal with reliable firms. It is often possible to get quotations both from local and distant firms. Lists of such firms may be obtained from your county agent, State experiment stations, or the United States Department of Agriculture.

### Buying Through Cooperatives

In some sections it will pay to buy fertilizers through cooperative buying associations. By pooling orders it should be possible for farmers to obtain price concessions, and also a chance to know exactly what the fertilizer mixtures are made of. The same care should be exercised in dealing with cooperatives as with fertilizer companies; because even though a low price is obtained, it may not be on a really competitive basis. In times of severe competition there is the same temptation in the fertilizer industry as in other industries to substitute cheaper materials in standard mixtures. This has been rather noticeable in the past when inorganic forms of nitrogen have been substituted for some of the expensive organic ammoniates such as animal tankage and fish scrap.

FIG. 92.—Getting acquainted with fertilizers. Their proper mixing and use depends on a knowledge of them

The problem of fertilizing the soil is an important one, and will be of greater importance in the future. The farmer's time spent in studying bulletins and textbooks on fertilizers will probably yield him as great a return as the study of other farm problems.

To help the farmer buy fertilizers intelligently the Department of Agriculture will be glad to give him information on the needs of his soil, the value of fertilizing materials, and the home-mixing of fertilizers. It will furnish lists of reliable firms which sell fertilizers in his community. The department believes that the use of commercial fertilizers is a profitable practice and that the quantities used in this country will steadily increase. It will pay many farmers to increase the use of fertilizers, but they must study the problem carefully and use common sense in making their purchases.

C. C. FLETCHER.

**FIRE-Scar Damage in Woodlands Heavy** The owners of small woodlands in the eastern United States when making a cutting often find that many trees are defective; particularly in hardwoods, most of the decay is in the butts. The highest grade and most valuable timber is found in the first log. When decay is present in this log, the actual loss is greater in proportion than in any other part of the tree.

Studies and surveys show that as high as 19 per cent of the volume of the hardwoods in our eastern woodlands is often lost because of decay. This means that approximately one-fifth of the timber crop is lost. No grower of timber can afford such a loss, especially where it is a preventable one. Investigation in hardwood forests indicates that more than 90 per cent of basal or butt rots enter through fire scars. This shows how important it is to keep fires out of the forest.

It is hardly necessary to call attention to the obvious amount of death of small trees that takes place during forest fires. In heavy fires a large number of trees, both small and large, are killed outright. Those remaining are often badly burned, especially at the base, nearest the ground. Such burns kill the bark and the growing layer of the sapwood beneath it, check all growth in the injured region at once, and result in fire scars. Fire scars tend to dry out, and form cracks or checks. Tiny spores or seeds of numerous species of wood-rotting fungi blow about in the forest, especially during the growing season. Some of these spores lodge either in wood cracks, or on the surface of the scars, and germinate, producing a moldlike growth which penetrates and rots the wood.

### Classes of Wood-Rotting Fungi

Three general classes of wood-rotting fungi, not sharply set apart, are found in forests; one attacks and rots the dead sapwood, another preferably rots the heartwood, and another may attack both the sapwood and the heartwood, the latter being composed of dead wood cells. Young trees usually contain little or no heartwood and when fire-scarred are attacked in the scars by fungi which rot sapwood. In older trees when burns are severe, as they usually are after repeated fires, the heartwood is exposed. It is through these deep-seated scars that the fungi which rot the heartwood are most likely to gain entrance.

In fire-scared trees the scars commence to heal by the formation of folds of new sapwood and bark on the outer edges. These folds enlarge and gradually grow together, closing the fire scar. If the wood beneath the scar has begun to rot, this rotten wood is now shut in, and confined to the interior of the tree. In case of large compound fire scars, due to repeated fire injury, the scars often remain open, and a cavity is formed by the action of wood-rotting fungi at the base of the tree. This cavity due to continuous rotting may extend upward for several feet in the interior of the trunk.

The growth of fungi which rot the sapwood is usually checked as soon as the wound is closed by healing and the decay ceases. There are, however, some species of fungi that attack both the sapwood and the heartwood. These and the fungi which attack only the heartwood may continue to rot the heartwood of trees after the fire scars are closed by healing. Trees more than 25 to 30 years old, while less likely than young trees to be killed outright by fire, are more likely to suffer from decay under fire scars.

### Other Places Where Rot Enters

Not all wood rots gain entrance through fire scars; some may enter sprout trees at the base through the old stump. They may also enter wounds, especially those with exposed heartwood, on any portion of the trees, such as severe lightning scars, broken limbs, branch stubs, ax wounds, etc. Pines, spruces, and other coniferous trees in farm woodlands frequently suffer from heart rots which gain entrance through branch stubs, etc., but in such trees there is also a large amount of butt rot entering through fire scars.

From this it will be seen that it is as necessary to keep fires out of woodlands as it is to keep the weeds out of cultivated crops. The highest yield of best grades of timber can be obtained only in woodlands where fires are prevented. It pays to prevent fires in woodlands.

George G. Hedgcock.

## FLAX—A Drought-Resistant Form Now Developed

"Saginaw" is a variety of fiber flax adapted to conditions in the United States, where the climate is generally warmer and drier than in the flax-growing regions of northern Europe. It has been developed by selection, by the office of fiber investigations in the Bureau of Plant Industry. Nearly all of the fiber flax of the world is grown from seed originating in the region of Pskof in Russia. That is a region of abundant moisture with a short growing season of long days, between 56° and 58° north latitude. None of this Russian seed is of a pure type. Some of it produces tall slender stalks with few seed bolls and a tendency to mature late; other seeds in the same lot produce shorter stalks with more seed bolls ripening earlier.

When this seed is sown by the fiber flax growers in Michigan and Oregon between latitudes 42° and 45°, where the summer days are shorter, the climate warmer and drier, and the crops are harvested for both fiber and seed production before all of the plants are fully ripe, there is an increase in the proportion of seed from the shorter early maturing plants. The growers said that the type deteriorated or the " flax ran out " in a few generations and it was necessary to import fresh supplies of seed at least once in four years. Most of the seed imported was Blue Blossom Dutch, of Russian origin grown one or more years in Holland.

In 1909 more than 40 fields of fiber flax were inspected in the "Thumb" district east of Saginaw Bay in eastern Michigan and 1,200 tall plants were selected. Each plant was wrapped by itself to prevent any loss or mixture of seeds. The selections were based on height and straight slender stalks free from basal branching. These plants after drying were measured, weighed, and the seed bolls and seeds counted. The seeds from 100 of the best plants were saved separately and planted at Croswell, Mich., in May, 1910. They were planted, one seed in a place, 3 inches apart, at a uniform depth, in uniform soil, and a further selection was made from the plants produced.

### Superior Type Produced

Selection and comparison were continued until a type was produced that grew taller and better than others in dry seasons as well as in moist years. This type had tall slender stems but with comparatively few seed bolls. The seed supply, beginning with a few ounces, was increased with difficulty. It was sown in drills and cultivated to increase the production. Winter crops were grown in Porto Rico and in Alabama to increase it twice in the same year. Storms destroyed the increase plats three different years and a fungous disease necessitated its destruction one year.

Sufficient seed was finally obtained to distribute small quantities to commercial growers who have increased it and have very carefully kept it pure. These growers state that it is the first fiber flax they have ever grown that does not "run out." It makes an especially good showing compared with Blue Blossom Dutch or other European flaxes in a dry season.

There were 700 acres of "Saginaw" flax grown in Michigan in 1925, and more than 8,000 bushels of seed for sowing have been saved from an especially good crop of 1,000 acres in 1926.

## FLAXSEED Price Largely Influenced by Argentine Crop

The size of the flaxseed crop in Argentina, the most important flaxseed-producing country, appears to be the major factor affecting flaxseed prices in the United States. The influence of the Argentine crop, which is harvested early in the winter and begins to come on the United States market toward the end of January, is felt in our flaxseed prices through the following fall when the bulk of our crop is marketed. In addition to the Argentine crop, the production of flaxseed in the United States and Canada are important price factors, and also the level of building-material prices, which reflects variations in demand in the building industry as well as variations in the general level of commodity prices.

For many years the United States has been on an import basis for flaxseed. It draws its additional supplies chiefly from Argentina, and to a less extent from Canada. During the five-year period, 1921-1925, the production of flaxseed in Argentina averaged 54,000,000 bushels, as compared with an average of 18,000,000 for the United States, the second largest producer. The next most important countries, arranged in order of importance, were India, Russia, and Canada.

Figure 93 shows the relationship of the production of flaxseed in Argentina in the preceding winter, plus the current season's production in the United States and Canada, to the price of No. 1 flaxseed at Minneapolis, average September to November, divided by the Bureau of Labor index of building-material prices. The years included are 1910-1925, omitting the year 1917, when a crop failure in Argentina the previous winter, in addition to shipping difficulties caused by the war, brought on an abnormal market situation. The low demand for flaxseed during the years 1918 to 1922 is evidenced by the lower curve, which follows the same general tendency as the main curve. but on a level averaging some 50 cents a bushel lower.

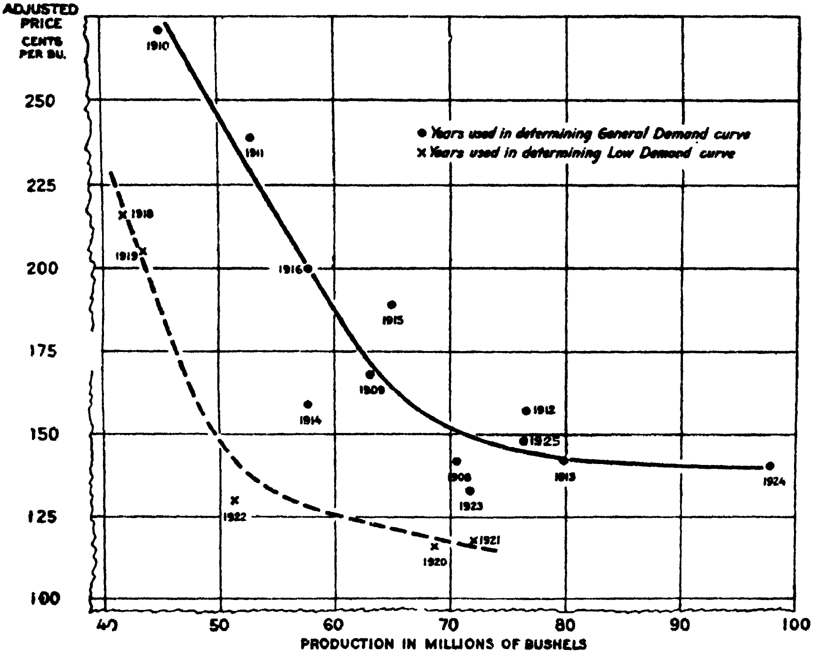

FIG. 93.—Relation of flaxseed production in Argentina, United States, and Canada, to average Minnesota No. 1 flaxseed price, September-November adjusted, 1908–1916 and 1918–1925

The year 1923 was a period of transition between the two levels of demand. The shape of the curve indicates that when prices fall to a certain level there is a tendency for them to become stabilized near the level, owing to the fact that when the price of linseed oil is sufficiently low it displaces other oils, particularly in soap making, with a consequent broadening of demand.

## FLAX Rust Control Through Immune Strains Possible

Flax rust is similar to the familiar black stem rust of wheat, in some respects, and yet very different in others. It can not attack wheat, nor can the wheat rust attack flax. Each of these rusts has four distinct stages, the most conspicuous of which are the red and black stages. All four stages of the flax rust are produced on flax, and on no other plants, except that certain species of wild flax are attacked. The stem rust of wheat, on the other hand, produces its red and black stages on wheat, but requires an entirely different host, the common barberry, on which to develop its two other stages and complete its life history. The organism causing flax rust lives over winter, in the black stage, on infected straw and can go directly back to flax the following summer, when the spores of the black stage germinate. The wheat-stem-rust organism lives over winter in a similar manner, but can not go directly back to wheat from the black stage. It must first go through the barberry. The wheat-stem-rust parasite, therefore, has a weak place in its life history which the flax rust parasite does not have.

As the control of flax rust can not be effected by destroying an alternate host, other methods must be used. The most promising of these is the development of rust-resistant varieties. This method has been used with success in controlling the destructive wilt disease of flax, but, unfortunately, most of the wilt-resistant varieties now in use are susceptible to rust. This fact has not been generally appreciated. It has become the practice among some of the growers of wilt-resistant flax to sow the crop several years in succession on the same land, feeling they are safe in doing so because their flax is resistant to wilt.

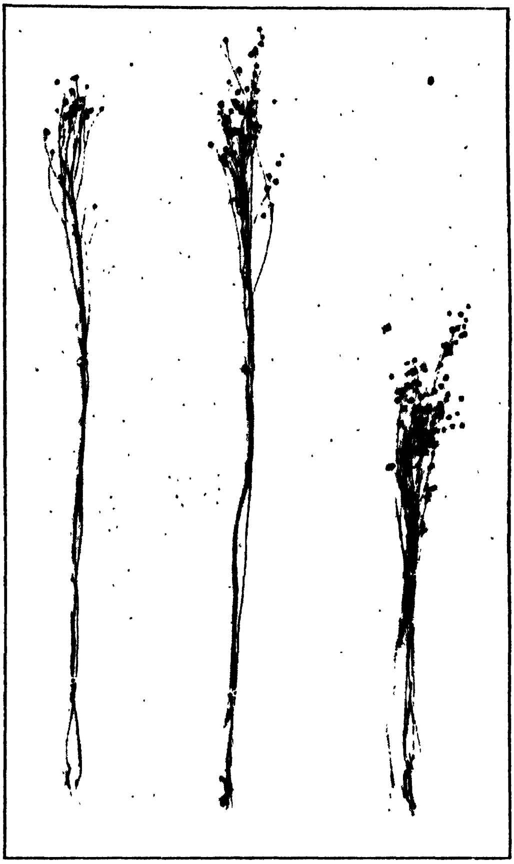

FIG. 94.—Rust immune flax selection (center) produced by crossing susceptible fiber flax (right) with rust-immune, wilt resistant seed flax (left)

### Susceptible to Other Diseases

The fact that the wilt-resistant flax is susceptible to other diseases either is not recognized or is overlooked. The multiplication of rust is especially favored by such a system of farming, and, when it is followed, damage from rust is likely to be severe. Flax rust not only causes reduced yields of seed, but may also cause the stems of fiber flax to be of very inferior quality, or even useless for fiber purposes.

During the past five years, investigations on the control of flax rust have been made in cooperation with the Minnesota agricultural experiment station. Varieties of seed flax which are entirely immune from rust have been found. Some of these are also highly resistant to wilt. These have been crossed with susceptible varieties of both seed flax and fiber flax in order to develop improved varieties of both types of flax, combining immunity from rust wilt resistance.

Figure 94 shows the progress in the development of varieties of fiber flax immune from rust. The selection in the middle is immune from rust and was produced by crossing the susceptible fiber flax on the right with the rust-immune, wilt-resistant seed flax shown at the left.

ARTHUR W. HENRY.

## FLOODS and the Farmer

Not the least in importance among the many hazards of farming in the United States is that of loss by floods.

In some sections, especially in the rich bottom lands along many streams, the hazard is present a large part of the crop-growing season; in other regions and these form much the larger area, the hazard is absent or of little moment. The menace is greatest in the spring and early summer and again in the fall when, although crops have matured they may not have been gathered into barns or other safe places. Severe midsummer floods are infrequent and, as a rule, confined to limited areas.

A demand for accurate statistics of flood loss has existed for many years. Owing to the difficulties attending the collection of such statistics the demand has been met only partially and those put forth herein, although the best obtainable, are submitted as little more than rough estimates and, moreover, probably do not cover more than 75 per cent of the total. For this reason an additional 25 per cent has been added as will appear in the next paragraph.

### Flood Loss in United States

During the 15 years ended with 1925, the reported loss from floods aggregated $530,542,660 or more than $35,000,000 annually. Adding to this estimate 25 per cent for unreported losses (loss to railroads is rarely reported) the amount becomes $707,390,213 or more than $40,000,000 annually on the average.

Of this huge total the loss to agriculture—crops, livestock, farm buildings and property and erosion—was $172,186,987. Nearly 33 per cent of the total loss fell upon the farmer. These figures are impressive when it is considered that loss to the farmer is largely unavoidable, that growing crops can not be removed to places of safety. On the other hand, the loss of matured crops in the fall when left in the fields along river bottoms that are subject to overflow is on a different footing. The obvious remedy is never to leave a matured crop in fields subject to overflow.

The Weather Bureau undertakes to warn dwellers of the lowlands along the larger streams of the coming of dangerous floods, but that service can not be extended, for reasons well understood, to the small streams that are liable to flood from the so-called cloudburst rainfall.

Incomplete statistics for the 15 years considered show an estimated saving to agricultural interests through the medium of flood-warnings of $38,185,240 or a little more than $2,000,000 per annum on the average.

The cost to the taxpayer for this service is very small, probably about 1 per cent of the total amount saved, interest included.

The farmer is indirectly affected by flood loss beyond the farm, as the cost thereof must be absorbed somewhere in the world of business and finally reflected back to the consumer in the shape of increased cost of the supplies which he must purchase; on the other hand, he is benefited, although to a less extent, by decreased costs passed on to him by business interests that have been able to make a saving through the medium of flood warnings. These warnings have been freely distributed in the past, yet the very recent development of radio transmission has so enormously increased their distribution as to now make it practicable for almost every one interested to receive them more readily and much earlier than ever before.

H. C. FRANKENFIELD.

## FLOUR Consumption Falling in the United States

For the past 40 years, the per capita consumption of wheat flour in the United States has declined more than 20 per cent. In 1879, the earliest year for which adequate data are available, the annual consumption of wheat flour was equivalent to 5.6 bushels per person. Since 1919 it has been approximately 4.25 bushels. This decline in per capita consumption is about 16 per cent below what it was before the war and 24 per cent below that of 1879. From 1879 to 1905 there was a slight gradual decline, amounting to about two-tenths of 1 per cent a year. From 1914 to 1921, there was a much more rapid decline which averaged more than 2 per cent a year. The low point of the decline, less than

4 bushels per person, was probably reached in 1918, the year of war-time restrictions. In 1919, when war-time restrictions on the use of flour were removed, consumption increased to 4.7 bushels, but declined to the present average of 4.25. Since 1921 the consumption per person has remained practically the same.

In Figure 96 these statements are borne out by two sets of data. One set shows the per capita disappearance of wheat flour for census years, as computed from total flour millings, exports, and changes in stocks. The other, the disappearance for food, feed, and loss for each crop year since 1900, is based on the total supply of wheat at the beginning of the year from which have been deducted exports, seed requirements, and stocks on hand at the end of the year. The variations shown in these figures are probably due to changes in the quantities fed and used for other than food consumption. Both sets of data, however, show a general downward trend, particularly between 1900 and 1921.

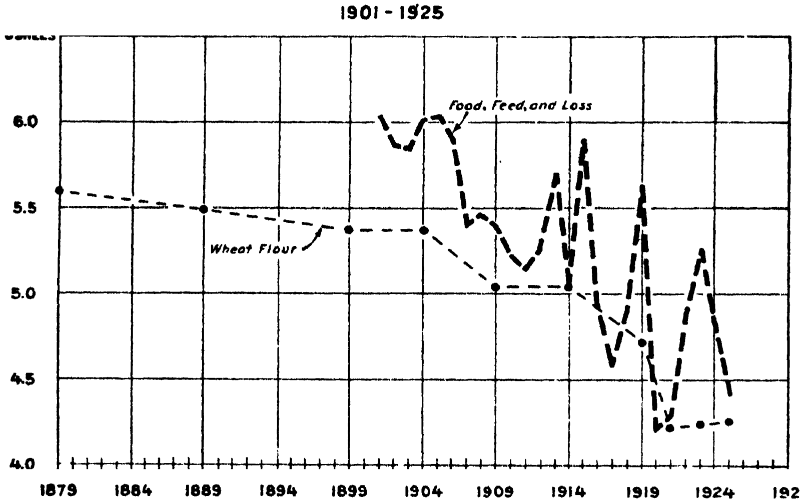

FIG. 96.—Disappearance of wheat flour per capita expressed in bushels of wheat for census years 1875–1925, compared with the disappearance for food, feed, and loss in the crop years 1901–1925

### Causes of Decline

The reasons for this long-time decline in consumption of wheat flour are the drift of population to the cities, increased average purchasing power, the rise in the commercial bread-baking industry, and the possibly continuing effect of war-time restrictions on wheat consumption. Our city population, which in 1920 represented 51 per cent of the total, compared with only 35 per cent in 1890, consumes proportionately less flour and proportionately more other food than the rural population. As country people adopt city habits when they move to town, it is inevitable that the shift of population should be accompanied by a decline in per capita consumption of flour. This tendency has been further strengthened by the increased average purchasing power. The present money income of industrial employees will buy at least 20 per cent more goods than the corresponding pre-war income would have purchased. This greater buying power enables consumers to purchase larger quantities of fruits, vegetables, and dairy products at the expense of wheat flour.

With the relatively greater increase in city population has come the rise of the baking industry. Large bakery units undoubtedly now use flour more efficiently than did the smaller units two decades ago. Moreover, the development of high-quality wheat makes possible the manufacture of bread and wheat products with less flour than was formerly required. Furthermore, other ingredients than flour may now form larger proportions in the composition of the commercial wheat loaf. According to the census of 1923, for instance, the baking industry, besides consuming 31,000,000 barrels of flour valued at $218,000,000, used other ingredients such as eggs, butter, lard, milk, fruit, and nuts, valued at $265,000,000. These other ingredients undoubtedly tended to satisfy wants which otherwise would have meant a greater consumption of flour.

### Facts Have Bearing on Production

These facts have a bearing on the production of wheat in the United States for domestic consumption. Should the general downward trend in wheat-flour consumption be continued into the next decade, the total quantity of wheat consumed as flour would remain approximately at the present quantity of about 500,000,000 bushels, even with an increase of population. On the other hand, if it be assumed that the per capita consumption of wheat flour has now become stabilized at approximately 4.25 bushels, and if population continues to increase at the rate of 1,500,000 persons a year, the production of wheat for domestic flour purposes would need to be increased by about 65,000,000 bushels by the end of the next 10 years. Any increase in production greater than that would enlarge the quantity of wheat grain and flour to be disposed of in foreign markets.

## FOOD Studies Throw Light on Diet Problems

A few years ago doctors, dietitians, and experts of one sort or another were the only ones who cared much about the composition of foods. The average person was satisfied if the food that appeared on his table three time a day tasted good and kept him from being hungry between meals. But times have changed. Calories, protein, carbohydrates, iron, and calcium are household words applied to foods. Everybody is trying to eat the proper number of calories and to be sure that he is getting enough iron to make red blood and enough calcium to build bones and teeth. The tables on food composition issued 25 years ago by the Department of Agriculture are still the best answer to some of the questions raised. Many new facts have come to light since these tables were published, however, and the Bureau of Home Economics is now bringing these food figures up to date.

Foods vary a great deal more in what they contain than even the scientists used to think. Milk is not just milk. Every dairy farmer knows what a difference even 1 per cent of butterfat will make in his creamery check at the end of the month. He knows also only too well that every cow in the herd can not be relied on to give milk of a certain standard. So it is with apples, onions, pork, beef, poultry, and all the other foods raised on the farm and many prepared in factories. They may differ widely in the food elements they contain.

These differences may count just as much in food value as the change in butterfat in milk does in dollars and cents. It is not possible to say that a pound of beef or of cheese or other food contains so many calories, so much protein, and all the rest without knowing more about that particular piece of beef or cheese.

### Variations in Meats

Meat is one of the hardest foods on which to make general statements about composition. It is not difficult to see why the carcass of a very thin steer, for example, that would have sold as " common " must be entirely different in its make-up from one that came from a well-fattened animal that would have been graded "good" or "choice." Compared on a percentage basis with the fat one, the thin carcass might have nearly twice as much bone and its edible portion only about one-third as much fat. One might have a fuel value of 850 calories per pound and the other 1,900 calories. Even wider extremes than these can be found on the retail market. Plainly, the steaks, roasts, and stews from two such animals will not be much alike in food value.

Moreover, the cuts even in one carcass vary almost as widely. Some cuts are bony, others are almost entirely lean meat, and others are marbled with fat or have borders or sections of fat. But in studies of diet it is necessary to know, approximately at least, the composition of some particular cut of beef. Some kind of a classification is needed that will take into account round steaks with only 5 per cent fat as well as rib roasts with as much as 50 per cent. To this end new figures have been derived for beef which are believed to be typical of the market grades and of the standard wholesale cuts. Bone, " visible fat," water, protein, " chemical " fat (ether extract), and ash are given in percentages and the number of calories per pound are stated. Such figures are given for chuck, flank, loin, rib, round, and other wholesale cuts from thin, medium, fat, and very fat carcasses, which correspond to common, medium, good, and choice and prime grades of beef.

Pork, mutton, and other meats, dairy products, fruits, vegetables, cereals, sugars, and all the other food materials commonly used in the United States will be studied in this same way. The results will be published as rapidly as possible for the benefit of persons " counting the calories " in their own meals or studying food problems with a view to fitting the supply to the demand and insuring a well-balanced diet for everybody.

CHARLOTTE CHATFIELD.

---

**FOOD Habits of Farm Families** Suppose you were asked how much food your family consumed last year. Could you tell? You probably could in general. Thousands of farm housewives have answered that question for the United States Department of Agriculture during the last five years. But suppose you were asked what your food is giving you in the way of food value, whether the quantity and kind of food consumed are suitable for the health and physical development of your family, and whether you are getting the best food values for the money and time expended. Could you answer that? Probably not, for such questions can be answered only after food-consumption figures have been carefully analyzed and studied, and the work usually has to be done by someone specially trained in that field. The Bureau of Home Economics is making a study of food habits in which the figures that have been collected from the farm families are being studied to find answers to all these questions.

In this study not only the value of the food consumed by the average farm family is calculated, but also the amount of nutrients, such as energy, protein, minerals, and vitamins, in each family's food. By the use of standards for measuring the amount of each nutrient needed by the family one is then able to judge whether the food that has been consumed is adequate to promote growth in the children, to furnish energy for work and heat, and to maintain the health and well-being of each member of the family.

Almost 2,000 of these farm records have been studied for the purpose of learning two things. It was desirable to know first what the average farm family is eating. Then the diets of individual families were analyzed to see how many of them differed from the average diet. According to these records it was found that the average farm family probably consumes quite as much if not more than it actually needs. But when the food used by individual families was analyzed it was discovered that a large proportion of them do not get enough minerals, such as calcium, phosphorus, and iron, to insure the best growth and development in the children and good health in the adults. In every case this deficiency was caused by the fact that milk, fruit, and vegetables were not provided in sufficient quantities by these families.

### Food from Farms

The families spent on the average in time and money about $650 per year for food and of this amount two-thirds was furnished by the farm. Since energy is the simplest measurement for comparing the food value of different foods it is used in studying food expenditures.

Of the total diet the animal foods furnished on the whole 50 per cent of the energy at 60 per cent of the cost. When a comparison of food value and cost was made of the different food groups it was found that meat, fish, and eggs furnished 16 per cent of the total energy at 28 per cent of the cost. Milk and cream made a better showing than meat, fish, and eggs. They furnished 15 per cent of the energy at only 19 per cent of the cost. Fruit and vegetables gave figures much like milk, furnishing, as they did, 13 per cent of the energy at 19 per cent of the cost. Fatty foods, cereals, and sweets, which yielded 56 per cent of the total energy of the average farm diet at only 29 per cent of the cost, are the least expensive.

Animal foods, as these figures show, are on the whole more expensive than vegetable foods. This is due especially to the high cost of meat, fish, eggs, and cheese, and the low cost of cereals and sweets. Milk, fruit, and vegetables, which are especially good sources of minerals and vitamins, furnish in addition almost twice as much of the energy of the farm diet as do meat, fish, and eggs. Since these are the foods commonly furnished by the farm it will doubtless interest you to know that if you are consuming the average farm diet you can improve the quality of your food supply with less expenditure of time and money by furnishing for your table more milk, fruit, and vegetables and less meat, fish, and eggs. The cereals and sweets are usually purchased by the farm family. Although they are cheap sources of energy they are lacking in many of the minerals and vitamins. It is therefore safe to increase their use only when a large quantity of milk, fruit, and vegetables is also used.

EDITH HAWLEY.

**FOOD Spoilage in Distribution Heavy** If all of the food produced upon the farms could reach the consumer without loss from leakage, souring, rot, the attacks of rodents or insects, or just plain waste through carelessness or ignorance, the farmer's crop would increase in value and the unit price of many commodities to the consumer could be reduced. However unattainable this ideal may be as a generality, in a single commodity—sweet potatoes (The Plant Disease Reporter Supplement 45, May 1, 1926, p. 55)—losses totaling 30 per cent of the crop, or 40,000,000 bushels, in 1918, have been progressively reduced to 6.9 per cent, or roughly 5,000,000 bushels, in 1925. Not all losses are so conspicuous or so preventable, but the changes introduced by the sweet-potato grower followed lines already clearly marked out by meat packers, the citrus-fruit industry, and many other organized groups.

Spoilage for the purposes of this discussion takes two general forms, (1) the total destruction of food values, and (2) such injury to appearance, odor, taste, or texture as renders the product unsalable for human food. In the first case the entire investment may be and commonly is lost, as, for example, the rotting of ripe berries, peaches, apples, or spinach, or the freezing of potatoes in transit. In the second case, products ordinarily sold for human food may frequently be used for stock, for example, damaged flour and heated grain.

The annual reports of Federal, State, and city regulatory agencies summarize the quantities of food condemned and destroyed. These totals mount into many millions of pounds, which under proper handling would have been distributed for human consumption, while other millions of pounds are released only for animal feeding or for technical purposes. Besides the products eliminated from human use, a vast amount of material actually consumed is lowered in quality and acceptability by the same destructive agencies without having reached the stage of deterioration at which it might be condemned. It therefore becomes desirable to define the causes of the wastes encountered, the nature and extent of the loss involved in food spoilage, the dangers to health involved in the consumption of spoiled and mishandled food, and the measures necessary to cut such wastage to the minimum.

Three general groups of agencies in this wastage must be remembered: (1) Those inherent in the raw product itself, such as respiration or other metabolic changes or enzymic activities, illustrated by overripening and ultimately the complete breakdown of many products; (2) fermentation and rotting processes due to the activity of molds, yeasts, and bacteria; (3) the depredations of insects and rodents or predatory animals. These agencies need not be discussed in detail; their existence and general characters are common knowledge. Overripe fruit, soured milk, tainted meat, musty cereals, wormy fruit, and the marks of the activity of rats and mice are well known, although few appreciate the extent of the damage thus done.

Some consideration of the conditions underlying spoilage is necessary as a foundation for constructive measures to stop waste. We must at the outset admit that some or all of the agencies of destruction already listed are always present. Hence we must learn to live with them, yet reduce their toll to the minimum.

The composition of each food product is the primary factor in determining whether it is stable and easily kept and handled, or perishable and difficult to preserve. But there is no sharp line between them. Although some products may be handled easily and kept almost indefinitely with few precautions, most products make specific demands upon intelligent care for their preservation. Moisture, temperature, and time are the three major factors in spoilage. These factors, together with the initial composition of a product, largely determine the demands of that product upon our handling facilities and upon the knowledge and skill of the handler.

### Moisture in All Food

Moisture is present to some degree in practically all food, ranging from a fraction of 1 per cent in a sample of granulated sugar to 90 per cent and more in ripe fruits like the strawberry. The sugar is staple, but only so long as it is kept dry. The fruit is perishable at best and can only be carried in sound condition to a distant market by the exercise of the greatest skill in packing and in refrigeration and the utmost promptness in shipment. Between these extreme cases there is every gradation of stability and instability, in which water at varying concentrations in the kind and quantity of the nutrient present sets a limit upon our selection of handling practices. In the stable groups of products—grains, manufactured cereal products, and dried, brined, or sweetened foods—there is, product by product, a concentration of nutrients at which the internal activities of the product itself are minimized and the attack of microorganisms from without is reduced or stopped. From such critical concentrations only a slight increase in water content will often permit spoilage agencies to become active. Flour becomes musty, corn meal will sour and become lumpy, preserves ferment or "work," pickles become slippery and soften, dried apples get moldy, if, all other conditions remaining the same, just a little too much water is added in manufacture.

Water does not act alone. A product will keep in cold weather at a water content at which it will spoil promptly in warm weather.

Decomposition and fermentation seem to stop entirely only when every particle is frozen, but practically very little spoilage occurs at temperatures near the freezing point of water. These same processes are retarded, not stopped, in the cool storage of the household refrigerator or of the cellar. They are useful to carry food from one day to another, but inefficient with perishables when long storage is demanded.

Time thus enters as the third great factor in spoilage. A few products kept from water and from vermin remain unchanged for, perhaps, indefinite periods. Most of our foodstuffs deteriorate with age, no matter what our precautions may be. Some may remain upon the shelf for years without offensive change; some can be kept frozen with little or slow deterioration; but for the larger number we must use all the apparatus and all of the skill available, and yet, to have high quality they must be consumed within a reasonable storage period.

### Where to Improve Methods of Handling

If we disregard the problem of the large market and the long shipping line, for which expert service is usually constantly available, the local store, the home, and the farm represent points at which improvement in food handling is imperative.

In the local store all kinds of products, from the most stable to the very perishable, are brought together under one roof and frequently in one room with inefficient and often ill-trained help. Common sense and human experience go a long way in the efficient handling of many of these products, but with a multiplicity of new and untried foods, some of them experimental even to the manufacturer, the storekeeper's experience as a guide to practices breaks down at many points. Urged on by the representations of the distributor on the one side and the demands of the consumer on the other, these stores constantly carry numerous products in which the losses to the seller are excessive and the conditions of the product delivered to the consumer's household often very unsatisfactory. Vegetables eaten fresh may be discussed as illustrating this general problem.

### Keep Fruit and Vegetables Under Refrigeration

The inclusion of green vegetables in every dietary recommended has brought lettuce, celery, spinach, and many related forms to all our markets throughout the year. During a large part of the year, however, these products must be shipped for long distances, involving transportation dangers, delays, and changes in temperature and humidity, thus adding greatly to the exposures. As a result, many shipments become a total loss and others are partially spoiled. The unit price to the consumer must cover not only the cost at the point of production and the distributing cost, but the spoilage as well.

Experiments have shown, however, that the simple expedient of chilling these products thoroughly, while dry, and packing them in that condition for shipment will slow down the activities of the vegetables until they are practically negligible and largely stop bacterial multiplication during a reasonable market period. Supported by cool weather or ordinary refrigeration en route and at the selling point, it is possible to reduce greatly the spoilage in this series of products Even more important, however, is the improvement in quality which makes the vegetables attractive instead of scarcely edible. Yet the improvements proposed would demand radical changes in the provisions for handling commonly found all the way from the producer to the retailer. Such changes follow the pressure of public demand for products not merely edible in the sense of being tolerable, but high in quality, a demand which is supported by evidence that the saving and improved prices obtained will actually more than cover the added expense.

Increased provision for the control of temperature and humidity in the market stall and retail store is clearly demanded in the interest not only of economy but of the added safety of the foodstuffs which, if properly handled, could be made to reach the consumer in clean, crisp, sound condition. Protection against flies, rodents, and animal and human contaminations would be incidental to proper care against decomposition, but would be an inestimable gain in the battle against the spread of enteric diseases through mishandled food. The conditions in the local store are intensified when food is transferred to the home, and here again better provision for safe handling and better knowledge of safe limits in handling are needed.

Take the single factor of temperature control. Some type of refrigeration in every home is an ideal to be promoted in every way possible. Nevertheless, it is recognized that there are great sections of our country in which ice or artificial cold storage has been thus far physically or economically impossible for the people upon farms and for many of those in villages. In many of these areas cellars which make cool storage possible are practical and widely used. In others supplies of cold water are available. Although they materially improve the situation, they are often inefficiently used.

Again, the many types of "iceless refrigerators" which utilize the cooling power of evaporating water are found to be useful and to be within the economic reach of all who will take the time and trouble to make them from plans freely in reach of all and materials already in every home. Nevertheless, a great many houses lack any provision for the proper control of temperature during the hotter part of the year. In a great many more homes there is need of more systematic care to preserve food under the best conditions available and to cut down the very high percentages of loss which are to be seen on every hand. For them the procedure to be recommended depends upon the source of the perishable food. If the supply comes from the home garden, only so much as can be quickly consumed should be cooked for the table. There should be little left over, and that should ordinarily be consumed within the next two meals or recooked if held to the end of a 24-hour period. The excess produced may be sold if a market is in reach. Otherwise proper home canning or drying of all material in prime condition from day to day will keep the excess for a season of shortage.

### Test of Fitness of Food

The test of fitness for use should not be the ability of the consumer "to get food past his nose," but "is it right?" Not merely is food so filthy or so decomposed as to be dangerous, but is it fresh, sound, and clean? The cooperation of producers, shippers, transportation agencies, and all distributors is necessary to get food fit for consumption to the consumer's household. The safety and satisfaction of the ultimate consumer rests finally upon the ideals of cleanliness and soundness held by the one who actually prepares that food for human use.

CHARLES THOM.

**FOOT-and-Mouth Disease in the United States** The highly contagious malady, foot-and-mouth disease, exists in most of the countries of the world. In many of them it has gained such a foothold that no attempt is made to eradicate it. In view of the close trade relations that exist between the United States and countries where foot-and-mouth disease is prevalent, the danger is ever present that infection may be introduced and, unless promptly recognized and effectively combated, become permanently established.

Foot-and-mouth disease has appeared in the United States on eight different occasions—1870, 1880, 1884, 1902, 1908, 1914, and twice in 1924. All these outbreaks were stamped out; some quickly, others only after long and expensive campaigns. The cost of eradication work for all outbreaks was approximately $20,000,000, divided about equally between the Federal Government and the States involved. By far the largest item of expense was payment made to livestock producers for animals and property destroyed. In eradicating these outbreaks more than 342,000 cattle, sheep, swine, and other cloven-hoofed animals were slaughtered. But even after allowing for the indemnity payments, losses estimated at more than $150,000,000 were sustained by stock owners and others directly and indirectly affected.

Stringent measures are being used to guard against further misfortunes of this kind. The importation of domestic ruminants and swine from infected countries is prohibited entirely. Such animals originating in countries free from the disease are detained in quarantine stations at ports of entry under close veterinary supervision until it is considered safe to release them. Vessels from foot-and-mouth disease infected countries with live animals aboard to supply the meat requirements of their crews are prohibited entrance into our harbors.

Hides, skins, fertilizers, animal feeds, and a great variety of other products derived from animals or intended for feeding purposes, which are considered likely to serve as carriers of the infection, are either excluded entirely or are admitted subject to disinfection or such other treatment as may be necessary to destroy any lurking germs. Hay or straw packing material from infected countries, unless accompanied by a satisfactory certificate of disinfection, is burned under official supervision.

The use of substitute packing materials, such as excelsior or paper, as advocated by the department, is becoming quite general, and at the present time less than 5 per cent of the shipments arriving in this country are packed in hay or straw, subject to restrictions. The disinfection of previously used bags and bagging material of foreign origin which might find their way to farms is another requirement designed to afford protection to our farming interests. Plants have been constructed for this purpose at ports of entry, equipped with steel chambers, in which the material is subjected to heat at a temperature sufficiently high to destroy the infection.

### Preparedness

A vast foreign commerce and rapid means of transportation make the task of repelling foot-and-mouth disease a most difficult one. It is probable, therefore, that in spite of all reasonable and practicable precautions that can be taken to keep out infection it will at some time be reintroduced.

In preparation for future outbreaks the Bureau of Animal Industry of the department has given special attention to a study of foot-and-mouth disease control and eradication under various conditions. Based on this study and on its experience in past outbreaks the bureau has formulated a comprehensive plan of procedure which has been submitted to the State livestock sanitary officials and approved. This plan covers every phase of work in the field and provides definite methods of cooperation between the Federal and State authorities.

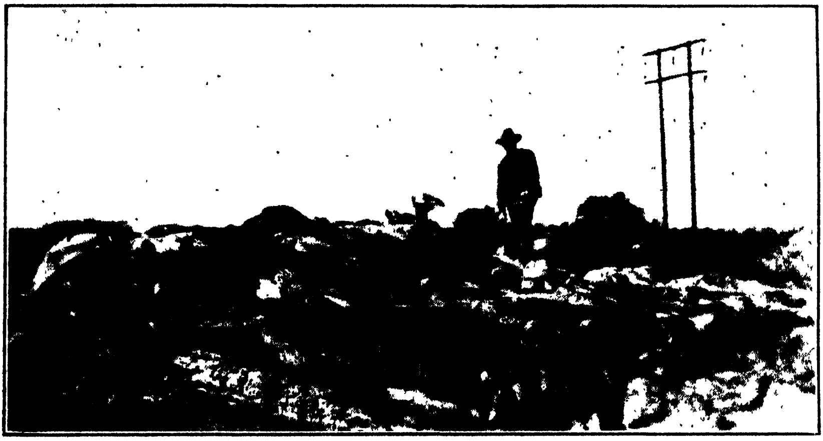

FIG. 97.—Cattle infected with foot-and-mouth disease slaughtered and prepared for incineration. Disposal by burning is rapid and a very effective means of checking the spread of the disease, though this method is most suitable for small herds

The bureau maintains a force of trained veterinarians and other inspectors who have had experience in previous outbreaks. This entire force is prepared to proceed to the scene of action on telegraphic orders. Its organization is somewhat similar to that of an army, with its supervisory officers selected in advance for important posts. It is made up of units each one of which handles a particular line of work, such as inspections, appraisals, trench digging, slaughter, disinfection, car cleaning, and shipments.

Owing to the extreme contagiousness of foot-and-mouth disease and the rapidity with which it spreads, the immediate slaughter and proper disposal of infected animals stand out as the most essential elements in prompt eradication. In earlier outbreaks great difficulty was experienced frequently in preventing the spread of infection while diseased animals were above ground awaiting slaughter and burial. During the recent Texas outbreak, however, the problem of holding infection in check and providing sufficient trench space for infected herds was largely solved through the use of steam shovels and oil-burning machines. The latter machines operate somewhat on the principle of a blowtorch. They are light enough to be placed on a truck, and thus can be moved rapidly where needed. A herd of a few animals in which infection manifests itself, after being slaughtered, can be burned within a few hours through the use of one of these machines. Where large herds, especially of range cattle, are involved, the actually diseased animals can be slaughtered and immediately incinerated, thus retarding the spread of infection through the herd until the steam shovels have had time to arrive and prepare trenches for the burial of the remaining animals. These machines and other apparatus adapted to this work in recent outbreaks will be of material assistance in case of future need.

FIG. 98.—When large numbers of cattle are involved, disposal by slaughter, quicklime, and deep burial has proved to be a certain means of checking the spread of this highly contagious foreign malady. The picture shows one of the largest trenches in the 1924 outbreak in California

### Cooperation of Farmers Essential

Despite the scope of eradication measures and the diligence with which they are applied, success in combating an outbreak of foot-and-mouth disease can not be attained without cooperation of the farmers and business interests of the community involved. This is especially true as it relates to farmers, who are the ones chiefly affected.

Posters placed throughout the quarantined area depict the symptoms of foot-and-mouth disease. The prompt discovery of a center of infection is a matter of the utmost importance. Farmers, therefore, can render a valuable service by immediately reporting suspicious cases in their herds or locality. Stock owners, through curiosity, have been known to visit neighboring quarantined premises and carry infection back to their own herds. Conscientious compliance with the provisions of a quarantine—the requirements of which are never more stringent than absolutely necessary to afford adequate protection to the interests of all concerned—will tend to guard against such a situation.

Although it is the duty of all to aid in the enforcement of quarantine orders, there will be misguided individuals in every outbreak who, through ignorance of the true nature of the disease or for other reasons, will oppose the slaughter of animals. This country has used the slaughter method of eradication with unfailing success. In various foreign countries, especially in Europe, where attempts have been made to combat the disease by methods of quarantine and treatment, it has invariably become so firmly established that the slaughter method no longer is feasible. The losses in such countries are heavy and continuous. A Federal scientific commission which returned to the United States in 1926, after more than a year's study of foot-and-mouth disease on farms and in the laboratories of European countries, gives unqualified approval to the slaughter method.

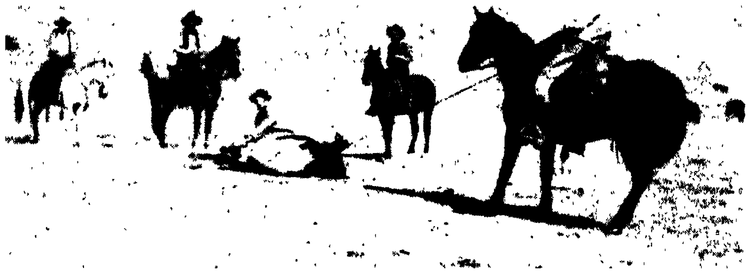

FIG. 99.—Inspecting a steer for foot-and-mouth disease on the range. Official field forces engaged in the work must have men qualified as riders and ropers, in addition to expert diagnosticians and veterinarians

Farmers can cooperate by informing themselves and by encouraging others to become familiar with the true and serious character of foot-and-mouth disease and the great expense and handicap to the livestock industry in countries where the disease has passed beyond the stage where it is possible to eradicate it. They can be especially helpful in using their influence against ill-advised movements to temporize with an outbreak and in opposing the issuance of court injunctions which tie the hands of officials who are fighting the disease and which tend to bring on the locality and State destructive embargoes by neighboring States. Farmers, through their organizations, may also serve a helpful purpose by assisting in any movement to obtain suitable State legislation which will place the State in a condition of preparedness to meet an outbreak of the disease.

A. W. MILLER.

**FROST Forecasting Indispensable in Orchard Heating** Through extensive experimental work and actual practice in orchard heating in the Pacific Coast States, it has been determined that fruit in that section of the country can be successfully protected against injury by frost under practically any conditions of temperature that are likely to occur during the critical period of growth. The success of orchard heating, however, depends very largely on the careful and painstaking manner in which the work is performed and the adequacy of the equipment used. As an aid in this work, and in cooperation with fruit growers, the Weather Bureau maintains a corps of frost specialists during the danger period in both the citrus and deciduous fruit-growing sections of the far Western States.

The service performed by these specialists is of a twofold nature—making temperature surveys and forecasting the occurrence of temperatures low enough to require artificial heat in the orchards. The practice of orchard heating has become very extensive in recent years, nearly a million new heaters having been purchased by the citrus growers of California alone during the years from 1922 to 1925.

It is well known that local topography plays a very important part in the frost hazard of an orchard, especially on clear, calm nights, when by reason of radiation of heat from the ground the surface layers of air become considerably colder than those at some distance above and a down-slope drainage of the relatively cold surface air occurs. This results in an accumulation of dense, cold air in the near-by lower lands or depressions and makes the frost hazard greater than on the higher slopes. It often happens that very small variations in elevation and slope make a marked difference in the frost hazard at near-by points.

By reason of variations in topography some of the more favored localities of a region may require little or no protection, while in others near by heavy firing may be required to prevent loss or serious injury to the orchard or grove. It is important, whenever new plantings are to be made, to locate and chart these cold areas, so that advantage may be taken of the local differences in topography. The temperature-survey work of the Weather Bureau consists in the establishment of many temperature stations, usually 30 or 40, in a relatively small area, equipped with standard thermometers and thermographs properly exposed and operated by trained men. From the record of these the relative frost hazard of different places within an area is determined and the information made available to growers as a guide, both for future plantings and in the matter of distribution of equipment for protecting existing orchards.

### Advance Preparations Required

Wherever orchard heating is practiced, advanced preparations, such as the placing of oil-filled heaters in the orchard, the convenient storing of a reserve supply of fuel, and many other preliminaries, are made before the frost-danger period arrives, so that when it becomes necessary, heating operations may be started on very short notice. When a frosty night impends, however, it is very necessary to know this during the afternoon of the preceding day, so that last-minute details, such as getting help for lighting heaters, final preparations for lighting, instructions to workers, etc., may be arranged in readiness for the coming battle against "Jack Frost."

The margin between the "danger" and "no danger" temperature is very narrow and the descending mercury in the thermometer often approaches the danger mark without actually reaching it. In such cases, in the absence of dependable information as to just what is going to happen, growers often make unnecessary final preparations for, and actually begin, heating operations at considerable expense.

A system of special frost forecasting by experts of the Weather Bureau has been developed through which growers are advised very definitely as to just what degree of cold to expect during the ensuing night. When it is known that the temperature will remain well above the danger point, a forecast of "no danger" is made, but whenever freezing or lower is expected at any place in the district that fact is made known, together with a very definite statement as to the minimum temperature expected at a "key" station located at some cold place in the area. The forecaster advises as to what parts of the district will need protection and whether or not heavy firing will be required. These facts are widely distributed by telephone to the headquarters of the various fruit organizations for dissemination to individual members, published in the afternoon papers, and put on the air daily through the radio.

### Confidence Gained from Results

The accuracy with which forecasts have been made for several years have given the growers complete confidence in them as a dependable basis for final preparations for firing operations. As previously stated, definite forecasts are made when the temperature is expected to go as low as 32° F. at any station in the district. Although this is not a damaging temperature, when it falls to freezing there is usually uneasiness on the part of the growers as to just how much lower it may go, and definite information is desired.

J. B. Kincer.

**FOREIGN Trade Index Number for Foodstuffs** By net foreign trade is meant the excess of exports over imports or the reverse. The index number of net foreign trade in foodstuffs is an attempt to measure the fluctuation in the net contribution of the United States to the food supply of all other countries. To this end imports of foodstuffs, each commodity with an assumed fixed weight, are deducted from exports and the difference in each year expressed in relation to the average excess of exports over imports in the five years ended June 30, 1914.

The weights assumed for the purposes of this index number are the average unit prices of various food products in the base period. By multiplying the volume of exports in each year by these fixed weights abstract aggregates are obtained which can be added together or subtracted one from another. But since the weights remain constant the fluctuations in the aggregates from year to year represent changes in volume of trade. The index number obtained by this method is an index number of the difference in volume between exports and imports. A higher index number in any year may result either from an increase in exports or from a decrease in imports or both, while a lower index number indicates either a decline in exports or an increase in imports or both.

In the computations 57 commodities were taken into account covering all the more important vegetable and animal-food products. Cacao was included, but coffee and tea excluded as having no appreciable food value. On the side of exports, in recent years pork products and wheat, including flour, are the most important items, while on the side of imports, sugar far outweighs all other items, with cacao second in importance.

In addition to the index number of trade in all foodstuffs, group index numbers were computed of trade in animal products, grain and grain products, sugar, and of fruits, nuts, and vegetables. These index numbers for the years ended June 30, 1880–1926 are presented in Table 10.

TABLE 10.—*Index numbers of net foreign trade in foodstuffs, 1880–1926*

| Year ended June 30 | All foodstuffs, net exports | Animal products, net exports | Grains and grain products, net exports | Sugar, net imports | Fruits, nuts, and vegetables, net imports |
|---|---|---|---|---|---|
| Average 1910–1914 | 100 | 100 | 100 | 100 | 100 |
| 1880 | 355 | 167 | 185 | 43 | 29 |
| 1881 | 358 | 169 | 185 | 47 | 20 |
| 1882 | 187 | 110 | 109 | 48 | 55 |
| 1883 | 187 | 88 | 130 | 52 | 42 |
| 1884 | 178 | 112 | 109 | 66 | 45 |
| 1885 | 208 | 113 | 127 | 61 | 32 |
| 1886 | 175 | 111 | 102 | 62 | 38 |
| 1887 | 199 | 111 | 135 | 72 | 43 |
| 1888 | 154 | 108 | 99 | 65 | 66 |
| 1889 | 177 | 122 | 97 | 67 | 38 |
| 1890 | 288 | 186 | 136 | 70 | 53 |
| 1891 | 225 | 188 | 95 | 82 | 68 |
| 1892 | 320 | 138 | 219 | 85 | 38 |
| 1893 | 263 | 151 | 172 | 90 | 73 |
| 1894 | 264 | 165 | 164 | 103 | 53 |
| 1895 | 255 | 162 | 125 | 85 | 49 |
| 1896 | 279 | 173 | 157 | 92 | 45 |
| 1897 | 375 | 202 | 224 | 116 | 30 |
| 1898 | 526 | 210 | 307 | 62 | 39 |
| 1899 | 488 | 234 | 275 | 93 | 40 |
| 1900 | 482 | 229 | 277 | 94 | 43 |
| 1901 | 488 | 223 | 282 | 93 | 30 |
| 1902 | 376 | 201 | 204 | 72 | 68 |
| 1903 | 407 | 165 | 204 | 101 | 42 |
| 1904 | 282 | 200 | 129 | 87 | 48 |
| 1905 | 232 | 200 | 86 | 87 | 51 |
| 1906 | 342 | 235 | 158 | 93 | 69 |
| 1907 | 297 | 202 | 160 | 104 | 67 |
| 1908 | 284 | 184 | 153 | 80 | 80 |
| 1909 | 153 | 144 | 105 | 99 | 112 |
| 1910 | 95 | 100 | 85 | 93 | 86 |
| 1911 | 115 | 111 | 87 | 86 | 88 |
| 1912 | 95 | 123 | 77 | 95 | 120 |
| 1913 | 165 | 102 | 150 | 106 | 72 |
| 1914 | 34 | 68 | 102 | 119 | 134 |
| 1915 | 359 | 112 | 322 | 116 | 90 |
| 1916 | 378 | 179 | 252 | 94 | 86 |
| 1917 | 317 | 193 | 216 | 96 | 171 |
| 1918 | 270 | 234 | 166 | 104 | 241 |
| 1919 | 524 | 338 | 288 | 113 | 238 |
| 1920 | 297 | 209 | 226 | 147 | 178 |
| 1921 | 331 | 146 | 315 | 151 | 159 |
| 1922 | 365 | 171 | 338 | 153 | 207 |
| 1923 | 238 | 171 | 256 | 179 | 230 |
| 1924 | 133 | 177 | 135 | 176 | 171 |
| 1925 | 172 | 138 | 237 | 198 | 201 |
| 1926 | (1) | 105 | 117 | 199 | 222 |

[1] Import aggregate in excess of export aggregate. The index number expressed as a negative.

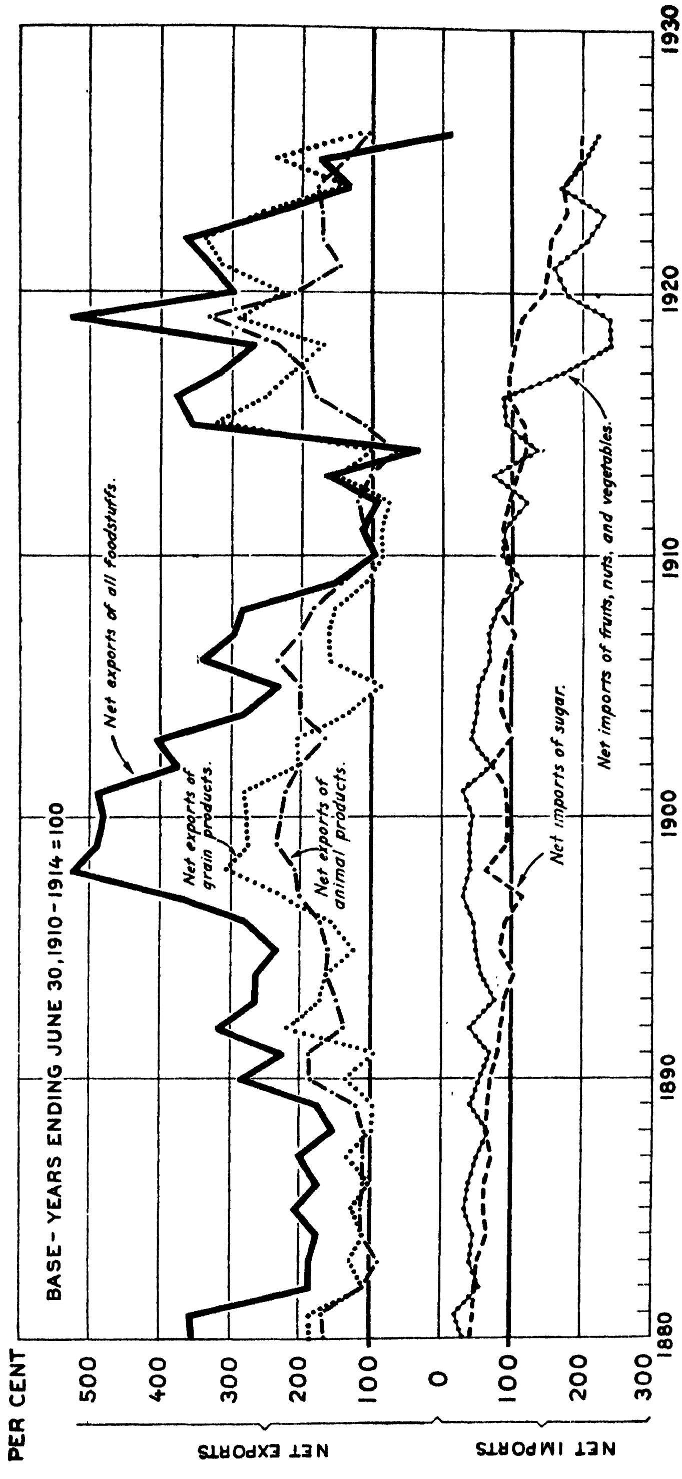

FIG. 100.—Index numbers of net foreign trade in foodstuffs for years ended June 30, 1880–1926

It will be noted that the excess of exports over imports of all foodstuffs and of the meat products and grain products groups increased rapidly from 1888 to 1898 with the rapid development of agriculture and transportation facilities in the Great Plains. But from 1898 to the outbreak of the World War net imports showed a distinct downward tendency, owing to increase in population in the United States, increasing competition in foreign markets and higher standards of living in the United States which increased the demand for foreign food products.

The war emergency brought net exports back to the 1898 figure, but since 1919 the decline is again apparent and in the year ended June 30, 1926, the import aggregate exceeded the export aggregate making the index number of exports of all foodstuffs less than zero. On the import side there has been a remarkably constant increase during the whole period of 46 years. In Figure 100 the index numbers of net exports are plotted on a natural scale while those of net imports are shown below on an inverted scale.

G. B. L. ARNER.

## FOREST Grazing Control Aids Tree Growth

In timber growing as in farming one can not expect good yields unless the land is well stocked with the right kind of plants. It is just as important to have a good "stand" in a forest as in a cornfield, and more so, because the trees must grow close together in order to produce straight, clear stems suitable for lumber. Most of the forests in this country are bearing less than half the timber they could support because they are understocked.

The reasons for poor stocking are not difficult to find. Old trees are continually falling victims to wind, lightning, fire, disease, and insects. Under normal conditions nature quickly replants the spaces thus left vacant; but outside agencies may interfere with this natural replacement, and then we have treeless openings within the forest. Fire has been the most common agency in preventing the restocking of these openings. A surface fire once in 20 years, even though not severe enough to kill many large trees, may destroy the young growth.

### Grazing and Fire Hazards

The grazing of domestic livestock has also been a factor. To some extent grazing has probably decreased the intensity of fires, but on the other hand it has been a cause of fires being set, as in "light burning." In the Southwest livestock has been a direct factor in perpetuating openings by eating seedlings.

It is quite generally known that livestock browse the shoots of broad-leaf trees, but the general impression is that they do not disturb conifers, such as pine, fir, and spruce. Fortunately this seems to be the case in some regions; nevertheless, much damage to conifers is taking place. In Arizona it has been known for more than 20 years that grazing is seriously interfering with reproduction of western yellow pine.

Prolonged investigations leave no doubt that if the kind of grazing carried on in the past should continue natural reproduction will be stopped in more than half of the great yellow-pine forest of the

Colorado Plateau. Information from other parts of the country indicates that there is more or less of a grazing problem also in Washington, Oregon, California, Idaho, Colorado, the Lake States, New England, the Appalachian region, and the southern pine belt.

### Damage from Overgrazing

Overgrazing is the most common cause of damage to tree seedlings. It does not always follow, however, that if overgrazing is avoided no damage will take place. Livestock exhibit well-defined preferences in selecting food. Generally they take what they like best first, and only when there is not enough of this to go around do they consume fully the less palatable forage. Contrary to the usual impression, tree seedlings, even the pitchy pines and firs, are not unsavory to livestock. In the Southwest only the junipers enjoy immunity from cattle and sheep, and even they are eaten by deer. Western yellow pine, white fir, and Douglas fir apparently are more palatable to sheep than many of the grasses.

In regions where most of the forage plants are relished more than tree seedlings, the latter are likely to escape unless the more desirable feed runs short. The same rule should hold in regions where only a small proportion of the forage is more palatable than the seedlings, but there the margin of safety is so narrow that it is easily overstepped. Moreover, the appetite for seedlings seems to vary greatly under apparently constant forage conditions. It is not uncommon in Arizona to find pine and fir seedlings defoliated when such choice feed as grama grass (*Bouteloua gracilis*) is scarcely touched. Sheep, especially, seem to crave a certain amount of " browse " which, in the absence of more palatable woody plants, is supplied by coniferous trees.

The effect of grazing is also greatly influenced by the density and rate of growth of the tree seedlings. If seedlings start in large numbers and grow rapidly a considerable amount of injury might be sustained without serious consequences. With a stand of 50,000 young seedlings per acre, the chances that 2,000 may survive are better than if the initial stand is only 5,000. If seedlings make an average annual height growth of 6 inches during the first 10 years, more are likely to get beyond the reach of livestock than if the growth is only 2 inches a year.

### Difficult to Lay Down Rules

Differences in forage conditions, in the vigor of forest reproduction, and in the food habits of animals make it difficult to formulate practical rules for avoiding damage. Very often the avoidance of overgrazing will solve the problem. It should be borne in mind, however, that an area as a whole may not have too many animals on it, and yet local areas where stock tend to congregate may be seriously overgrazed. In any case, it is necessary to be on the alert for signs of damage. To save a stand of seedlings requires action in the early stages before they become exterminated in patches and may call either for complete exclusion of grazing or for exclusion or reduction in numbers of certain kinds of stock.

The extent to which grazing should be restricted in order to promote forest regrowth depends not only upon the condition in the forest but upon such circumstances as the desire of the owner and the relative returns from the forest and forage crop. In the case of the national forests the owner, who is the public, desires to devote the land primarily to timber growing. Moreover, the true timber lands on the national forests are better adapted to growing timber than forage. In the Southwest, where grazing in the forests presents a particularly acute problem, it has been ascertained that the annual growth of timber on fairly well forested pine land is worth about fifteen times as much as stockmen are paying for the grazing privileges.

This does not mean that grazing should invariably be prohibited, but rather that it should be so managed as not to interfere with forest reproduction. Fortunately, there are some regions in which reproduction will succeed with moderate grazing. In many places it will be necessary to exclude sheep and goats, and permit cattle grazing, if at all, only under rigid restrictions.

### Obstacles to Quick Adjustments

In some cases it may be difficult to make the necessary adjustments in grazing as promptly as desirable. Private owners whose timber is not marketable may be sorely in need of the income which may be derived from grazing. In Government or State-owned forests it often happens that communities in remote localities where the timber can not be exploited are dependent upon the grazing industry. Under such conditions timber growing may be called upon to yield temporarily in favor of grazing. Where the land is known to be permanently more valuable for timber than for forage crops, however, timber growing should not thus be set aside without adequate provisions for restoring it to its rightful place. In making the grazing adjustments needed to safeguard forest reproduction it should be understood that if an area has been overgrazed a reduction to what may be considered proper grazing from the standpoint of forage will not result in loss of grazing revenue but, on the contrary, will increase it.

The forest owner, be he the Government, State, or individual, should determine the relative value of the timber and the stock business on his land. He should also consider indirect forest values such as recreation and water resources. If greater returns can be realized from growing timber than from growing livestock, he will see the wisdom of not allowing grazing permanently to jeopardize regeneration of the forest.

G. A. Pearson.

---

## FOREST Trees for Planting

Farmers who plant young forest trees on the waste rough parts of their land are joining in a very popular movement to increase farm values. In the year ended June 30, 1926, State forest nurseries distributed over 25,000,000 little trees to farmers. These trees were distributed by 32 States and 1 Territory, a remarkable increase over the year ended June 30, 1925, when there were not over 20 State forest nurseries in the country. At the rate of 1,000 trees to the acre, 25,000 acres of idle farm land were put to work growing a profitable crop.

Forest-planting stock distributed by the States generally ranges in price from $1 to $10 per thousand, a higher price being sometimes charged for the larger stock. In some States no charge is made for the trees distributed.

### List of Sources

The following list gives names of State organizations from which young trees can be obtained, together with figures on price and number distributed last year.

**California**, State forester, Sacramento: 1,090 Arizona cypress, eucalyptus, and other hardwoods at 10 to 50 cents each.

**Colorado**, State forester, Fort Collins: 110,000 (information incomplete).

**Connecticut**, forester, Agricultural Experiment Station, New Haven: 423,000 red pine, white pine, Norway and white spruce, and others at $4.25 to $12 per thousand.

**Delaware**, secretary, State Board of Agriculture, Dover: 10,000 tulip poplar, black locust, white oak, and black walnut. No charge.

**Idaho**, professor of forestry, University of Idaho, Moscow: 82,500 black locust, willow and poplar, western yellow pine, and others at $1 to $4 per thousand.

**Indiana**, State forester, Indianapolis: 127,200 locust, white oak, white pine, and others at $5 to $10 per thousand.

**Iowa**, professor of forestry, Iowa State College, Ames: 30,200 Carolina poplar, white pine, black locust, and others. No charge, except for packing and shipping.

**Kansas**, State forester, Manhattan: 27,750 Osage orange, arbor vitae, elm, and others at 5 to 50 cents per tree.

**Kentucky**, State forester, Frankfort: 12,400 chestnut oak, black walnut, and tulip poplar at one-half to 1 cent each.

**Louisiana**, superintendent of forestry, New Orleans: 89,000 slash and loblolly pine, black locust, and catalpa. No charge, except for shipping.

**Maine**, State forester, Augusta: 672,000 white and red pine at $10 per thousand.

**Maryland**, State forester, Baltimore: 226,400 loblolly pine, red pine, Norway spruce, and others at one-fourth to 15 cents each.

**Massachusetts**, State forester, Boston: 965,500 white pine, Norway spruce, and others at $7.50 to $10 per thousand.

**Michigan**, professor of forestry, Michigan State College, East Lansing: 308,600 Norway spruce, white and jack pine, and others at $2 to $16 per thousand.

**Minnesota**, commissioner of forestry, St. Paul: 43,000 Norway pine, white spruce, white elm, and others at $10 per thousand.

**Nebraska**, State forester, Lincoln: 33,900 jack pine, elm, Scotch pine, and others. No charge for jack pine; 1 to 8 cents per tree for others.

**New Hampshire**, State forester, Concord: 453,750 white and red pine, white spruce, and others, at $3.50 to $7.50 per thousand.

**New Jersey**, State forester, Trenton: 592,000 red and Scotch pine, Norway spruce, and Douglas fir, at $4 to $6 per thousand.

**New York**, supterintendent State forests, Albany: 9,300,000 white pine, Norway and white spruce, and others, at $1 to $5 per thousand.

**Ohio**, State forester, Wooster: 1,154,700 Norway spruce, Scotch pine, black locust, and others, at $1.50 to $8 per thousand.

**Pennsylvania**, secretary, department of forests and waters, Harrisburg: 8,967,300 white, Scotch, and red pine, Norway spruce, and others. No charge except for packing.

**Porto Rico**, Insular forester, Rio Piedras: 343,000. No charge.

**Vermont**, commissioner of forestry, Montpelier: 914,500 Norway spruce, white, Scotch, and red pine, and others, at $6.50 to $7 per thousand.

**Virginia**, State forester, University: 44,000 loblolly, white, Scotch, and shortleaf pine, at $1 to $10 per thousand.

**Washington**, department of forestry, College of Agriculture, Pullman: 2,360 black locust, Norway maple, and others, at 10 to 40 cents per tree.

**Wisconsin**, superintendent of State forests and parks, Madison: 227,175 white, Norway, and Scotch pine, and others, at $4 to $10 per thousand.

### Clarke-McNary Act is Authority

The foregoing distribution of trees by the States last year was made in cooperation with the United States Forest Service under Clarke-McNary Act agreements. In addition to this distribution of 25,133,000 trees to farmers, the cooperating State agencies in the fiscal year 1926 distributed 13,541,000 to other planters and furnished 13,994,000 for planting on State lands—a total distribution of 52,668,000.

Why should farmers plant trees?

They set idle acres, too rough or sterile for farming, to work growing an always marketable crop. Though trees take a number of years to reach maturity, a young plantation adds cash value to a farm, just as a young orchard does. In a few years it yields small material in the form of thinnings, such as poles and fence posts; later, fuel and pulp wood; and finally, tie and saw timber. It is a savings bank that pays compound interest. Timber growing is a necessary part of diversified farming, affording employment and wages for winter work. A farm wood lot is security to the banker and the farm loan board.

ALFRED B. HASTINGS.

## FREIGHT Rates Since War Period

In the general readjustment following the war, freight rates on farm products have been stabilized considerably above their 1913 average. They are about at the same level as prices of nonagricultural commodities, but, as shown in Figure 98, somewhat above farm prices. The result is that the farmer's freight bill has been out of line with the prices he has received and freight rates have added an additional item to his burden.

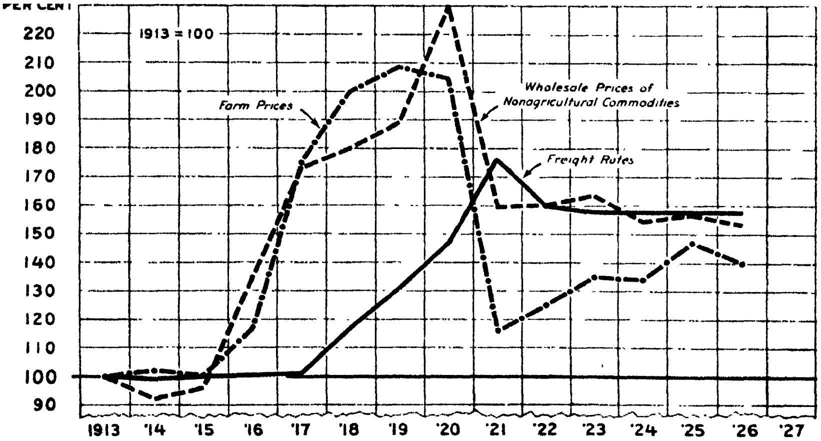

FIG. 101.—Comparison of freight rates, farm prices, and wholesale prices of nonagricultural commodities, 1913–1926

Generally, freight rates do not go up or down until some time after prices and costs have risen or fallen. There was no material increase in freight rates during the war until 1918 and again in 1920. At this later date, 1920, all rates were increased from 25 to 40 per cent. About the same time farm prices began a precipitous decline, reaching their low point in 1921. As shown in the chart, the result of this increase was that freight rates were at their highest the same time that prices were at their lowest.

An example of the effect of this may be seen in the case of wheat. In 1919, when the North Dakota farmer was receiving around $2.25 a bushel for his wheat, his average freight cost to Minneapolis was 5 per cent of the price. In 1921, when the price reached a low point of 84 cents, the freight cost was 18 per cent of the price. The same situation where freight rates were an excessive burden was true of other farm products and of nonagricultural commodities as well. Since this low point, however, when the burden of high costs was the heaviest, farm prices have gradually risen and in 1922 there was a 10 per cent reduction in freight rates.

Farm prices and freight rates on agricultural commodities are still out of line. At the present time freight rates have stabilized at 158 per cent of their pre-war level or in line with the price level of nonagricultural commodities, while prices are 10 to 15 per cent lower.

B. R. Gould.

**FRUIT - Tree Stocks Are Improving** The stocks which make the root system of budded and grafted trees have received more attention in recent years than formerly, although our knowledge of the underground part of such trees and the important part it bears in the trees' well-being is still far less than what we know of varieties and many other factors in fruit production. Evidence clearly indicates that some improvement in the performance of orchard trees may be had by better choice of stocks.

The interest of nurserymen, growers, and scientists has brought about a great deal of experimental work which is now beginning to yield results. Much time and energy must still be expended on such experiments, however, before the choice of the most suitable stocks can be made with the certainty of results now obtainable in the choice of the best adapted varieties.

At present a large proportion of the seed for the domestic production of fruit-tree stocks is imported. The seedlings themselves are also imported in large quantities. Aside from the danger of introducing insects and diseases, the behavior of imported seeds and seedlings has often proved unsatisfactory by reason of poor germination of the seeds or in variability of the seedlings. A search for domestic seed of good quality has shown that resources not hitherto utilized are already available for some of the important fruit stocks, while others can be produced without difficulty in a few years' time by growing trees for the purpose.

For apple stocks, French crab seedlings have been most largely used for many years. Seed from some of the widely grown varieties of apples appear to possess superiority over French crab, according to experiments by the United States Department of Agriculture which have been under way for the past five years. Many of these varieties supply seed that germinates well and the resulting seedlings are vigorous and make good unions when budded or grafted. Seedlings of several varieties are hardier than French crab. Among them are McIntosh, Tolman Sweet, Oldenburg (Duchess), Rhode Island Greening, and Fameuse. Seedlings of other varieties which give evidence of desirability except in the northern sections, are Delicious, Winesap, and Stayman Winesap. Seeds of all these are available in large quantities from cider pomace in sections where the varieties are grown commercially.

### Cherry Stocks from Europe

Mazzard and Mahaleb, the two principal cherry stocks, are at present mainly imported from Europe. Mazzard cherry seed from the roadside and pasture trees of Pennsylvania, Maryland, and Virginia within the past two or three years has been found superior to the imported seed. These wild trees are the descendants of the sweet cherries brought from Europe in colonial days. They have undergone vigorous selection under the severe conditions in which they grow in the wild. These wild trees occur over a wide range and are sufficiently productive to assure an ample supply of seed every year.

For Mahaleb cherry seedlings which are used in greater numbers than any other cherry stock, no adequate supply of seed is available in this country at present. Uncertain germination of imported seed has been one of the drawbacks to the production of seedlings in this country. On the other hand, seed from trees locally grown and handled to prevent severe drying during the interval between collecting and planting gives reliable germination. As Mahaleb trees come into bearing at an early age and are productive, no reason is apparent why a domestic supply of this species should not be grown for its seed.

A form of Morello cherry used in northern Illinois in a limited way for many years has recently received more attention on account of the excellent performance of the trees worked on it. It is a dwarfing stock propagated by suckers.

Myrobalan plum seedlings vary widely in their characteristics. Improvement in the quality of this most widely used plum stock is being brought about by selecting forms that produce the most desirable type of seedlings and growing these selections in orchards for their seed. In California a considerable proportion of the Myrobalan seed annually needed for the entire country is already available, and the supply is increasing.

Experiments are also being directed to another promising means of improvement in fruit-tree stocks by eliminating the variability recognized in nearly all seedlings. Individuals are sought that have outstanding superiority in such qualities as affinity for the varieties to be worked on them, hardiness, adaptability to a wide range of conditions, and resistance to insects and diseases. These selected individuals are propagated by cuttings or layers rather than by seed, thus reproducing their characteristics with uniformity. Such means of obtaining stocks is a departure from established nursery practice in the United States, seedlings nearly always being used except for dwarf apple and pear stocks. It is not a new idea, however, for in Europe it is very widely used.

### Problems of Propagation

Besides the selection and proving of individuals, the problem of inexpensive and rapid propagation is an important one. Most types of fruit stocks do not root easily from stem cuttings. Root cuttings, however, make plants readily in some cases, while in others layers are better. Stocks thus propagated necessarily cost more than seedlings, but this added cost of a few cents per tree would be more than justified if a better tree could be had by their use. Several apple, cherry, and plum selections already made give promise of exceptional merit and are now being propagated for further tests before introducing them.

Of the plants used for the adornment of home surroundings, the Japanese flowering cherries are being more generally planted as they become known. These are most frequently worked on Mazzard as being the most readily available stock. The trees, however, have often proved short-lived. Several oriental species and forms more closely related to the varieties appear more suitable. Among those that show special promise are *Prunus serrulata* and its form, *P. serrulata sachelinensis* and seedlings of the variety Yoshino.

Several stocks for hybrid tea roses that give evidence of merit are being tested in comparison with the stocks generally used, which are manetti, Japanese multiflora, and others. One of these is a form of *Rosa multiflora* introduced from China by Chenault and received by the department from the Arnold Arboretum. Besides having the desirable qualities of the Japanese multiflora, this form is even more vigorous and has larger canes which root easily as hardened cuttings. Plants grown from cuttings are more easily budded than the Japanese multiflora seedlings. Another promising rose stock is a form closely related to *R. canina* which has so far proved free from the tendency of that species to throw suckers from below the point of union. *R. odorata*, S. P. I. 22449, while lacking in the extreme hardiness of the two stocks just mentioned, is proving to be a valuable stock for greenhouse forcing roses.

GUY E. YERKES.

### FUR Farming a Growing Industry

That the existing natural supply of furs can be supplemented by raising fur animals in captivity is being more fully appreciated year by year. Conceived by a few individuals only a comparatively few years ago, fur farming has steadily developed until now there are more than 4,000 fur farmers in the United States, Canada, and Alaska, most of them engaged in raising silver or blue foxes. The total investment in the business in the United States and Alaska is about $30,000,000, and in Canada about $11,000,000. Fur farming is also being undertaken in European countries and in Japan, where it is having a steady, quiet growth.

Every developing industry sooner or later reaches a stage where it requires scientific study. Fur farming is no exception, and Congress has authorized the department, through the Biological Survey, to make investigations and experiments in the production of fur animals. These are now being conducted under wild and semiwild conditions with various species, including domesticated rabbits. Constant effort is made to obtain all information essential to the requirements of this growing industry, with special attention to disease and parasite control and the utilization of fur as a natural resource. The experimental fur farm, where the work is in progress, is in Saratoga County, N. Y., and is open to the public on Wednesdays and Sundays from June to November, that visitors may note the work the Government is doing to assist fur farmers.

FIG. 102.—Well-organized fox ranch. Fox farms are found in practically all the northern tier of States from New England to Washington and Oregon

FIG. 103.—On a silver-fox farm. Fox farms produce more than 90 per cent of the silver-fox pelts sold in the fur markets of the world

Blue-fox farming is confined chiefly to islands off the coast of Alaska, where the foxes have free range, but is gradually spreading to the mainland of that Territory and to Canada and the United States, where the animals are raised in pens.

For generations muskrats have been produced profitably with a small outlay of money and effort, chiefly on privately owned marshlands in New Jersey, Delaware, Maryland, and Louisiana. Scientific study of the requirements of muskrats is now being undertaken in their natural habitat with a view to their perpetuation as a valuable natural resource.

### Beaver Fur Production

Should beaver farming prove profitable, it would make remunerative large areas now unproductive but well suited to such an enterprise. The production of beaver fur might be readily increased by the simple expedient of restocking depleted areas within their original range, where the animals could feed and breed without molesting forest or farm property.

FIG. 104.—Section of a large rabbitry. Better meat and fur are produced by hutch-raised than by wild rabbits

Skunks, raccoons, and minks are not difficult to raise in pens, but at the prevailing raw-fur prices the undertaking with these species would not pay. Only in very exceptional instances have breeders been successful in producing litters of either martens or fishers in captivity. Rabbits, however, are being raised profitably for both meat and fur, and the rabbit industry is developing rapidly, especially in Pacific coast States.

There is ample basis for a sound industry in propagating fur-bearing animals. Fur farming is growing and should become a permanent addition to our agricultural development, for it is desirable both in the utilization of nonagricultural lands and in the production thereon of valuable crops of fur.

FRANK G. ASHBROOK.

**FURNITURE Destruction by Insects** The vogue during the last few years for furniture upholstered with mohair has placed in thousands of homes throughout the country favorable breeding places for a group of common household pests. Although this furniture, if properly constructed by the manufacturer and intelligently cared for by the retailer and housewife, need not suffer more than other furnishings of the home, the fact remains that lack of information has brought about a condition throughout all the States which has increased tremendously the calls upon the department for information concerning insects in upholstered furniture. To meet these demands a special investigation has been started and has progressed sufficiently far to date (September, 1926) to warrant a general statement regarding the insects involved, their methods of attack, and the means for controlling them.

Taking the country over, the most destructive pest on mohair-covered furniture is the webbing clothes moth (*Tineola bisselliella*). A very large percentage of real loss is due to this common fabric pest. This moth is present in nearly all homes, and if mohair-covered furniture is not properly manufactured or cared for the newly hatched "worms" work down through the pile, become established underneath the warp, and feed upon the woolen threads of the pile where they pass beneath the warp. By thus severing the pile they are responsible for the development of bare spots on the covers resulting from the falling out of the severed pile when the infested furniture is brushed or is treated with a vacuum cleaner. Although these bare spots do not injure the usefulness of the furniture, they destroy its aesthetic value and are responsible for the expenditure by the American public of a sum exceeding half a million dollars annually for fumigations, various other treatments, and the upholstering charges for repairing or replacing covers.

The second most serious pest on upholstered furniture is the furniture carpet beetle (*Anthrenus fasciatus*). This insect causes its greatest injury by establishing itself within the furniture, where it brings about a condition of flabbiness and shabbiness by devouring the curled hair used in the upholstering. In Washington, D. C., this carpet beetle is the most important furniture pest.

Two other insects often reported as infesting furniture are the ordinary tobacco beetle (*Lasioderma serricorne*) and book lice or psocids. These two pests are frequently spoken of as "tow bugs." They feed normally upon dried vegetable matter, and when in furniture they feed upon the flax or other straws or Spanish moss used in the upholstering. They cause practically no real injury to the furniture, although the adult tobacco beetle sometimes does eat small round holes in the mohair or leather covers in an attempt to escape. Both the tobacco beetles and psocids annoy the householder by crawling over the furniture and by dropping from it and crawling to all parts of the house.

Facts regarding the life habits of furniture pests and their control have been published and are available for distribution to those applying for them to the Department of Agriculture.

### GAME Surpluses Perplex Wild-Life Guardians

Accustomed as we are to think of game as requiring protection, it may seem incredible that under certain conditions it can become locally overabundant. As nature lovers we are prone to overlook practical problems in game conservation, and some of these are so vital that our oversight has at times defeated our main purpose. In protecting game from overhunting, natural enemies, and disease we sometimes fail through ignorance to provide an adequate supply of that prime essential to all living creatures—food.

Some of the methods employed in the successful handling of domestic animals are applicable in wild-life management. No wise farmer would long attempt to maintain more livestock in a pasture than could subsist there. Similarly, game stocks should not be permitted to increase until they consume more than the normal seasonal forage growth. With the more palatable plants injured or killed and the normal producing capacity of their range diminished, part of the game will face starvation unless their numbers are correspondingly reduced.

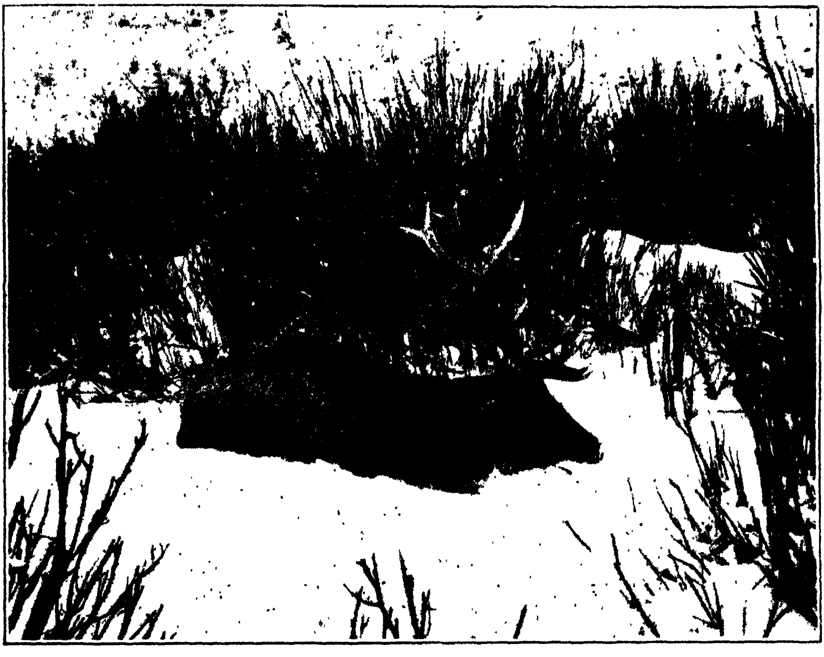

Fig. 105.—Starving elk. A splendid bull in Jackson Hole, Wyo., still alive, but too weak to rise from its last bed. Hundreds of elk had browsed the willows until the thick stems would yield little more than wood pulp. In such a place all the elk died of starvation, whereas a smaller number might have wintered well

An excessive stock of game may accumulate even when parts of its range are open to hunting. This is illustrated in the region about the Yellowstone, where elk have starved by thousands during severe winters, although feed for them is provided at the adjacent elk refuge of the Biological Survey. Following several disastrous winters, the latest in 1919, they have increased to an unwieldly number.

This asset may thus become a liability in the next hard winter by a disastrous reduction of the herds to smaller numbers than would have survived under wiser management.

A striking example of the baneful results of overstocking a refuge from which emigration is negligible is afforded in the Kaibab National Forest. Here the destruction of forage and young forest growth by excessive numbers of mule deer presents a serious problem that efforts of the Forest Service and cooperating bureaus have thus far failed to solve.

### Overabundant Buffalo

On the big-game preserves maintained by the Biological Survey the increasing numbers of buffalo and elk have made the disposal of a surplus imperative, to prevent the lowering of forage production and the consequent starving of the animals. Since no hunting can be permitted in such places, reduction is accomplished mainly through the capture and sale of animals for stocking or exhibition purposes. In the winter of 1924–25 a surplus of 221 buffalo was removed from the National Bison Range in Montana, and the next winter 388 surplus elk were shipped alive from the same reservation.

FIG. 106.—Apple orchard damaged by deer. The lower branches are killed by repeated cropping of deer from an adjacent State deer range in Pennsylvania that has become overstocked

The overstocking of well-located game refuges that are not too large may usually be prevented by regulated hunting outside. On larger preserves, or on those from which there is little or no overflow, hunting or reducing the surplus by other means may be of vital importance to the residue. Efforts to conserve and increase wild-animal life frequently call for wise control measures, including disposal of surplus stock for the welfare of the numbers that it is desired to maintain. Wild-life resources properly utilized will yield the maximum of economic and recreational returns.

EDWARD A. GOLDMAN.

## GARMENT Fitting for the Home Dressmaker

Fitting garments is the greatest difficulty which women encounter in home dressmaking. Cothing manufacturers find that much waste results from clothing which does not fit and which is eventually returned to them from the retail merchants. To retailers, also, the cost of fitting garments on customers is a large item of expense. These difficulties are a result of making patterns and ready-to-wear garments without accurate measurements for sizes.

Of course, differences in individuals also cause many of the difficulties in fitting. Few women approach or equal the perfect form or the forms which are used by pattern companies and clothing manufacturers. Racial and family tendencies are some of the chief causes for this wide variation. The work which people do, ways of sitting, standing, and walking, and food habits also have an effect on body development. Round shoulders, narrow chest, protruding abdomen, and many other irregularities result.

Some pattern companies as well as some ready-to-wear organizations are now making a special effort to get rid of the most outstanding difficulties. New sets of measurements are being established which are especially adapted to specific groups, such as the short stout figures, tall stout figures, and other irregular sizes. Women with figures differing greatly from the average should make use of such patterns and dresses.

A comprehensive study of group measurements which will give the group sizes of people living in the United States to-day has been planned by the Bureau of Home Economics. Many thousands of individuals should be measured in order that certain group proportions may be obtained. These size groups will eliminate much waste of time as well as material both at home and in the factories. Many measurements have been taken in the past merely to show physical development, but these are not applicable to the clothing industry. A beginning was made on this problem of scientific measurements during the World War when many thousands of American soldiers were measured for the purpose of establishing sizes for uniforms.

### Fitting Difficulties Studied

In the meantime, to help the homemaker in fitting her own clothes or those of her neighbor, a study was made of garment-fitting difficulties and their remedy. Dress patterns of similar design from the principal pattern companies were compared by placing those of the same size upon each other with the center front lines coinciding. The results show many variations. This is one reason for the wide range of fitting difficulties which developed when the patterns were used. Dresses of unbleached muslin were then cut from each pattern and basted. Women whose bust measure corresponded to those of each pattern were used as models and the dresses fitted on them. The wrinkles and all ill-fitting portions were noted, the necessary changes made, and recorded.

Comparatively few dresses and blouses worn at the present time are correctly fitted in every detail. Very often there are wrinkles which are unnecessary and which detract from the beauty of the garment. The underarm seams may not be plumb or the shoulder line may not be in its correct place. In many cases the armhole is too large or it comes at the wrong place on the shoulder and so gives either a pinched or a drooping effect. Bulges in the armhole which were not removed before setting in the sleeve may be the cause of ugly wrinkles in the back or front of the dress at the armhole. The effect of even a well-fitting sleeve is spoiled by an incorrectly shaped armhole.

One precaution which will eliminate part of the trouble in fitting is to experiment with different makes of patterns until the one is found that fits best and needs the least altering. It is not always best to buy patterns according to bust measure. For example, if a woman has a large bust and comparatively narrow shoulders or if the person is slender but has broad shoulders in comparison to the size of the bust, it may be best to buy a pattern that fits the shoulders.

After buying the pattern it should be carefully checked with the measurements of the body, especially the width across the back, the distance around the upper arm, and the hip and bust measurements. Once a dress is cut too small at any part it is a difficult thing to remedy the mistake successfully. However, the alteration of the pattern to correspond with these measurements will not eliminate all fitting problems.

In cutting a garment it is imperative that the pattern be kept straight with the grain of the material according to the pattern markings. Lengthwise or crosswise folds of the material should always be exactly parallel or at right angles with the selvages. The temptation is sometimes great to swing the pattern even a half inch off center, especially in cutting sleeves in order not to piece a small corner, but this is fatal to the appearance of the finished garment and can not be remedied. Also another important point is that the edge of the pattern must be followed exactly when cutting out a garment. Most patterns allow for seams. If the edges are not cut straight, the garment when basted up is larger than intended in some places and smaller in others, and fitting becomes more difficult.

## Locating of Seams

After cutting and basting the garment it is ready to be fitted. All important seams should then be properly located. The neck and shoulder lines should be the first to be corrected. The neck line should form a good curve from the bone at the base of the neck in the back to just above the collar bone in front. The line should be high rather than low at the sides.

A properly placed shoulder seam acts as an anchor to a well-fitted garment. It should be a straight line from the highest point at the neck to one-half inch back of the highest point on the tip of the shoulder. This line should not be visible either from the front or the back when the garment is worn.

The underarm seam should be located directly under the high point of the shoulder and should appear to be a continuation of the shoulder seam. It should form a perpendicular line from the armpit to the floor.

The location of the armscye and the fitting of the set-in sleeve into the armscye are two very important steps in fitting a garment. The armhole when viewed from the front or the back should lie parallel to the center front and center back of the garment. It should pass over the tip or highest point of the shoulder. From the side it should show a good curve over the top of the shoulder.

A good set-in sleeve will allow sufficient distance from the top of the armhole to the underarm line to correspond with the distance between the tip of shoulder and the armpit. The set-in sleeve should have no fullness on the lower half of the armscye and seldom any gathering over the upper half. However, the sleeve edge always measures an inch or more longer than the edge of the armscye. This fullness is eased in by pushing the material in place with the thumb while basting and prevents uncomfortable and unsightly strain across the arm.

In order that the fitting process need not be repeated on every garment, a guide or foundation pattern should be made of firm unbleached muslin, gingham, or cambric of good quality. A simple dress pattern with a normal shoulder seam, high neck line, and set-in sleeves is the best type of pattern to use for this model. Almost any style of dress can be designed from it, and much time will be saved if it has been correctly fitted to the figure.

Maude Campbell.

## GRADING Animals and Meat to Show Quality

What are the factors which make one piece of beef tender and another tough; one very juicy and another very dry; one pleasingly flavored and another tasteless and unsavory?

The livestock producer, the packer, the retailer, and especially the meat consumer are vitally interested in the answer to these questions. The consumer and retailer want to know how to tell the difference between a tough and a tender piece of meat before it is cooked, and the packer and producer want to know the characteristics in the live animal that will tell them the kind of beef that is under the hide.

The producer and packer have known in a general way that the blocky, thick-muscled, smoothly-finished steers, ranging in age between 1 and 3 years, usually produce the highest grade of beef. Meat dealers, both wholesalers and retailers, have learned that thick, blocky carcasses carrying a thick, even distribution of firm, creamy-white fat over the body; bright cherry-red color of well-marbled lean; and pinkish-white bones are likely to give greatest satisfaction when the meat gets on the consumer's plate. But the majority of consumers have not been able to distinguish the choice or prime from medium or common grade meat until the meat, already purchased and cooked, is eaten.

It has been rather well established that fat is one of the factors largely responsible for high quality in meat, but unfortunately the public often discriminates against it, in many instances for economic reasons.

The factors responsible for tenderness or lack of tenderness of fiber, the cherry or dark-red color of the lean, the white or yellow color and even or patchy distribution of fat, and the high flavor and juiciness of the meat or the lack of those characteristics seem to lie deeper and have not yet been fully determined. Doubtless there are many other factors which influence the quality and palatability of meat.

### Investigations Under Way

To segregate these various factors and trace them back to ultimate causes in the live animal, its breeding and feeding, is a problem to which much attention is now being given by the Department of Agriculture and a large number of State agricultural colleges and experiment stations in cooperation with the National Livestock and Meat Board. During the latter part of 1925 a project having for its object the determination of the factors which make quality and palatability in meat was begun and continued throughout 1926.

The cattle used for the study are those in cattle-feeding experiments at the various State and Government experiment stations.

The cattle are graded when they are placed on feed, after they are finished and ready for slaughter, and finally in the carcass after slaughter. The grading committee of three consists of one from the State experiment stations, one from the Bureau of Animal Industry, and one from the Bureau of Agricultural Economics. A score card is used each time an animal is graded, so that each man makes a word picture of the way the animal appears to him from the standpoint of grade. In a few instances photographs have been taken at the time of grading. By grading at the beginning and end of the feeding period it is possible to note differences that take place in the outward appearance of the animal during the fattening process.

By such methods it is hoped to discover the characteristics in the feeder which under certain fixed feeding conditions will produce certain results, thereby enabling the producer to select more accurately the kind of animals he desires and know more definitely, in advance, the grade of beef he can produce.

The purpose of grading the carcasses after the cattle have been slaughtered is to determine the correlation between the various characteristics of the live animal and its carcass and to work out cause and effect relationships. Such grading also serves as a means of tracing the results of histological, chemical, and cooking tests back to the live animal.

### Rib Cuts Sent to Washington

After the carcass grading, a good representative from each lot of animals receiving the same ration is selected for further study. A portion of the wholesale rib cut of this animal is sent to Washington, D. C., for physical and chemical examination and for cooking and palatability tests.

During the feeding season of 1925–26 about 900 animals were graded, and a still larger number were graded during the fall of 1926.

Cooking, chemical, and physical tests were made with more than 100 samples.

It is too early to draw positive conclusions but much is expected because of the combination of forces working on the problem. It is confidently expected that within a reasonable time we will know definitely what makes the T-bone steak tender or tough.

L. B. Burk.

### GRAIN-Dust Explosions Cause Big Farm Loss

We are coming more and more to realize the need for the adoption of precautionary measures against dust explosions. Explosions in large industrial plants are particularly spectacular because of the heavy loss of life and extensive property damage, but the smaller explosions, far greater in number, represent an enormous loss in life and property.

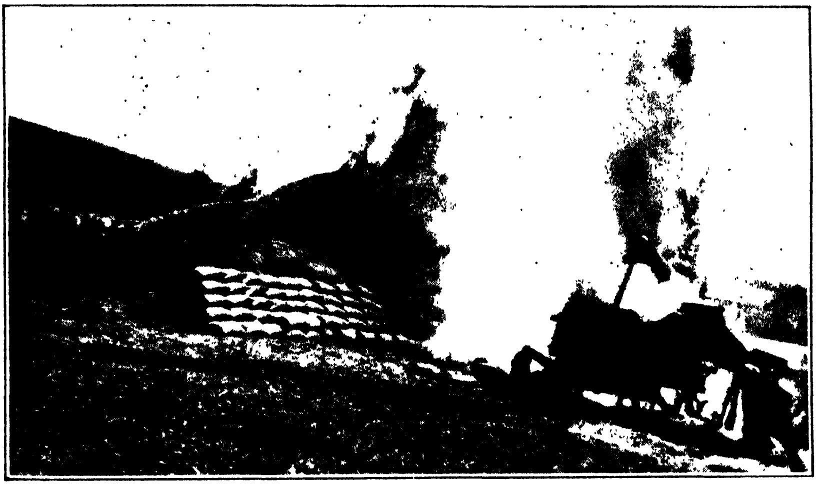

Fig. 107.—Dust explosion in a grain-threshing machine in eastern Washington. These explosions and fires have caused extensive losses to grain and machinery

Investigations by the Bureau of Chemistry have shown that practically all of the grain dusts are explosive when scattered as a cloud in the air and that the explosion hazard is present from the time the grain is cut in the field until it leaves the export terminal elevators. Many explosions have occurred during threshing, both in fields and in barns, in the small country elevators to which farmers deliver their grain, in the large elevators where grain is stored, and in the mills and industrial plants where grain is milled into flour, manufactured into starch, ground into feed, or made into any of the numerous cereal products now on the market. All that is necessary to produce an explosion is to have a cloud of the finely-pulverized product in suspension in air ignited by a spark, flame, or heated surface. A spark of static electricity is sufficient to ignite the dust cloud. A hot bearing on machinery can start a fire which may cause a dust explosion.

Dust explosions and fires in grain-threshing machines have been most frequent in the wheat-growing territory of eastern Washington (fig. 107), northern Idaho, and northeastern Oregon, although they have been reported from many other sections of the country. As a rule these explosions occur in dry sections or in places where the humidity is low. In the Northwest the explosions usually begin with the opening of the threshing season in July and continue until the middle of September. Here the explosion hazard is increased by the presence of wheat smut. When the smut balls are broken during threshing, the light, fine dust produced floats in the air to form a highly explosive mixture. Before the development of methods of preventing such explosions the losses in the Northwest alone were very high, being estimated at $1,000,000 during 1914 and 1915. In many cases not only was the machine destroyed (fig. 108), but the fire spread to the straw stack, the sacked grain, and the grain standing in the field. Even since the development of equipment to prevent such explosions and fires it has been estimated that the preventable losses in this part of the country amount to from $15,000 to $75,000 each season.

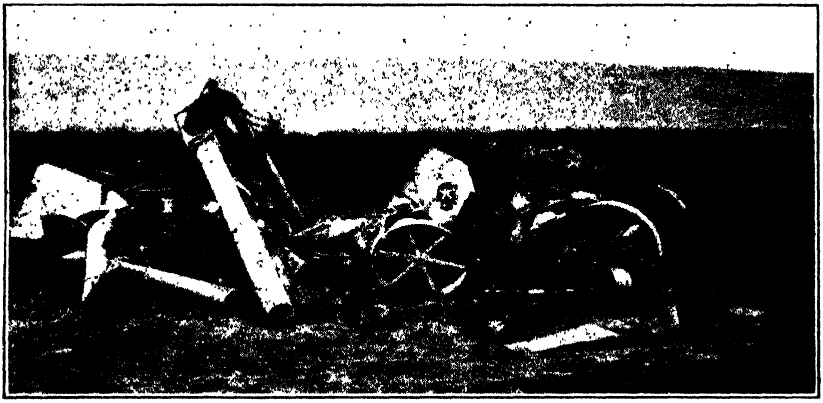

FIG. 108.—All that remained of a threshing machine following a dust explosion and fire

### Devices for Threshing Machines

To prevent dust explosions of any kind it is necessary either to eliminate the dust cloud or the source of ignition or to change the atmospheric conditions in such a way that combustion can not occur. In the case of threshing machines the problem has been attacked in several ways.

Fans have been designed to collect the dust formed in the interior of threshing machines and thus prevent the formation of explosive mixtures. These fans are light and relatively inexpensive and require little power for their operation.. They are usually installed on the deck of the machine. (Fig. 109.) Besides reducing the explosion hazard, they help to clean the grain, thus improving its grade and also prevent the dissemination of smut spores, which are likely to infect the ground and attack the next year's crop.

Investigations in the field indicated that a large proportion of the explosions occurred when dust clouds in or about the machine were ignited by sparks of static electricity produced by the friction of moving parts of the machine. Tests showed that heavy charges of static electricity were present on many of the machines—in some cases the measurements showed more than 50,000 volts. To remove these charges a system of wiring was devised in which the various parts of the machine were connected by wires with a main wire or cable that was thoroughly grounded by being attached to an iron rod driven into the earth. So long as positive contacts were maintained between the ground wire and the various parts of the machine this method proved effective in reducing the hazard of explosions due to the ignition of dust by sparks of static electricity.

To provide protection against loss from fires starting in threshing machines a chemical fire extinguisher was designed. This equipment consists of a cylindrical steel tank connected with pipe lines leading to different parts of the machine. The extinguishing liquid is held in the tank until it is released through the pipe lines by the opening of a valve. The valve can be opened by hand or automatically operated by the heat from a fire in the machine. The extinguisher is mounted on the deck of the machine. After the harvest season it may be taken down and used for general fire protection about the farm.

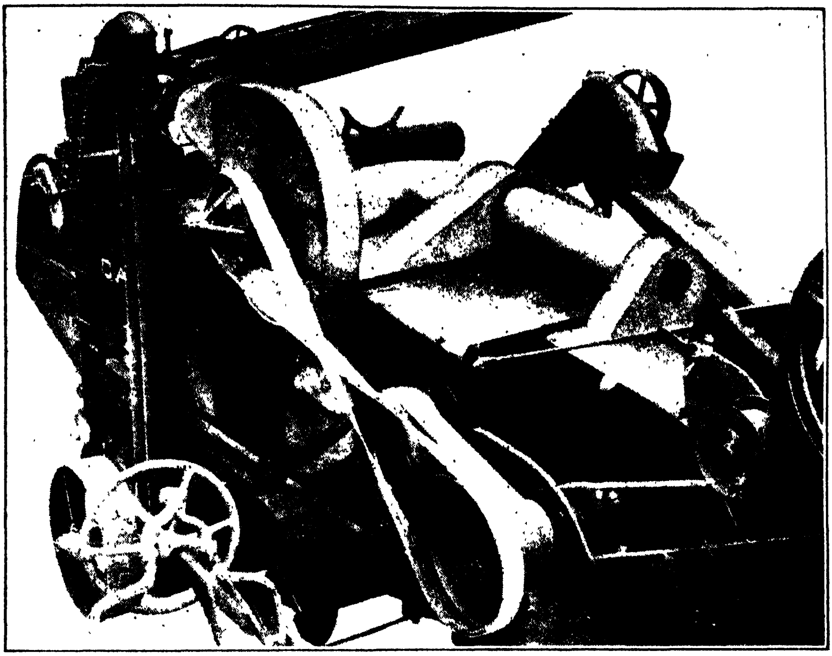

FIG. 109.—A threshing machine equipped with a dust-collecting fan

## Hazards in Elevators

The interest of the farmer is not confined to dust-explosion prevention on the farm. He is interested also in the work being done to reduce the explosion hazard in the elevators or warehouses where his grain is stored. Perhaps he has a share in a cooperatively operated elevator. Perhaps he has suffered a loss on grain which he has stored in an elevator without protection against damage from dust explosions. Again, the destruction by a dust explosion and fire of an elevator in his territory may mean a longer haul to get his grain to market or even make it impossible for him to market his grain when he wishes. For all these reasons the farmer, as well as the grain producer, the elevator operator, and the miller, or user of grain and cereal products, has a vital interest in the work of the Bureau of Chemistry on the cause of dust explosions and the development of methods of preventing them.

**GREAT Plains Agricultural Development** The agricultural development of the Great Plains has been an important economic problem for 50 years. The United States Department of Agriculture and the State experiment stations of 10 States have been conducting extensive coordinated investigations of this subject for the past 20 years. Much information has been obtained, and many publications have been issued, but many important problems still remain unsolved. Miscellaneous Circular No. 81, "The Relations between Crop Yields and Annual Precipitation in the Great Plains Area," seems to present some of these problems in a new light, and to indicate methods for their solution. These facts and suggestions, supplemented by 45 years of experience and observation, may be summarized briefly as follows:

The disastrous experiences of hundreds of thousands of settlers in the Great Plains during the last 50 years have been due largely to (1) lack of experience with the soils, the climate, and the adaptation of crops in this region; (2) the absence of an economic justification for the bringing into agricultural production of large areas of raw prairie; (3) the adoption of a one-crop system of grain farming and the failure to develop the livestock industry in connection with grain production.

The premature development of political, social, mercantile, financial, and transportation organizations, that could have no permanent support except agriculture, in advance of the agricultural development of the region, has been another serious handicap to the early settlers in the Great Plains. These desirable but none the less exploitational organizations were supported in the earlier stages of the influx of settlers into this undeveloped region by issuing bonds and by the funds brought in by the settlers. The next source of revenue for their support was the money obtained from farm-loan companies. Much of the land was preempted by adventurers who mortgaged their land for all the money they could get from the loan companies. Many of these preempters made no effort to bring their land into agricultural production, but the money they borrowed went into circulation and helped to support the parasites. When these mortgages came due, they usually were foreclosed. The mortgagor seldom received any returns from the foreclosure, the money being absorbed by the land agents.

### Speculation Became Rife

The title to the foreclosed land also fell into the hands of land speculators. Thus began, in the early eighties, the most gigantic organization of farm-land speculation that this country has ever experienced. Practically every individual over many thousands of square miles was interested, directly or indirectly, in the sale of farm land at the highest price obtainable. The slogan, "If you can't boost, don't knock" became a sentiment that was almost religious in its fanaticism, and was supported by powerful financial and political organizations. Inflation of land prices in utter disregard of the revenue-producing capacity of the land or the economic laws governing the increase in agricultural production was inevitable.

Such were the conditions in 1905 when the dry-land agricultural investigations were established in the Department of Agriculture. At that time the State experiment stations of the 10 States lying wholly or in part within the Great Plains had done but little investigational work in dry-land agriculture, and there was no coordination of the work of the several stations with each other. Charlatans of all descriptions, employed by land-selling agencies, were traveling over the country, each claiming to have discovered some new system that was to revolutionize the agriculture of semiarid regions, and to make possible the profitable production of crops where repeated efforts to do so had previously failed. Land exploitation was well organized by shrewd, capable, and unscrupulous men. The comparatively few legitimate farmers who still remained in the Great Plains with a fixed determination to develop permanent homes and a stable agriculture, eventually found themselves handicapped by inflated land prices, high taxes, and low prices for their products, and much misinformation as to farming methods.

The dry-land agriculture investigations of the department began in 1905, in a small way, by first enlisting the informal cooperation of the State experiment stations throughout the Great Plains. In 1915, 24 field stations had been established in this region. Owing to lack of funds, this number has since been reduced to 19, which are now in operation. The results from 23 stations, for an aggregate period of 303 crop years, have been used as a basis for the publication already mentioned. From a careful study of these data the following facts are deduced:

### Soils Are Very Fertile

It is now known that a major portion of the soils of the Great Plains are of great fertility and well adapted to the growth of staple crops, and that the rough, broken sandy and stony lands are so interspersed amongst the tillable lands as to make them available for pasture for livestock. It is also known that the mean climatic conditions of the entire area are such as to make possible the development of successful agriculture throughout this vast region of over 450,000 square miles.

It should be constantly borne in mind, however, that soil and climate do not alone insure a profitable agriculture in this or in any other region. Next in importance to soil and climate is the assurance of a permanent market at profitable prices for the crops that are raised. This is an economic factor over which the individual farmer has no control, except in so far as it is affected by the kind and quality of the crops produced, and possibly by the local marketing facilities. Closely associated with this, is a knowledge of the adaptation of crops to the local environment in relation to both the production and the sale of crops. The relations to each other of the crops grown in rotations also must be given thoughtful consideration. Of no less importance is the selection of the livestock to consume the roughage and the coarse grain produced, and to provide motive power. All of the above-mentioned factors may be grouped under the general designation of farm organization. Next comes the selection of the necessary implements for tillage, seeding, harvesting, and handling the crops grown under the conditions, and in the relations to each other in which they are grown. The extent to which the tractor, the motor truck, and the combine harvester are to be used will be important factors in the selection. The general character of the soil and the topography of the farm should be considered in this connection.

### Problem of Implement Use

Having adopted a system of farm organization and selected the implements, the problem of how to use these implements in the most economical manner—how to accomplish a given purpose with the least possible expenditure of energy and money—presents itself. This is, perhaps, the most difficult group of problems to meet, for they are constantly changing and there is no solution of any of them that will be the same under constantly changing conditions. When and how deep to plow; when and how to summer fallow, and when to grow a cultivated crop in the rotation between crops of small grains; when to use the self-binder, when the header, and when the combine harvester, and scores of other problems of like nature must be met and solved on very short notice and in connection with combinations of conditions prevailing at that particular moment on that particular farm or field. Only long practical experience in that particular locality can fit a man to successfully cope with such problems.

In the eastern United States, where the land was originally heavily timbered, it usually required about three generations—a hundred years—to clear a farm of from 100 to 200 acres and bring it into full production. During all that time there was accumulating the results of practical experience on each particular farm. It is doubtful whether any member of the third or fourth generation that has grown up on such a farm ever fully realized that the traditions that he inherited were the most valuable part of his estate. It is still less probable that any owner of a virgin farm in the Great Plains could be convinced that it will take about a hundred years before he can reasonably expect his farm to arrive at full production through cumulative practical experience; but there are elements of probability in both these statements worthy of careful consideration by those who are interested in the agricultural development of the Great Plains.

The problem of the adequate capitalization of a farm in the Great Plains has been left until the last, when perhaps it should have been the first to be considered. There is a very general opinion that a man with small capital has a better chance of success in agriculture in the newer than in the older settled portions of the United States. Experience, observation, and investigation make this assumption appear of doubtful validity. It is true that raw land costs less per acre in some parts of the Great Plains than improved farms in some parts of the eastern United States, but it is also true that the economic farm unit in the West is probably twice the size of that in the East. It is also true that all kinds of farm improvements cost more in the West than in the East. In fact, there are many farms for sale in the East at a price that would not cover the cost of the improvements now upon them, at present cost of material and labor. Freight rates, on both what a farmer sells and what he buys, are higher in the West than in the East. Farm labor is higher in the West than in the East, except near large cities.

### Average Wheat Yields Large

Investigations show that, on an average, through a long term of years, larger yields of wheat per acre can be obtained in the northern Great Plains than the average for the wheat-growing States of the whole United States. In the southern Great Plains, the sorghums largely take the place of wheat and corn in the Northern and Eastern States. The opportunity for a direct comparison of crop yields are, therefore, not as good in the southern as in the northern Plains, but the evidence at hand indicates that there is little difference in the general crop-producing capacity of these two regions of the Great Plains, and that they both compare favorably with other portions of the United States. There is, however, this difference. In the Eastern States a complete failure of all crops is almost unknown, whereas in the Great Plains such failures are common, and in only about two years out of three are the yields sufficient to yield a profit. This makes it necessary for the farmer in the Great Plains to have sufficient working capital to tide him over these lean years.

On the other hand, investigations show that the average yields in the northern Great Plains, measured in terms of bushels of wheat per acre, are 16 bushels. If, however, the inhibiting factors other than deficient annual precipitation could be reduced to the same extent on the average throughout the entire period that they have been in some instances these average yields would be over 30 bushels per acre. It is a fact that some of these inhibiting factors, such as hailstorms, hot winds, and extreme drought at critical periods in the development of the crop, are entirely beyond the control of man. There are, nevertheless, many other factors, such as the loss of moisture from weed growth, faulty systems of tillage and crop sequence, poor seed, plant diseases, and insect pests that are more or less under man's control.

It therefore seems reasonable to expect that the average crop yields of the Great Plains may in time be increased by better farming practices from the equivalent of 16 bushels of wheat per acre to 20 bushels, or an increase of 25 per cent. When this time comes, and there is a real economic demand for increased agricultural production in the United States at prices that will yield the farmers fair profits on their investments of money, labor, and managerial ability, the Great Plains will become one of the greatest food-producing regions of the world. In the meantime, the agriculture of the Great Plains should be allowed to develop naturally without artificial stimulation, and investigators and practical farmers now established in that region should continue to add as rapidly as possible to the store of agricultural knowledge that is absolutely essential to the ultimate development of the undeveloped agricultural resources of the Great Plains.

E. C. CHILCOTT.

## HAY Standards and Inspection System

Hay marketing is a comparatively simple business procedure when the seller and the buyer are together to barter and negotiate the transaction. The seller quotes his price, the buyer can examine the hay and use his own judgment as to its quality and condition for his purposes, and controversies are either settled then or the sale is not made.

If all hay marketing could be conducted under these simple conditions the hay producers, dealers, and consumers in the United States would have little need for hay standards. But, as a matter of fact, only a small percentage of the carlot shipments ever move directly from the producer to the distant consumer. The vast majority of all shipments pass through at least two middlemen. Many shipments pass through four or five middlemen before they reach the consumer.

### Hay Moved Long Distances

In spite of freight rates on hay that are much higher than those which prevailed before the World War period, baled hay is hauled hundreds, even thousands of miles by the railroads of the United States. It is a farm-management truism that farmers and stock feeders should produce their own hay wherever possible in order to eliminate the freight and handling costs incidental to the purchase of baled hay; but specialized American agriculture and climatic limitations often provide exceptions.

The Cotton Belt States, for example, prefer to utilize their best lands in large measure for cotton and their soils and climates are not widely favorable to hay production. Thus these States purchase thousands of carloads of timothy, clover, and alfalfa from Michigan, Ohio, New York, Indiana, Kansas, Nebraska, Oklahoma, Arizona, New Mexico, and the Province of Quebec in Canada. Similarly thousands of car and truck loads of alfalfa move from Arizona, New Mexico, and the Imperial and San Joaquin Valleys of California into the thickly settled areas of southern California where land is too valuable for hay production. Baled hay is transported by water routes in considerable volume from the Sacramento Valley of California to the Atlantic seaboard, from San Francisco and Seattle to Alaska, Mexico, Hawaii, the Philippines, and the Panama Canal Zone, and from New York City and Norfolk to Cuba, Porto Rico, and the Panama Canal Zone.

### Contract is Essential

In this hay commerce where the producer and consumer are widely separated and where country shippers, dealers, brokers, distributors, bankers, and carriers function in the marketing process, the use of the contract becomes essential to evidence the quantity, quality, and value of the commodity that is involved in any given transaction.

Contract specifications for quantity and value are relatively easy to make definite and precise for the benefit of the parties to a hay contract, but specifications for quality are more difficult and complex. If the quality specifications of a hay contract are indefinite, loosely drawn, and based largely on personal opinion, the contract is questionable and of little value. On the other hand, a contract containing definite quality, quantity, and value specifications is of distinct value in all hay commerce.

Quality specifications may be written into a hay contract by means of descriptive terms or standards. The use of descriptive terms is not universally satisfactory. Orders and confirmations based on such descriptive terms as "good feeding timothy" or "pea green leafy alfalfa" are impossible of definite interpretation and the opinion of the buyer may differ radically from that of the seller, thus causing rejections, demands for discounts, diversions, demurrage, telegraphic expense, occasional lawsuits, and general dissatisfaction. Hay standards, on the other hand, which provide a definite basis for the quality specifications in a contract, are of material assistance to all parties to the transaction, and can be definitely interpreted by disinterested experts in case of disputes and claims.

The value of standards in the business of marketing hay is in direct proportion to their soundness, adaptability to many kinds of hay, and to the confidence of the public in the standards. Local hay standards, irrespective of their soundness, are of little value in interstate commerce, and standards formulated by either shippers' or dealers' organizations can not well enjoy the full confidence of all parties engaged in the business.

Standards have been formulated and promulgated by the United States Department of Agriculture as the official hay standards of the United States which meet the needs of hay marketing. They include standards for timothy and clover hay, alfalfa and alfalfa mixed hay, prairie hay, Johnson and Johnson mixed hay, grass hay, and mixed hay. They provide a common language for producers, dealers, and consumers to employ in the marketing of hay as well as definite quality specifications that will constitute a basis of contract. Wherever United States hay standards are employed they provide the foundation for a market news service that gives producers, dealers, and consumers more accurate information about the money value of various kinds and grades of hay than it is possible to obtain where sales are made on sample, description, or local grades. This is a matter of exceptional importance in hay marketing and in great need of improvement.

### Value of Standards

Hay standards are of inestimable value to producers, shippers' organizations, and cooperative marketing associations in the development of direct marketing, because properly graded hay establishes confidence among consumers and creates premiums for high quality. The consistent shipping of hay out of any community on the basis of official United States standards advertises the community product, gives it a national brand of quality, establishes confidence, and eventually develops wider and more profitable markets than when hay is sold by description or local grades.

Shippers in Wisconsin, Alabama, Nebraska, Kansas, and Wyoming are now making use of United States standards and inspection in the development of direct marketing from the producing communities to the consuming communities, and they are finding a big and profitable field into which they can extend their operations. Thousands of dairymen, stock feeders, and purchasing agents for lumber camps, road contractors, etc., constitute a group of consumers that is greatly desirous of purchasing car lots of graded and uniformly loaded hay direct from the producing communities.

To the consumer it may be said that ordering hay on the basis of United States standards and demanding confirmations on the same basis, together with a Federal hay-inspection certificate to evidence the contract specifications, will insure the delivery of the kind and quality of hay wanted. Experience with United States hay standards in such consuming markets as Chicago, Denver, and Fort Worth has shown that the use of recognized standards and disinterested inspection has been of value in assisting the consumer to purchase the kinds and grades of hay wanted and in eliminating many controversies with shippers. Inspection at receiving markets is proving a strong educational force, also, in educating shippers to load cars uniformly and with those classes and grades of hay in greatest demand and for which the highest prices are paid.

The Department of Agriculture maintains a hay-inspection service in numerous markets and at numerous shipping points in cooperation with commercial exchanges and State departments of agriculture. This service is constantly increasing as shippers and consumers become aware of its value in the marketing of hay. The service provides original inspections, secondary inspections to show a change in condition, and appeal inspections on grades in dispute. Such inspections are disinterested and are made by licensed men who have been given thorough training and whose work is supervised by Department of Agriculture supervisors located at Washington, D. C., Chicago, Atlanta, Kansas City, Salt Lake City, and San Francisco.

EDWARD C. PARKER.

## HIGHWAYS and How They Are Paid For

On January 1, 1926, there were 3,001,825 miles of public rural roads in the United States. Of this large mileage, about one-eleventh, or 270,653 miles, were classed as State highways and the remaining 2,731,172 miles were county and local roads. The smaller mileage has been set apart for improvement under the supervision of the State highway departments, and the larger balance is for the most part under the jurisdiction of county, township, and other local authorities.

At the same time, New Year's Day, 1926, there were 145,509 miles of the State highways, or 54 per cent of the total, that had been improved with some form of surface, varying from the inexpensive sand-clay and gravel surfaces to high-class and expensive pavements.

Classifying as higher types all surfaces better than water-bound macadam, and as lower types the macadam, gravel, sand-clay, and similar surfaces, the roads improved with the higher types of surfaces accounted for 44 per cent of the surfaced mileage, and those improved with lower types made up the remaining 56 per cent. In addition to these surfaced roads there were 32,219 miles of the State highways that had been improved by grading and drainage.

Turning to the county and local roads we find that there were 376,406 miles, or 14 per cent of the total that had been surfaced; and of this surfaced mileage 12 per cent had been improved with surfaces of the higher type and 88 per cent with those of lower type.

### State Highways Most Improved

It will be seen from these figures that the State highways are much more highly improved than the county and local roads; and this condition is entirely consistent with the usage of the two classes, as shown by traffic surveys made by the Department of Agriculture in a number of States. In Maine, for example, the survey showed that each mile of the State highway system was used by an average of 1,044 vehicles daily; and in comparison the State-aid or secondary highways were used by 244 vehicles, and the local or third-class highways by only 29 vehicles daily. As a similar condition has been shown to exist in each of the other States in which the department has made surveys, it is apparent that a higher degree of improvement of the State highways is fully justified by the greater/traffic which they serve.

But granting that the heavier traffic on the State highways requires a higher degree of road improvement, the reader, remembering that the mileage of local roads is 10 times as great as the total length of the State highway systems, may still want to know whether the expenditures for the two classes of roads are fairly proportioned to their total service.

This question can be satisfactorily answered. The total expenditure in 1925 for the construction and maintenance of State highways, exclusive of overhead and interest charges, etc., was $506,270,431. In the same year the expenditure for county roads was $461,539,280. The expenditure for State highways in 1925 was therefore approximately 52 per cent of the combined expenditures for State and county road construction and maintenance during the year.

### Traffic on State Roads

That this is a very reasonable relation is shown by the facts revealed by the department's traffic surveys. In Maine, for example, the survey shows that approximately 53 per cent of all highway traffic in the State moves over the State highway system which includes only 7 per cent of the total highway mileage. In Connecticut approximately 60 per cent of the total traffic is served by the State system which also includes approximately 7 per cent of the total highway mileage. In Pennsylvania the State highway system includes 11 per cent of the total mileage of highways and carries 68 per cent of the total traffic.

"Very well," says the farmer reader, "the money spent for the State roads seems to be pretty well justified, but how much do farmers use them?" The answer is definite and clear—very little. The traffic on the State highways is largely a traffic of city-owned vehicles. In the Maine and Pennsylvania traffic surveys only 5.4 per cent of the passenger cars observed on the State highways were farmer-owned. In Ohio the percentage was 12.4, and in a count of the traffic on the Bankhead Highway at the Georgia-South Carolina line the farmers' cars made up only 8.9 per cent of the total number. A similar situation is found with respect to the motor trucks.

Although the department's surveys do not indicate the relative use of the county and local roads by farmer-owned and city-owned vehicles, it is known that the former make up a very much larger percentage of the total traffic on the local roads than on the State highways. The probabilities are that the great majority of local roads are used almost exclusively by farmer-owned vehicles.

### How Farmer is Burdened

It is this difference in the usage of the State and the local roads that makes it unwise to spend county revenues on the State highways; for the county road funds are obtained largely by property taxes, and, as the farmer is a large property holder, he pays a large part of the tax. When, therefore, the county revenues are used for the building of the main State highways the farmer is paying for highway facilities which he uses to a very small extent, and whatever amount is so used is not available for the improvement of the local roads which are really the farmer's roads.

The wiser plan is to pay for the main State highways with motor vehicle and gasoline taxes and State-wide property taxes, all of which are paid by the residents of cities in fair proportion to their use of the main roads. The fact that most of the traffic on the main roads is not confined to county limits is another reason in support of this plan.

Considering the United States as a whole the expenditure of county revenues for State highways is not a very large part of the total State highway expenditure. In 1925, when the total of current revenues (not including bond issue receipts) for State highways was $523,022,549, the portion raised by the counties was $71,737,028, or 13.7 per cent. But the percentage thus provided has increased in recent years instead of decreasing as it should; and the average county contribution would be much higher were it not for the fact that a number of the States, recognizing the responsibility of the State to provide for the main roads have practically or completely released the counties from the burden of contributing. There are still a number of States in which the counties supply upwards of 20 per cent of the current revenue required for the building of State highways and one in which the county contribution is more than 40 per cent of the total. Such county contributions are excessive in view of the small proportion of local usage of the main highways. Their effect is to place an unfair burden upon agriculture by excessive land taxation, and they should be greatly reduced, if not entirely discontinued.

The total funds available for State road purposes in 1925 amounted to $780,081,292. Of this amount $115,656,721 was carried over from the preceding year and the funds raised during the year amounted to $664,424,571. Twenty-one per cent of these current funds were obtained from the sale of bonds and other State securities, 14 per cent was received as Federal aid from the National Government, and nearly 11 per cent was contributed by the counties. The balance of $359,105,115, about 54 per cent of the total current funds, was raised by State taxation.

Of the portion of the State highway funds raised by State taxation in 1925, more than 80 per cent was supplied by motor vehicle license fees and gasoline taxes, amounting in the aggregate to $289,173,503. The balance of $69,931,612, or nearly 20 per cent, was raised directly or indirectly by State property taxes.

### Gasoline and Vehicle Taxes

Since 1921 there has been a great increase in the portion of the State highway tax revenue raised by motor vehicle and gasoline taxes and a considerable decrease in the funds secured by property taxation. In that year the two forms of taxes paid by road users made up only 55 per cent of the current tax revenues, and property was taxed more or less directly for the remaining 45 per cent. In view of the direct benefit of these main roads to the road users of the State as a whole this tendency toward the relief of property taxation is a very desirable reform.

Contrasted with the methods of financing the State road improvements, the methods employed by the counties depend to a much greater extent upon property taxation and to a lesser degree upon vehicle and gasoline taxes. This is entirely consistent with the greater service rendered by the local roads to agriculture and the lesser service to motor vehicle owners as a class.

### County and Local Road Funds

The total funds available for county and local road improvement and maintenance in 1925 were $780,912,729, of which $97,895,087 were carried over from the previous year. The current funds, therefore, amounted to $683,017,642. Of this amount 21 per cent was obtained by the sale of county bonds and other securities, from which it appears that the States and counties were carrying about the same portion of their improvement program with borrowed money.

Of the remaining current funds of the counties, nearly 6 per cent were received from the State governments as aid; 13 per cent were raised by motor vehicle and gasoline taxation; and the balance of 81 per cent was raised more or less directly by property taxation.

H. S. Fairbank.

**HOG-Cholera Control Calls for More Immunization** Of all the diseases of swine, hog cholera is by far the most serious, as it is so highly contagious and destructive. Farmers of every State have more or less knowledge concerning it, since there are few, if any, hog-raising communities that this plague has not visited at some time or other since its first appearance in the United States in 1833. To understand present problems of hog-cholera control, a brief review of past events concerning the disease is desirable. Following its appearance hog cholera spread rapidly, considering the scant hog population at that time, and by 1875 was causing a loss of about $21,000,000 annually. In some sections swine raising was practically destroyed through recurring outbreaks and the high mortality in the affected herds. Numerous remedies were advocated and tried but they proved ineffective, though the value of quarantine and disinfection became recognized as a means of keeping the disease from spreading.

The discouraged swine breeders were not disposed to continue under the prevailing conditions and appealed to the Federal Government for assistance. In response Congress, in 1878, made it possible for the Department of Agriculture to undertake a study of this disease. An important epoch in these investigations was the discovery, in 1903, of the true cause of hog cholera. This important discovery led to the development in 1905 of the immunization treatment. From 1908 to 1913 there was a growing demand for the new treatment. But in the absence of restrictions or supervision over the production of serum and virus, impotent and contaminated products appeared on the market during those five years. This condition, together with faulty technic and the inability of some veterinary practitioners to make proper diagnoses of swine diseases, produced disappointing results in so many instances that the immunization treatment did not grow in popularity as was expected and as it deserved.

FIG. 110.—Typical appearance of pigs affected with hog cholera. A rough coat, lack of appetite, and watery eyes are among the most noticeable symptoms

As a consequence hog cholera continued to spread, and the losses were increasing yearly. The swine industry faced these conditions in 1912, the year that marked the most extensive and destructive outbreak of hog cholera in the history of the disease in this country. The situation was so grave that it became a matter of consideration by the department and by Congress.

The next step taken was the passage of the virus-serum-toxin act of March 4, 1913, which placed establishments producing serum and virus under the supervision of the Department of Agriculture. Simultaneously an appropriation was made by Congress to enable the Bureau of Animal Industry of this department to conduct hog-cholera work in restricted areas in cooperation with several States. The principal objects were to study serum-virus immunization under field conditions and to establish, or rather reestablish, confidence in the treatment. This was the beginning of our hog-cholera field work, which now is conducted in cooperation with State regulatory authorities, State extension forces, veterinary practitioners, and swine growers in 32 States. The funds for field work for the current fiscal year are sufficient to enable the department to maintain 37 veterinarians in the field.

### Work of Bureau Veterinarians

In Northern States, where local veterinary service is readily available to administer the treatment, the bureau veterinarians confine their activities to investigational, supervisory, and advisory lines in controlling outbreaks. In sections of the South, where local veterinary service is not available, they administer the treatment, and in some States where the laws permit it, they train a few reliable laymen to apply the preventive treatment.

In the period from 1913 to the current fiscal year swine mortality from cholera has been reduced from 130 hogs per thousand to approximately 30 per thousand.

Notwithstanding the savings brought about through the development and use of the immunization treatment, the disease is still causing much greater losses than need prevail—the monetary loss is still about $20,000,000 annually. Many farmers are slow in adopting improved methods of swine husbandry and some refuse to have their herds immunized because they are skeptical concerning the treatment. Others delay until heavy losses are inevitable, since serum is primarily a preventive and not a cure. This skepticism and delay result in maintaining centers of infection and the consequent reappearance of the disease.

### Disease More Prevalent

Reports from the field indicate that the disease is more prevalent in some States than it has been in any year since 1912. Owing to the decrease in cholera during the last five years many farmers ceased to keep their herds immune, with the result that most of the hogs in the country are susceptible. During the two years ended June 30, 1926, only 21,000,000 doses of serum were produced as compared with 44,000,000 during 1923 and 1924. This indicates a reason for the unusual prevalence of the disease during the fall of 1926. The condition has been especially serious because serum producers soon exhausted their reserves and for a time were unable to meet the demands. The nature of serum production is such that it can not be hastened to meet emergencies. Ordinarily about 55 days are required to produce and test a quantity of the product ready for marketing.

From time to time so-called "breaks"—meaning symptoms of cholera among treated hogs—are reported in herds that have been immunized, but the proportion is small compared with the number treated. No doubt some breaks are due to a loss of potency in the virus, or possibly the serum used, but experience shows that breaks are most liable to occur in hogs heavily infested with internal parasites or those affected with intestinal inflammation or other disease at the time of treatment, which lowers their vitality and resistance.

Generally it is not economical to use either serum or virus sparingly. The condition of the animal as well as its weight should be considered in determining the dose. Many successful practitioners administer, regularly, larger doses than are prescribed on the labels affixed to the bottles, especially if the herd is not in a perfectly healthy condition. When properly administered to hogs which are in fit condition and which receive proper care, the results of the immunization treatment against hog cholera compare very favorably with the results obtained from the use of other biological products in either human or veterinary medicine.

FIG. 111.—Giving the preventive serum treatment. Swine owners need have no serious fear of cholera if their hogs are properly immunized

### Stocker-Hog Business Based on Preventive Treatment

The stocker-hog business at the large public markets has grown beyond early expectations. A large number of pigs reach market when they are too thin to sell to advantage for slaughter. Formerly such animals were excluded from interstate trade for purposes other than slaughter owing to the danger of disseminating hog cholera. The perfection of the immunization treatment made it possible to prevent much of this economic loss, and regulations were issued which permitted the shipment of such pigs to country points after they had been immunized under the supervision of representatives of the department. The regulations required that the immunized pigs be held at the market for three weeks after receiving treatment. The expense involved was so heavy that comparatively few could be sold for farm distribution.

Later the regulations were modified to permit shipment promptly after immunization to States where the regulations provided for the quarantine of the animals for a period of not less than three weeks.

This gave an impetus to the stocker-hog business, but it was found that heavy losses occurred in many shipments. After careful investigation the conclusion was reached that if this enterprise was to be placed on a stable basis it would be necessary to take the temperatures of all pigs to be immunized at public stockyards and to withhold treatment from those showing marked elevations of temperature, also those which had been held in the yards for a considerable time. The regulations were modified accordingly, with the result that there has been a marked reduction in the losses. At present the immunization of swine at public stockyards is giving fairly satisfactory results. The average loss is estimated at 3 per cent. Since the work was begun, in 1922, there has been a fluctuation in demand depending upon conditions. During the fiscal year ended June 30, 1926, 425,995 hogs were immunized. This number was exceeded in 1924, when 509,567 received the treatment.

### Complete Eradication Desirable but Costly

It has been suggested that efforts should be made to eradicate hog cholera in the United States. While eradication is desirable, the general distribution and prevalence of the disease and the enormous expense make such a gigantic undertaking inadvisable, especially while large sums are being expended by the Federal and State Governments for the elimination of the southern-cattle tick and the eradication of bovine tuberculosis, dourine, and scabies of cattle and sheep.

The eradication of hog cholera would require the application of no less comprehensive and rigid measures than those adopted for the eradication of foot-and-mouth disease in this country, and our hog industry is in no condition to withstand such measures. Furthermore, we have an effectual, practical preventive treatment against hog cholera, which is not the case with tuberculosis and some of the other contagious diseases with which we are contending. Therefore, it seems advisable to continue present efforts to minimize losses through the proper use of the preventive treatment rather than to attempt the complete eradication of hog cholera.

U. G. Houck.

## HOG Cycles and Possibilities of Regulating Them

The hog industry in this country has been characterized by successive periods of overproduction and underproduction ever since it became an important commercial part of American agriculture. These fluctuations are illustrated in Figure 112, which shows the variations in the number of hogs slaughtered each year since the Federal inspection of slaughter was begun. The figures are shown for the 12 months from November to October, inclusive, which covers substantially all of the pigs farrowed during the previous calendar year.

These fluctuations in the supply of hogs have been accompanied by similar fluctuations in hog prices and are the major cause of the recurring periodic swings in prices.

This continuous variation in the number of hogs produced and marketed is due to two causes: (1) The erratic changes from year to year in the production and price of corn which result from variations in weather conditions and in the yield, and (2) the length of time which must elapse after farmers decide to make changes in their hog production until the time such changes begin to show up in increased or decreased receipts at the markets.

This latter element is due to the natural conditions which govern the production of hogs. If a farmer decided in the fall of one year, say 1925, that hogs had been unusually profitable, and increased the number of sows which he was breeding, that would result in a larger number of pigs farrowed the following spring, in 1926. These pigs would grow and be fattened through the summer and fall of that year, 1926, and not until the fall would they begin to move to market.

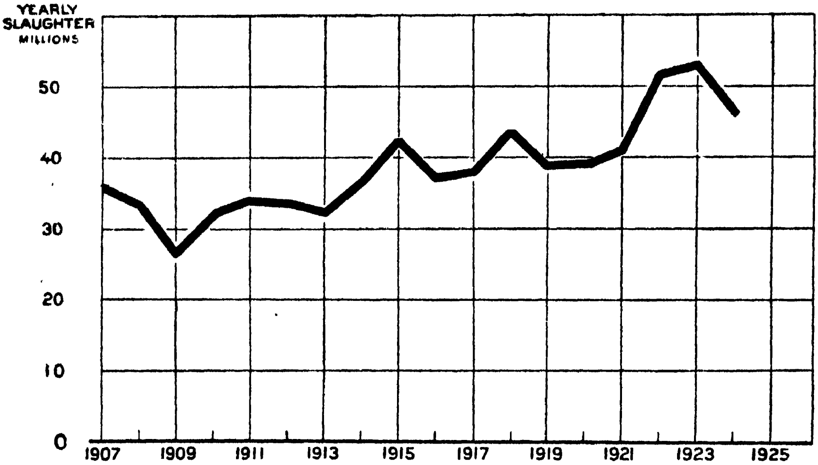

FIG. 112.—Annual slaughter of hogs under Federal inspection, November to October, inclusive, 1907–1924

### Effect Felt Later

There is thus a lapse of from 12 to 15 months or even more after the time that the farmer has decided to increase his production of hogs before the increased supplies begin to reach the market. Meanwhile, if hogs had been scarce and high in price in the fall of 1925, they would still be scarce and high in the fall of 1926, since the increased supplies would not yet have begun to affect the market. Consequently hog producers would be encouraged, by the high prices in the fall of 1926, to expand their hog production still further. By the time these hogs would reach the market in the late 1927 and in

1928, however, the successive increases would have resulted in an oversupply of hogs and the cycle would already be swinging the other way once more.

This tendency to first go too far in expanding production of hogs and then go too far in contracting their production has been the principal cause of those erratic variations in supply which have resulted in the hog-price cycle.

The persistence of this cycle may be shown most vividly by comparing hog prices with corn prices. The fairly regular changes in this relation are very marked. Except under the disturbed conditions of the World War period, the tendency for changes in hog supplies to follow changes in the relation of hog prices to corn prices is clearly marked.

The corn-hog cycle is thus seen to be the resultant of variations in the production of hogs owing largely to the way in which farmers respond to corn and hog prices. If farmers were willing to store corn over from years of large crops to years of small crops in sufficient quantity, it would be possible to produce a practically constant number of hogs each year, and to make up for the difference in corn crops by merely increasing or decreasing the volume of corn in storage. The general adoption of this plan, it is true, would entail considerable expense for storage facilities, some loss through the deterioration and wastage of the stored corn, and the employment of a considerable amount of capital to finance storing the corn.

### Partial Prevention Possible

On the other hand, the fluctuating production of hogs might be prevented to a limited extend if hog producers understood what was happening in the hog market and made only such changes in production as were necessary to keep production sufficient to use up the corn, without being led to make such great changes as they have made in the past in the hope that high prices could still be obtained when their increased supplies were ready for market.

One other way in which the hog cycle can be smoothed out to some extent is by feeding hogs to heavier weights when corn is plentiful compared to hogs, and feeding them to lighter weights when the reverse is true. Farmers have made much use of this practice in the past and it is possible that it has already been carried as far as it pays to go.

Considering the three possibilities, it seems probable that the hog-price cycle, or at least some variation in hog supplies resulting in variations in corn yields, will never entirely be done away with. With full appreciation of what is happening in the hog market and what is probably going to happen, producers should be able to reach such a balance between storing more or less corn, producing more or less hogs, and feeding them to a greater or less weight as would result in a much more stable production than has been true in past years. This, however, would probably not render production and prices entirely level and continuous. At just what point this adjustment would be reached would depend upon the expense and returns from storing corn, the effect on prices of a more constant production of hogs, and the changes in total returns to producers resulting from more stability in the numbers and weights of hogs.

Much publicity has been given to the hog cycle and its causes during recent years and it seems that now an increasing number of producers are intelligently controlling the number of hogs they produce. As more and more producers come to recognize the possibilities of increasing their own returns through better understanding of the hog market and better adaption of supply to the relatively constant demand, it is probable that this country's hog production will approach nearer and nearer the condition of ideal balance between corn crops, hog production, and hog weights suggested above.

MORDECAI EZEKIEL.

---

**HOG Price Changes Studied** Like other classes of livestock most hogs are sold through the great central livestock markets, and it is at these markets that the central wholesale price is determined. Although there are many of these markets they are in very close touch with each other by wire, telephone, and radio, and as a result the prices move very closely together at all markets, as is shown in Figure 113. This shows that in general the forces which determine the prices at one market are the same as determine the prices at another market, and the significance of the different elements in these forces may be stated in a general way for all markets.

The greatest cause of changes in hog prices in the past 10 years has been the changes in the value of the dollar. For example, in 1919, $1 would buy only about one-half as much as it would in 1913 and in 1926, $1 would buy only about two-thirds as much as in 1913.

In ordinary times the greatest changes in hog prices are caused by changes in the supply of hogs. In the past the market has got its idea of the supply of hogs principally from the actual receipts of hogs. In recent years, however, the Department of Agriculture has been making semiannual pig surveys, which give advance information as to how many hogs will come into market within the next few months. It now seems that the market is beginning to pay attention to these surveys as an advance estimate of supply.

### Daily Supply Only One Factor

With some products, like peaches or strawberries, the supply is so perishable that each day's supply must be disposed of almost as fast as received. For such products it is therefore largely the daily supply which sets the price. In the case of hogs, however, it takes several days or weeks to slaughter, pack, and distribute the products to the retail markets, while various fresh or cured products may be kept in cold storage for weeks or months. For that reason daily changes in supply do not have so great an influence on prices as do changes in the general supply over a considerable period. The number of hogs marketed during a period of a half year or so thus has more to do with the general level of prices during that period than does the supply during any shorter period such as a day or week. In general, an increase of 10 per cent in the quantity of hogs marketed

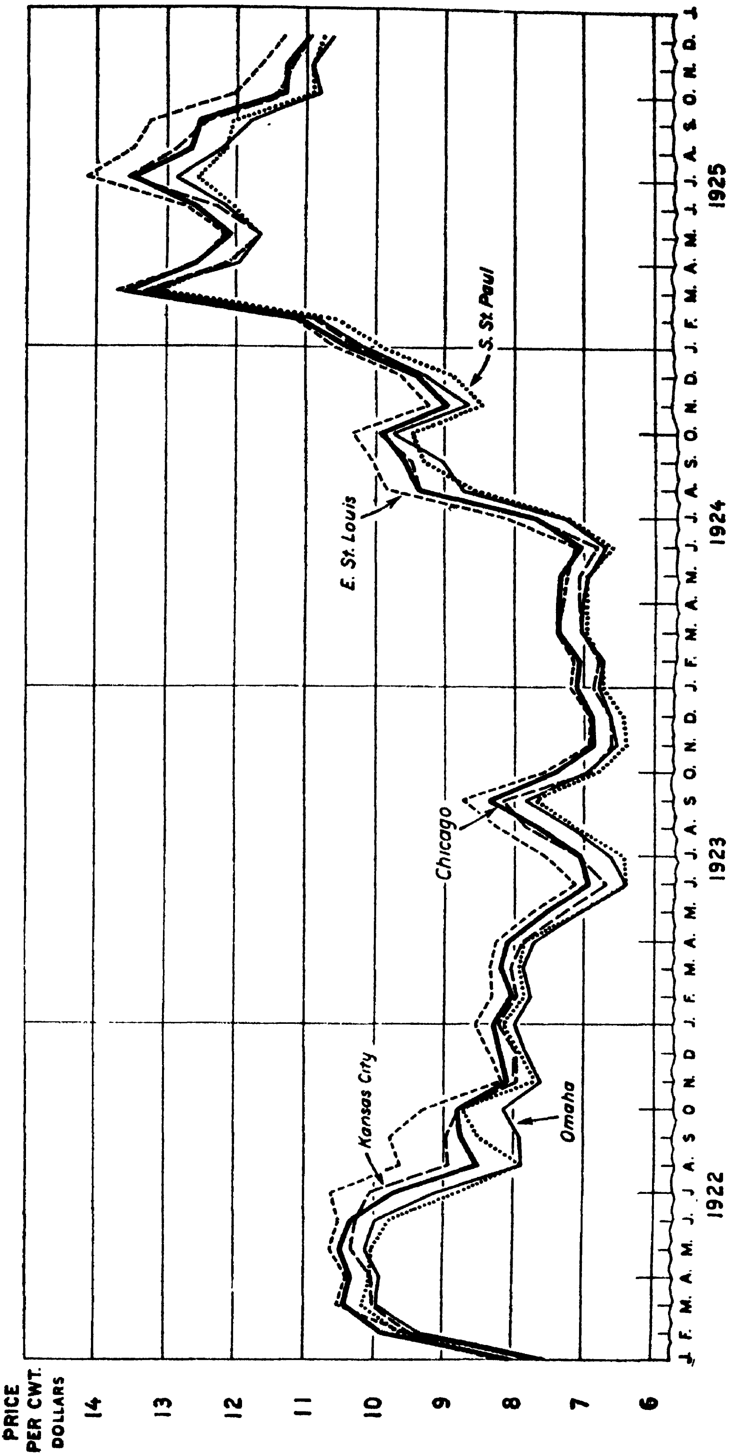

FIG. 113.—Monthly average prices of heavy hogs, medium to choice, at five markets

over a given period tends to reduce prices during that period about 6 per cent.

The demand for hogs depends upon a number of different factors. One of the most important of these is the supply of beef and other meat products which may be substituted for hog products and the prices of these other products. Another very important factor on the demand side is the strength of the demand from our foreign customers. The United Kingdom and Germany, in particular, take great quantities of pork products, especially lard. Changes in their demand for these products due to changes in their own supplies of hogs and the competition from other countries, and in the purchasing power of consumers in these countries, must be reckoned with as one of the most important forces in the hog market.

The ability of consumers to buy hog products also varies in this country from time to time as the general industrial activity, number of workers employed, and the level of wages shows changes from periods of active business to periods of dull business.

### Supply Factors 'Predominate

As a whole these demand factors are not so significant as are the supply factors in setting hog prices. In the past the supply of hogs has shown repeated swings every few years, and with the exception of the period of the World War, it is these large changes in supply which have caused the greatest changes in hog prices. The cause of these changes in supply and what can be done towards their elimination are discussed in the article on the possibility of smoothing out the corn-hog cycle (p. 419).

Part of the variation in supply through the year is smoothed out by putting provisions into storage during the months of large supplies and taking them out during the months of small supply. Although this helps to make up for the seasonal variation in supply through the year, it does not help much in years of heavy production, as then storage stocks accumulate to such an extent as to have a weakening effect on the market.

Statistical studies of hog prices have indicated that between 80 and 90 per cent of the changes in hog prices can be mathematically accounted for by the factors discussed. It seems that a certain portion of the remaining changes in hog prices are due to the inability of men in the hog market to foretell properly what will be the changes in supply and in demand during the immediate future and hence the tendency for them to be uncertain as to just what will be subsequent changes in hog prices. Thus during the period from February to July, 1925, hog prices at Chicago for the same grade of hogs swung upward from $11 to $14, dropped back to $12 and then advanced again to nearly $15, all within a relatively short period.

Although it is not possible to say how much of this erratic movement was due to speculation and how much was due solely to indecision on the part of the market, the inability of the market to arrive at a stable price is certainly one factor contributing to the changes in hog prices which must be considered as well as the more basic factors which have been discussed.

MORDECAI EZEKIEL.

### HOG Raising by Low Cost Operations

Do farmers make more money raising early spring, late spring, or fall pigs? If all of the conditions which limit the production of hogs were constant throughout the year, it would be as easy and as profitable to produce and sell hogs at one time of the year as another.

But these conditions change normally with the seasons. Consumers eat pork products more readily in cold than in hot weather. Therefore, if demand alone is considered, prices should be high in the winter and low in the summer. But the supply of hogs coming to market during the winter is so great that the price is low in spite of the greater demand, or keener appetites of consumers. The price of hogs varies from month to month in accordance with conditions affecting the demand for and the supply of hogs.

#### What Are Costs?

Even though the price is lower, the supply of hogs is greater during the winter because the obstacles or difficulties encountered in their production are less than those encountered in raising pigs for a summer and a fall market. These obstacles to production are costs. The price of feeds, especially corn, varies with the season and affects the cost of hogs accordingly. More equipment and labor are required in caring for them at some seasons than others. Seasonal climatic conditions influence the death rate among pigs as well as their rate of gain. When pigs do not do well, the feed required to make a pound of gain increases.

When everything is considered—the price of hogs, the seasonal difficulties of production, the quantity of corn to be marketed, and many relationships between the hog enterprise and the entire farm as a unit—it may be almost as profitable to raise one class of pigs as another. The following outline contrasts some of the factors which tend to equalize hog profits throughout the year.

| Factor | Early spring | Late spring | Fall |
|---|---|---|---|
| Price of hogs | High | Low | High. |
| Cost of production | do | do | Do. |
| Price of corn | do | do | Do. |
| Old or new corn | Old | New | Old. |
| Death losses before weaning | Heavy | Medium | Light. |
| Death losses after weaning | Light | do | Heavy. |
| Use of pasture | Minimum | Maximum | Minimum. |
| Daily gains | High | Medium | Low. |
| Usual finished weight | Light | Heavy | Light. |
| Necessary housing | Excellent | Fair | Good. |
| Necessary labor | High | Low | High. |
| Pressure of other farm work | Light | Heavy | Heavy. |

#### Follow a System

Various combinations of the one and two litter systems, early or late farrowing, and full or limited feeding are used in raising hogs. A farm organization with a relatively small quantity of corn for hog feeding would probably be most profitable if the hogs were fed to lightweights. Large farms with large quantities of corn for feeding will usually feed heavier hogs as it is usually impracticable to increase the hog enterprise in proportion to the corn enterprise.

Larger herds of late spring pigs than early spring pigs can be handled since the weather at farrowing time is more favorable. The production of fall pigs greatly increases the size of the enterprise and makes a more economical use of the breeding herd. A system should be followed closely. The pigs should be ready for market on schedule time. Early spring pigs which have missed the fall market usually lose because of their higher cost as well as a lower price during the winter. If the prices of feeds and hogs warrant it at the time the pigs are finished, feeding may be continued to heavier weights. The following outline compares the significant features of the one and two litter systems of hog production:

| System | Class of pigs | Time of farrowing | Rate of feeding | Finished weights | Time of marketing |
|---|---|---|---|---|---|
| | | | | *Pounds* | |
| One litter | Early spring | February-March | Full | 200 or less | September-October. |
| | or | | | | |
| | Late spring | April-May | Medium to full. | 200 and up | December-March. |
| Two litter | Early spring | February-March | Full | 200 or less | September-October. |
| | and | | | | |
| | Fall | September-October | Full | 200 and up | April-June. |

### How to Reduce Costs

Select good breeding stock which have the capacity to make good gains.

Give the hog a chance to live and grow by providing sanitary living quarters.

Give the brood sow enough feed and care to properly develop her unborn litter. It is good economy to increase the cost per sow if necessary, to produce large, strong, healthy litters.

Wean large litters and thereby reduce the cost of the weanling pig.

Keep the pigs growing. Full feeding is the most economical in making gains. Future prices of feeds and hogs may warrant limited feeding until that time is reached. But a stunted pig seldom catches up.

Provide good pastures for sanitary purposes, to stimulate growth, and reduce feed requirements.

Develop a system of raising hogs with convenient arrangement of hog lots, houses, and feed and water equipment. This reduces labor costs and provides better care for the pigs.

Don't capitalize your hog profits in too expensive hog houses and equipment.

Increase the rate of turnover in your hog business by maximum gains.

Oscar Steanson.

### HOME Industries for Farm Women and Girls Numerous

More than half a million country homes were remodeled, improved, or beautified in 1926 through the returns from home industries carried on by women and girls enrolled in home demonstration clubs. Where these women and girls have become interested in profitable productive work more of the raw products of the farm are being refined or manufactured at home, thereby giving the farm family more of the profits on many crops. Hundreds of women have succeeded in establishing profitable canning and preserving plants which had small beginning in home kitchens. Large quantities of fruits are canned or preserved in a thin syrup in 10-pound tin cans or other large containers to be held over until a less busy season of the year, when they are made into finished preserves as orders are received. Fruit juices are bottled for jelly making. Different kinds of vegetables are cured in kegs of brine during the rush season at harvest time and made into finished relishes or other pickled products as needed. Quantities of garden herbs are also dried and made ready to mix into kitchen bouquets for home use or for sale as the demand arises.

Materials on the farm are gathered, cured, and stored away for work during the long evenings of the winter months. Supplies of cured pine needles, honeysuckle vines, oak splits, etc., are stored by basket makers. Dyed, cut, and sewed strips of rags are prepared and rolled in huge balls ready for braiding or weaving into rugs. Clean feathers are put up by the fan makers. Hides and skins of animals are cured and tanned and a supply of leather made ready for another fireside industry. One of the unique specialties developed was pine-needle tapestries of Indian design. The woman originating this specialty last year sold some of these pieces for $50 each and a single tapestry suitable for a table top brought $1,500.

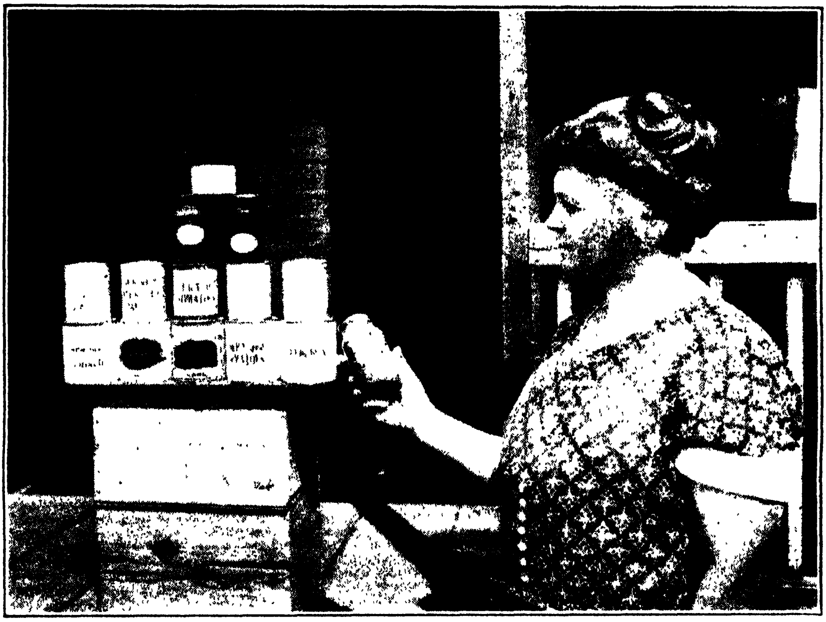

FIG. 114.—Farm woman displaying some of her specialized canned products

### Cooperation is a Result

Successful beginnings in home industries made by individual women naturally lead to the formation of cooperative marketing organizations to market high-quality standardized home products. The success of women and girls in home industries has been due (1) to economical production, (2) standardizing products, and (3) cooperative marketing with neighbors. The local club market has been the most significant development in this field. Club markets have been organized and conducted by many of the home demonstration clubs. This market is usually located in the nearest town that offers a natural market for the members of the club and is managed by them. All kinds of raw material and refined home products are sold in these markets including fresh fruits, vegetables, meats, butter, eggs, cheese, honey, canned goods, smoked and cured meats, flowers, and bulbs. The total value of products marketed at these club markets in 14 States under the guidance of 114 home demonstration agents in one year was $1,008,568. In Georgia, South Carolina, and North Carolina alone in 1925 the total value of products sold through the club markets was $705,717.

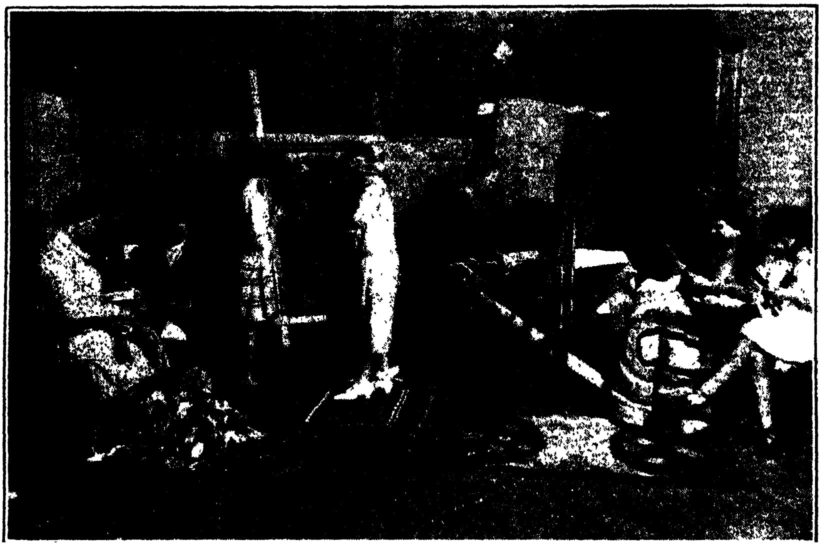

FIG 115.—Home demonstration agent showing farm women and girls how to make rugs

In addition to club markets, in many States county commodity marketing organizations have developed as subdivisions of the county home demonstration councils. Special products are standardized for sale by the members of these county cooperatives. Some associations maintain a salesroom for their goods and they have their own printed stationery and folders illustrating and describing the special article which the organization has for sale. Examples of such associations are county weavers, pine craft, basket makers, and handicraft associations.

Members of the county weavers' associations in Arkansas and Tennessee standardized certain sizes and patterns for rag rugs and also their recipes for mixing dyes in order to obtain good uniform colors for use with a few selected designs on which members of the association are specializing. Some of the members are making braided rugs, some woven, and others the hooked rugs. The rug making association in Hamilton County, Tenn., expanded its business to such an extent that it became necessary for them to procure materials and supplies in larger quantities than could be found at home. With the aid of the county home demonstration agent, arrangements were made to procure the surplus waste from hosiery mills and other factories located in the county. The total sales on rugs in this county amounted to $4,000 in 1925, as compared with $500 worth sold in 1921. Orders for rugs were received from 10 different States. About 100 women are working members in this association.

### Handicraft Association Shipments

County handicraft associations in the northern counties of Mississippi and pine-craft associations in the southern section of the same State standardized for sale certain patterns of baskets made from native materials. Shipments were made regularly to florists, gift shops, candy manufacturers, grocers, and others. One year the sales from baskets made from wild honeysuckle vines and pine needles by women and girls in Mississippi totaled $12,000. Women in about 46 States are making baskets under the guidance of home demonstration agents, utilizing many different kinds of native materials, including willow, pine needles, honeysuckle vine, wire grass, bulrushes, corn husks, iris leaves, buckbush, and white oak splits.

In a number of States each year a large portion of the fig crop is wasted because the fruit can not be shipped satisfactorily in the fresh state. Fig clubs have been formed for the special purpose of canning and preserving figs for sale. In Alabama 12 members of the Dallas County Fig Club, in spite of a poor crop season, had ready for market 500 dozen standard containers of fig preserves beautifully packed and labeled with a special Dallas County label. The use of this label added to the attractiveness of each package. The value of the output was $1,225 and more orders were received than could be filled.

Another group of 100 women from Georgia worked together to standardize a high-grade commercial pack from the by-product of a field crop. Uniform containers were purchased in quantity by county home demonstration councils and each of the 100 women agreed to pack 1 dozen jars of watermelon rind preserves. The pieces of rind were cut uniformly so that exactly 12 pieces would fill an attractive 12-ounce jar. The same recipe was carefully followed by each one and any jar taken at random from the lot was an exact duplicate of the others. When the entire 100 dozen jars were assembled in the main aisle of a grocery store they presented a beautiful exhibit. Each woman was as proud of her work as if she had packed the whole lot of 1,200 jars. The 100 dozen were all sold in one day and netted the women a 50 per cent profit. In addition, the advertisement this sale gave to their high-quality products brought to these women orders not only from this store but also from other business concerns, club houses, and hotels for as much as they could pack during the next season.

In many States the women and girls have sold unique farm home products successfully. Some of these women have specialized and standardized for marketing beautiful and useful articles made of feathers from the farm flocks. In other States women have made gloves and other articles from the hides and skins from animals butchered or trapped on the farm. Large numbers of purses, bags, desk sets, book covers, wallets, and bill folders of attractive durable patterns have been designed, tooled, and made from calfskins. The young calfskin untanned sells for 35 to 50 cents, but often there is no market for such skins and they become a waste product of the farm. In cooperation with interested farm women, extension agents have demonstrated that between $60 and $75 worth of tooled leather articles can be made from one calfskin.

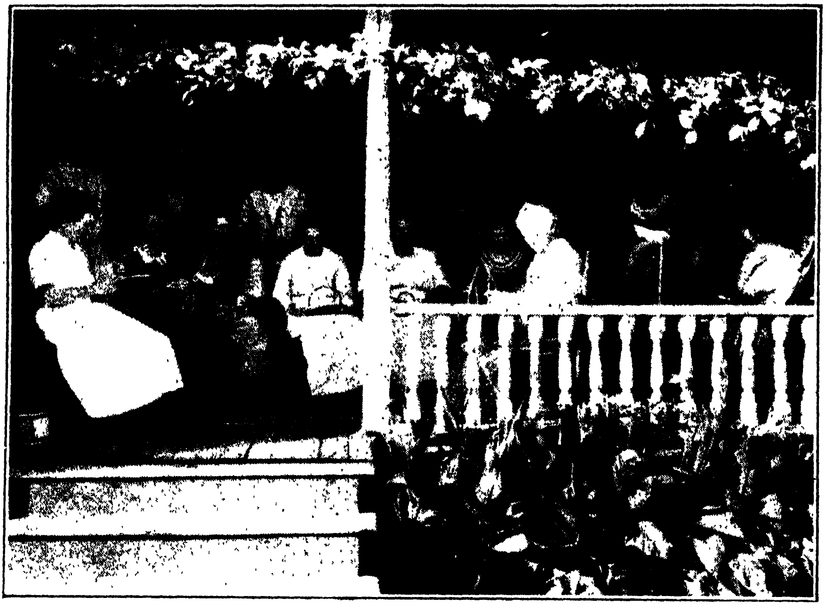

FIG. 116.—Members of home demonstration club making baskets for cooperative sale

## Leather Work Popular

So popular has some of the work with leather become that county officials in different States granted their home demonstration agents leave of absence with salary for from three to four months for the purpose of undertaking with selected groups of agents intensive courses in glove making and other leather work in England and France. More than 20 home demonstration agents, representing 9 or 10 different States, have had the benefit of such study and travel in Europe and are now giving to the women and girls of their counties the benefit of their knowledge gained through these courses.

When the finished product of these home industries are of the highest grade and show skill and perfection in workmanship they meet a ready demand and bring good prices. The wholesome interest which has been aroused among women and girls in the profitable utilization of farm resources by extension workers has resulted in increasing each year the number of women and girls who find greater satisfaction and contentment in living in country homes.

Ola Powell Malcolm.

---

**HOME Life on the Farm** The last 10 years have seen revolutionary changes within the farm home in the United States. Good roads, transportation, mechanical inventions, and improved service of the press and educational agencies have been as important factors in improvements in the home as they have been in the well-recognized improvements brought about in American agriculture.

Probably the most important change made within the home has been in the thinking of the farm woman. She has come to recognize satisfying home making as her objective rather than simply efficient housekeeping. She has found that rest and recreation are needed for all members of the rural family if their duties are to be performed more efficiently, and if their life is to be satisfying. She has become conscious of the necessity of procuring efficient tools for her work and of obtaining scientifically accurate knowledge regarding adequate methods of caring for the physical well-being of her family. She has developed a keen desire to make the home beautiful within and without, to developing correct habit formation in her children, and to make the home and community a place of satisfaction and pride to all concerned.

This viewpoint has developed rapidly, particularly during the past five years. Rural women in all sections of the country have begun to meet regularly in small groups to obtain the desired information, and to enjoy the satisfaction of group discussion and of social contact thus afforded.

### Farm Surroundings Improved

The results of such activity by farm women and the resultant effort is in evidence on every hand. The yard and fences about the house have been put in orderly condition and a well-designed scheme for using grass, trees, flowers, and shrubs has made of the farm home a place of beauty.

The interior of the farm home has been made equally attractive. Simplicity, usefulness, and beauty have been made the keynote of selection and arrangement of house furnishings. Family recreation and music have been planned for in many homes. Such an atmosphere in the farm home has made rural children love their home and think of it as a place of satisfaction rather than one from which to go to seek pleasure elsewhere.

Through increased efficiency in the performance of necessary duties the farm woman has gained time which she has learned to use constructively. She has had more opportunity to study her mode of living and its possible improvement. She has been able to give more time to rest and recreation, to training her children in correct habits of acting, speaking, and thinking, to companionship with her husband and friends, and to carrying out her responsibilities as a member of the community.

The farm family has become more satisfactorily clothed. Clothing has been economically purchased. Becomingness, appropriateness to needs, and hygienic properties have been considered in its selection. Clothes have been made with less consumption of time and energy. The family has been more attractively dressed and has possessed that sense of poise and of satisfaction which comes from such knowledge. This has helped to overcome self-consciousness, and has encouraged participation in group endeavors and acceptance of a place of responsibility in the community.

### Food is More Adequate

The food of the farm family has become more adequate as to desirable quantity and variety. It has been procured more economically. The more general use of a garden and a canning budget based upon family needs has developed. This has tended to prevent physical ills, and this improved health of the family has made for greater efficiency at work, and increased enjoyment of leisure time.

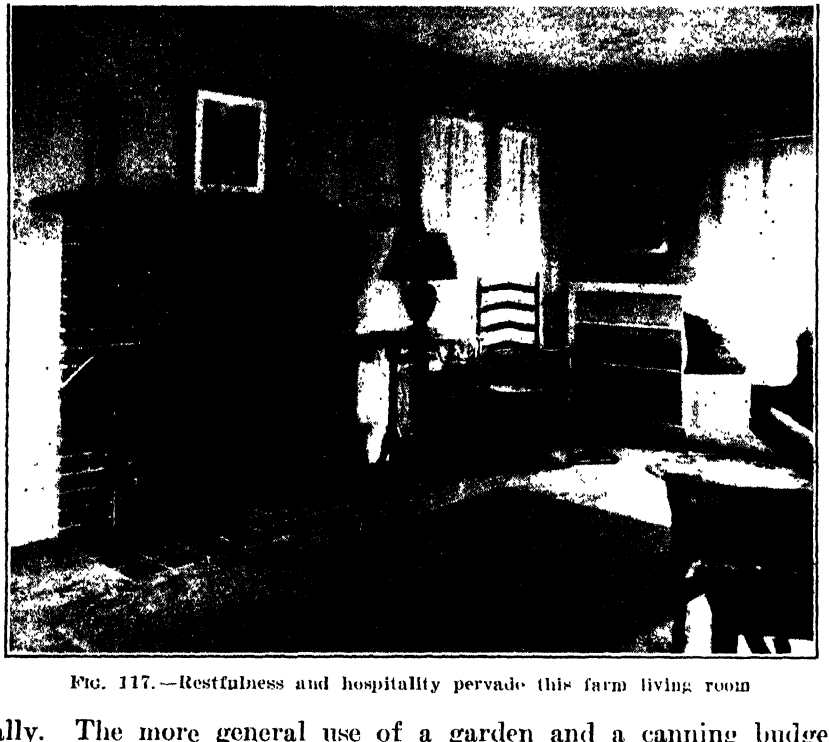

FIG. 117.—Restfulness and hospitality pervade this farm living room

Unavoidable illness on the farm has been cared for with greater skill and correct methods, and the healing processes have been accomplished with satisfying results and with less delay.

With her husband, the farm woman has studied the family income and the type of life desired for the family. They have come to use greater discrimination in the use of their income, so that desired objectives may be realized more surely, either immediately or over a period of years.

The farm woman has come to see more fully her opportunities and responsibilities in the community. She has come to regard the community as a modern day extension of the home. Through her vote and personal activity she has promoted better services in schools, churches, public health, recreation, merchandising wares, public office, and the like. She has helped increasingly to promote civic pride through bringing about beauty in the community environment.

During the decade just past many thousands of farm women have come into this larger consciousness of the importance of the farm home and of their opportunity in serving it and the rural community. Each year the number has increased of those who have joined with their neighbors in setting up wholesome standards of rural family life, in obtaining helpful information, and in checking improvements made. The growth in vision and abilities of these women has been the outstanding result of this group endeavor. They have intelligently evaluated the possibilities in home making, in community life, and in citizenship. They have set up goals of desired accomplishment for themselves in relation to each of these factors.

### Aided by Extension Workers

On this forward movement, farm women have been aided to a large degree by the State and county home demonstration agents and home economics specialists of the cooperative extension service of the United States Department of Agriculture and the State agricultural colleges. Through these extension workers there has been made available in a practical form the results of home-economics investigations by the State agricultural colleges, the Bureau of Home Economics of the Department of Agriculture, and other institutions and agencies contributing to the science of home making. In addition, these extension workers are helping farm women to assume intelligent leadership in all affairs having to do with promoting economic and social well-being in rural home and community life.

At present approximately 1,000 county home demonstration agents and 300 home economics specialists are aiding farm women in this constructive undertaking. The demand for this type of leadership is steadily increasing.

By the hundreds of thousands farm women have accomplished these changes in their thinking and in their home conditions. By the tens of thousands they have given volunteer service in interesting their friends and neighbors in like undertakings. In addition they have given time and energy to receiving practical training in these fields from technical experts and have voluntarily aided their neighbors to become equally skillful in these lines. In 10 years farm women have become more conscious of the possibilities of satisfying life on the American farm. The results accomplished point to marked further development in the future in the interested and efficient conduct of daily tasks, the intelligent and constructive use of leisure, and in making of the rural home and community places affording greater beauty and satisfaction to those who live in them.

GRACE E. FRYSINGER.

**HONEY Market Reports Now Issued** Like other salesmen, beekeepers who have honey to sell need market information in order to dispose of their crops to the best advantage. It is to their advantage to know at what price other beekeepers in competing sections are selling honey of the same flavor and grade. They are interested, too, in hearing of the condition of bees and honey plants in other areas, so that the probable size of the crop in different regions, with its effect on prices, can be known.

Information of this sort can be found mainly in three sources: (1) Letters put out by honey buyers, (2) discussions in the bee journals, and (3) the honey market news reports issued by the United States Department of Agriculture. Of these the Government reports are easily the most comprehensive, and several journals now copy them in whole or in part, instead of obtaining market information themselves.

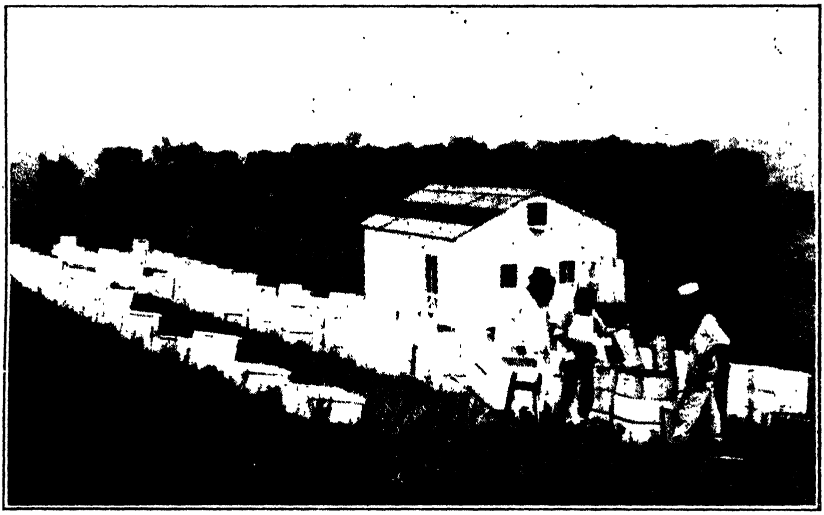

FIG. 118.—Working with bees in Iowa. Honey house in center of picture

The market news reports published by the Bureau of Agricultural Economics have been issued for nearly 10 years. At present reports are prepared on the 1st and 15th of each month, at Washington, D. C. only. No charge is made for the bulletins, and they will be sent to any beekeeper upon request.

The first two pages of each report are devoted to news from the important producing sections of the country. A large number of beekeepers and honey shippers, from Vermont to Washington and from Minnesota to the Gulf, send the department, twice a month, statements of prices and crop and market conditions prevailing in their sections, with other news items of interest. These are combined and published by sections such as "Intermountain region," "Northeastern States," "Texas," etc. The cooperation of other large beekeepers in furnishing reports would be welcomed by the department.

These price reports from producing sections are confined chiefly to the sale of comparatively large lots of honey. Most of the extracted prices refer to 60-pound cans, although, especially in sections where most honey is sold in small pails, sales of 5 and 10 pound pails are also recorded. Sales of comb honey are on the basis of the glass-front case holding 24 sections. Prices on chunk, or bulk comb honey are also obtained in Texas.

### Prices and Local Conditions

Prices and local conditions in leading city markets appear on the third page of the report. Boston, New York, Philadelphia, Chicago, Minneapolis, St. Louis, Kansas City, Denver, and San Francisco are all reported on at this time. In these cities salaried representatives of the department call upon the leading receivers and dealers and obtain the prices at which bottlers, confectioners, bakers, and wholesale dealers can buy extracted honey, in 60-pound cans or barrels, and the price obtainable for comb honey when sold by large receivers to retail grocers. Prices are obtained on all flavors and grades which are on the market in any quantity. Quotations on domestic and imported beeswax are also obtained in some cities.

In order to reply to requests which are frequently received by the department, address lists have been compiled of leading honey dealers in over 20 of the important markets. No pretense of completeness is made for these lists, but they are probably more accurate than any other similar register ever compiled. These names will be furnished to beekeepers on request.

Millions of pounds of honey are shipped to foreign countries every year. As an indication of the countries most interested in American honey, import and export statistics are published in detail once a month as a feature of the market news report, and twice a year total figures for the preceding 12 months are tabulated and published. Consular articles dealing with bee and honey interests in foreign countries and the possibilities of selling American honey in those countries, are occasionally obtained through the Bureau of Foreign and Domestic Commerce of the Department of Commerce and published in the market report.

HAROLD J. CLAY.

## HONEY Grades Set Aim for Beekeepers

The standardization of food products is a necessary outgrowth of modern business methods and the wholesale transportation and marketing of such products. Realizing that honey also must be standardized, the division of bee culture investigations of the Bureau of Entomology, in cooperation with the Bureau of Agricultural Economics, has established standard grades and grading rules for both comb and extracted honey.

The Federal standards have unified the various grading rules already in use so that a grade name for color or finish when applied to honey anywhere in the United States will mean the same thing. Only thus can producers and consumers meet each other satisfactorily.

Our foreign trade in honey is now about 8,500,000 pounds annually. This should increase largely through the use of uniform, standard grades. If any foreign purchaser, in buying honey, specifies that it shall be graded according to United States grading rules for honey, he can be assured that he will receive such honey as he orders and that it will be of good quality.

Two chief commercial grades of comb honey are specified. It is expected that 25 to 40 per cent of the honey produced in the best commercial practice will grade as U. S. fancy, the remaining 60 to 75 per cent of commercial honey grading as U. S. No. 1. A variable percentage, depending on the season and on the skill of the producer, will grade as No. 2 and should be sold on local markets instead of being shipped. Provision is also made for special grades for particular purposes, such as export and exhibition grades. Color is also considered in the grading, and there may be a fancy grade of amber or of dark honey as well as of white honey.

In extracted honey, fancy and No. 1 grades are also provided, with a range of color division comparable to that for comb honey. The chief difference between U. S. fancy and U. S. No. 1 extracted honey is in the clearness, fancy being ready for sale direct to the consumer, while No. 1 is a product to be sold to the bottler, and contains particles of wax, etc., which must be removed before it will class as fancy honey. A No. 2 grade is also provided for extracted honey which does not come up to the standards required for fancy and No. 1.

It is impossible, on account of the great diversity in character of honey marketed, to make grades to fit exactly the needs of each producing area, but it is believed that beekeepers can adapt their methods of management reasonably to meet the standards of the grades.

It is necessary for the beekeeper, as for any other producer of commodities, to set a standard for his merchandise, and to plan his management so as to produce honey that will grade well. The Federal grading rules provide a standard which will obtain for the beekeeper the best financial returns from the accepted best commercial practice in beekeeping. The beekeeper should study each detail of production and adjust his methods so that the nectar gathered from the flowers by the bees may be made by them into the largest possible quantity of the most salable honey. Often some fairly good method must be discarded because it results in too large a proportion of a product that does not meet the grades. As competition becomes more keen, methods of production must be improved so that the honey obtained from the bees may be equal in grade to that of competing producers.

Many beekeepers are now working in this way and are financially successful. They do not merely produce a crop of honey and then grade it according to Federal standards, but they have the standards in mind while managing the season's work and thus succeed in obtaining the largest proportion of fancy and No. 1 honey possible for their locality. By the use of good beekeeping methods, the required grade of honey can be produced profitably.

E. L. Sechrist.

**Horse Production Falling Fast in U. S.** The demand for horses for farm and city work has fallen rapidly since the close of the war in 1918. The automobile and auto truck have made the horse-drawn vehicle of relatively little importance in city streets and even on country roads, while the tractor has replaced some of the work stock on a great many farms. With the improvements that are being made in tractors, it is difficult to foresee the extent to which tractors will eventually replace horses on American farms, but it is not likely that the horse will ever be entirely displaced. At least one team will be necessary on most farms.

The decreased demand for horses in cities and on farms has resulted in a decrease in horse values of more than 35 per cent from 1918 to 1924, with continued low values since. In fact horses were worth relatively less in 1926 than at any other time in the past 60 years. With the sharp drop in demand and the rapid falling off in the values of horses came a startling decrease in the number of horse and mule colts foaled in the past seven years. While the number of horses and mules over 2 years of age decreased about 6 per cent from 1920 to 1925, the number of colts under 2 years of age decreased 51 per cent. The census of 1925 showed 73 colts under 2 years of age per 1,000 horses and mules of all ages, as compared with 132 colts in 1920, or a reduction of 45 per cent in the ratio.

### Reports from Crop Correspondents

Reports from farms of crop correspondents show that 41 horse and mule colts were foaled during 1925 per 1,000 head of all horses and mules on their farms January 1, 1926, as compared with 91 during 1919 per 1,000 head of all horses and mules on farms January 1, 1920. Unless more colts are raised in future years than were raised in 1925, either the number of horses and mules on farms will eventually fall to approximately one-half the present number on farms, or their average life must exceed 15 years.

While this downward trend in colt production continued unabated in the South Central States and the range country, an increase in the number of colts foaled in 1925 over 1924 was shown in the Corn Belt and Northeastern States. Most of the States where surplus mules are produced showed a decline in the birth rate of colts during 1925 as compared with 1924—Missouri showed a decrease from 54 to 46 colts, Kentucky from 40 to 35, Texas from 47 to 36, and Oklahoma from 49 to 45; only Kansas and Nebraska showed an increase.

Without colts and young horses to replace our present number of work animals the number will fall off rapidly during the next few years. The number of horses and mules on farms since 1910 and the outlook for the next five years is shown in Figure 119. A reduction in the number of work animals on farms of 30 to 40 per cent within the next five years is practically inevitable. This rapid reduction will first develop into an acute shortage in those States where the horses now on farms are the oldest and where there are fewer colts coming on as replacements, and where the topography of the country, the character of labor available, or the type of farming followed make the use of tractors less satisfactory than in other parts of the

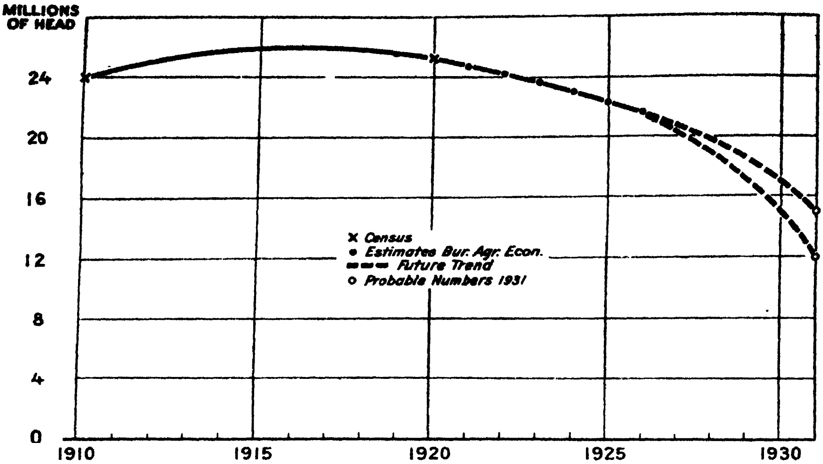

FIG. 119.—Number of horses and mules on farms in 1910 and 1926, and estimated number in 1931

country. Figure 120 shows that on the farms of crop correspondents in February, 1926, there were more horses over 10 years of age in the Northeastern and Southeastern States than elsewhere. The Southeastern States have the largest percentage of mules over 10 years of age.

### Replacement Effected in Far West

Neither of these sections raises as many colts as the Middle Western and range States. These are also sections which are not as well adapted to tractor farming as are the broad plains of the Central States. Only in the far Western States are the present number of colts anywhere nearly sufficient for replacement purposes.

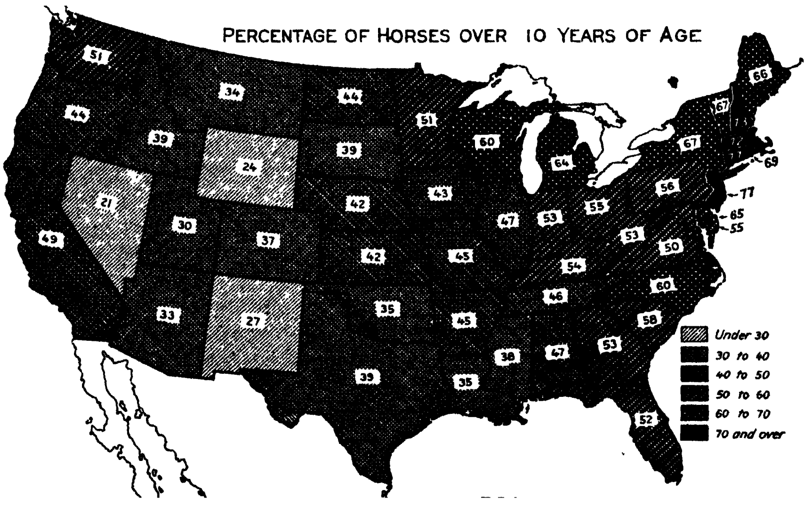

FIG. 120.—There are more horses over 10 years of age in the Northeastern and Southeastern States than elsewhere. Only in the western range States are the present number of colts anywhere nearly sufficient for replacement purposes

The individual farmer should study carefully the type of power best suited to his own farm and plan now for the necessary horse and mule replacements 3 to 10 years hence. Present low prices for horses may be expected not to continue indefinitely. The average value of horses on farms has not changed much for the past three years although the average age has increased considerably.

C. F. SARLE.

**HOSPITALS for Agricultural Communities** What farm family would not welcome the assurance that in case of serious injury or sickness an ambulance would appear on call at their home and take the patient to a near-by public hospital for treatment; that superior medical and surgical skill, including that of their own family physician, and aided by modern medical appliances would be at their command; that sympathetic trained nurses, drawn from the home community, would care for them; that friends and family could make daily visits to the patient?

This is becoming a reality as public hospitals, long considered a necessity by city people, are being erected in rural communities with financial assistance of farmers themselves.

A recent rural hospital survey by the Department of Agriculture[7] has revealed a growing movement in the establishment of such public hospitals and has disclosed a variety of types.

Twenty States have recently enacted legislation facilitating the erection by taxation of hospitals by rural counties. Establishment is by the regular county legislative body usually after popular vote, the law generally specifying a maximum tax rate of 2 mills on the dollar, which in practice is often much less.

Cost figures run from $30,000 to $250,000. Maintenance expenses are met largely from the hospital receipts; deficits, if any, from taxes. Government is through a board appointed by the county governing body or elected by the people.

Jefferson County, Iowa, population 16,440, erected a $43,000 25-bed hospital at Fairfield in 1912 (fig. 121) and later a nurses' home which cost $15,000. Bonds voted by people, $27,000; cash donations for building, $7,982; equipment donations, $8,000. Hospital earnings, 1923, $20,776.68; expenses, $24,666.96; deficit, $3.890.28. Average 11-year deficit, $3,289.74. Number of patients in 1923, 746; one-half farm people. Receipts from county taxes, $7,726.60. Tax rate, 1 mill, which was one thirty-seventh of the total county tax. Country patients are conveyed in the hospital ambulance.

McPherson County, Kans., population 21,845, built by popular vote through taxation, a modern 50-bed hospital plant costing $250,000, which, in 1924, had 828 patients. It maintains a training school for nurses and 18 additional employees.

### A Successful County Hospital

A variation of the type is the County Home Hospital at Urbana, Ohio. The county built a public hospital adjacent to the county infirmary which has proved very successful. It more than maintains itself, as the same superintendent, engineer, matron, and other help are in both institutions, and the same heating, lighting, and refrigerating plants, water system, kitchen, etc., are used.

---

[7] NASON, WAYNE C. RURAL HOSPITALS. Farmers' Bul. No. 1485, 48 pp., illus., 1926.

A 45-bed hospital costing $109,000 was built, in 1923, at Shelby, N. C., with a population of 3,609 and a township population of 8,409, by popular bond vote. Operating expenses in 1924 were $22,882.76 and receipts, $22,682.40. Daily average of 20 patients, one-third farm people.

Three Rivers, Mich., took over a private hospital, the people voting a maximum maintenance tax of 1 mill. Waseca, Minn., population 3,908, in a farming community, voted bonds and erected a $63,000 soldiers' memorial public hospital accommodating 26 patients. Citizens subscribed $8,000 to furnish rooms.

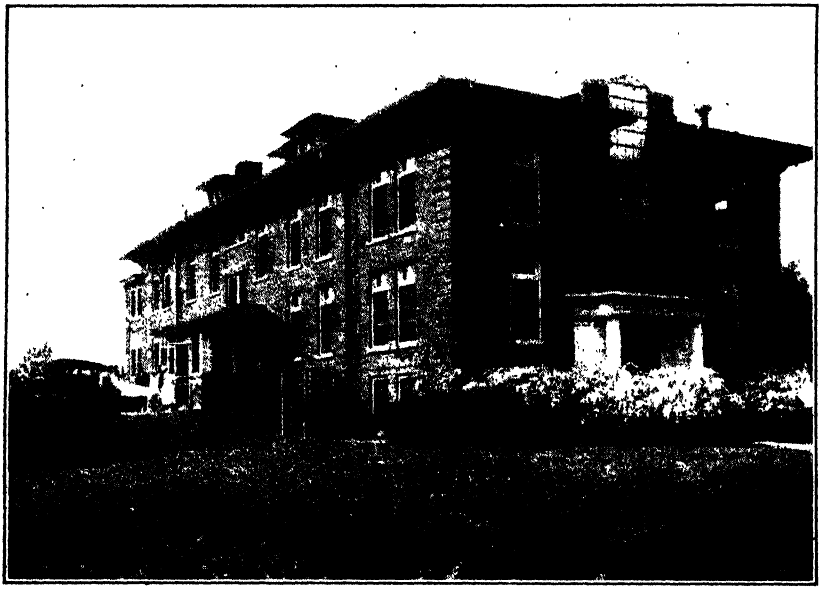

FIG. 121.—The modern county hospital at Fairfield, Iowa

Ohio solved the difficulties surrounding the union of several political units for public-hospital taxation by special legislative enactment. Whereupon the people of four townships and one village in two counties, with a population of 9,569, voted a 0.75-mill tax for 10 years for construction and maintenance and, supplemented by $65,000 subscribed by 3,500 people, built a $130,000 public hospital of 30 beds at Berea. Government rests in a board of trustees, including representatives from each political unit, six of them farmers.

### Community Hospitals

Rural people form community hospital associations and, through stock sales or public subscriptions, finance such hospitals. At Montevideo, Minn., then a town of 3,056 population in a county of 14,158 population, a community hospital association was formed with

650 stockholders, one-half farmers. A $40,000 hospital was built which is out of debt and financially self-sustaining. (Fig. 122.) Of its 627 patients in 1924 three-fourths were farm people.

At Creston, Iowa, a $200,000 "greater community hospital" of 50 beds was erected with money from 1,000 subscribers, a farmer giving $25,000. It serves 100,000 rural people in eight counties, has subsidiary governing units in each county, is open to all doctors, is self-supporting, and owned by the greater community. It is controlled by a hospital association which elects a board of trustees which in turn elects an immediate control executive committee, three of them farmers. Of the 1,402 patients in a recent year, one-half were farm people. The average cost of hospitalization per patient per day was $4.23. The proponent of this hospital was a country doctor who felt unable to practice medicine properly without a hospital, the nearest one being 60 miles distant by rail.

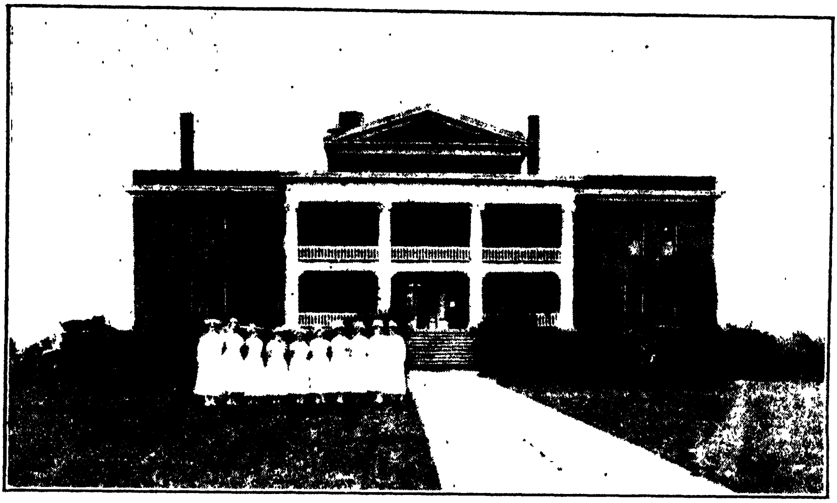

FIG. 122.—Community hospital and nursing staff, Montevideo, Minn.

The farming community of Sandy Springs, Md., organized an association and erected a $65,000 hospital financed by the sale of stock to 350 stockholders, $39,297; public subscriptions; and a loan. From the opening, February, 1920, to October, 1926, 2,301 patients, mostly farm people, were treated.

### Community-Private Hospitals

A less populous and wealthy community sometimes forms an association and finances a hospital in conjunction with a private party, perhaps a physician. At Addison, Mich., a farming village, the physician furnished the building and the association equipped it.

A doctor-community type is also found at Forney, Tex., population 1,345, where a hospital became necessary in order to retain local physicians. A corporation of 80 people, including 60 farmers, through stock sales erected a $30,000 institution. The doctors furnished half the stock and rented quarters in the building. Hospital; profits averaging $2,000 yearly, none of which accrue to the doctors, have gone into the plant, including a new home for nurses. Four-fifths of the patients are farm people.

Philanthropic people have done considerable in the establishment of hospitals among the backward and neglected old American stock inhabiting a southern mountain region. Holman Hospital at Altapass, N. C., is a personal achievement. A trained nurse from the North, after 20 years of health service among these people, has seen her work rewarded by the establishment of a hospital with a physician in charge, erected with the help of philanthropic people and appreciative local labor.

### Rates at Hospitals Surveyed

In the hospitals surveyed rates for general care and nursing vary from $2 to $3.50 per day for ward beds and from $3 to $6 for private rooms. Some hospitals employ graduate nurses; others maintain training schools. A women's auxiliary is often effective assistance. In communities with hospitals there was an adequate supply of young progressive physicians sympathetic toward rural people.

Most of these rural hospitals give service comparable to city hospitals at lower rates, thereby filling a distinct need for rural people.

WAYNE C. NASON.

## INCOME from Agricultural Production

Changes in farm prices alone or in farm production alone do not measure the current economic well-being of the agricultural industry. When it is desired to appraise the condition or progress ot any industrial enterprise, it is customary to examine not its prices or production alone, but its gross income, its expenses, and its net income, and then to see whether the net income is sufficient to pay the owners of that enterprise a reasonable reward for their capital, labor, and management. Such a comparison may also be made for the agricultural industry as a whole.

### The Source of Farm Income

Farm income is derived largely from agricultural production. Some farmers may derive additional income from work in near-by towns or cities, from investments, gifts, or inheritance, but when all farmers are considered as a group, these additional earnings form a very small part of the total. Although farmers derive most of their income from production, their total production does not constitute income. A good part of some crops is fed to animals, or used for seed, or is of nonmerchantable quality. It is only that part of the production which is either sold for cash, or consumed by the farm families that constitutes gross income. The difference between the gross value of all farm production and gross income appears in Table 11. In 1919 about one-third of the gross value of all farm production was used for other purposes than for sale or for farm home consumption; in 1925, about one-quarter. Ordinarily about 80 per cent of the gross income is in the form of cash derived from sales, and 20 per cent in consumption of food and fuel on farms.

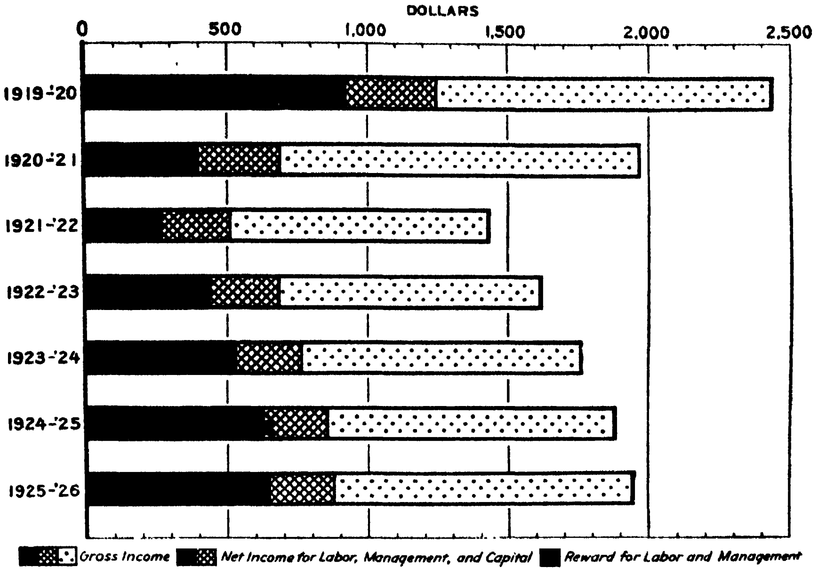

FIG. 123.—Income per farm from agricultural production in the United States

TABLE 11.—*Gross value of farm production and gross income*

| Year | Gross value of all farm production[1] | Deductions for products fed, used for seed, and waste[2] | Gross income from farm production | | |
|---|---|---|---|---|---|
| | | | Total | Value of food and fuel consumed on farms | Cash income from sales |
| | *Million dollars* | *Million dollars* | *Million dollars* | *Million dollars* | *Million dollars* |
| 1919-20 | 24,025 | 8,306 | 15,719 | 2,887 | 12,832 |
| 1920-21 | 17,800 | 5,132 | 12,668 | 2,645 | 10,023 |
| 1921-22 | 12,894 | 3,680 | 9,214 | 2,129 | 7,085 |
| 1922-23 | 14,909 | 4,543 | 10,366 | 2,168 | 8,198 |
| 1923-24 | 16,249 | 4,961 | 11,288 | 2,360 | 8,928 |
| 1924-25 | 17,086 | 5,083 | 12,003 | 2,327 | 9,676 |
| 1925-26 | 16,847 | 4,432 | 12,415 | 2,524 | 9,891 |

[1] These gross values of all farm production are here evaluated in terms of crop year (practically July-June) production and weighted average farm prices.

[2] These deductions, to obtain gross income, cover portions of crops and dairy products fed to livestock, used for seed in further crop production, and waste. For the industry as a whole these deductions constitute raw materials, the income from which is derived from the finished products sold or consumed in the farm home.

## Gross Income, Expenses, and Net Income

A large part of gross income from production is paid out in the form of expenses of production, taxes, rent, and interest on mortgages and other indebtedness. The greater the proportion of these payments paid out to nonfarmers, the smaller the net income available for the farmer's own capital, labor, and management. As shown in Table 12, about half of the total income in 1919-20 went to meet the costs of production, taxes and the use of rented land, and borrowed money or credit. During the depression much larger portions of the reduced income were required for these purposes so that very little remained as a reward for the farm operator's own capital investment, his labor and managerial efforts.

TABLE 12.—*Gross income, expenses, and net income for operator's capital, labor, and management*

| Year | Gross income | Expenses of production[1] | Net income for operator's capital, labor, and management |
|---|---|---|---|
| | *Million dollars* | *Million dollars* | *Million dollars* |
| 1919-20 | 15,719 | 7,685 | 8,034 |
| 1920-21 | 12,668 | 8,262 | 4,406 |
| 1921-22 | 9,214 | 5,917 | 3,297 |
| 1922-23 | 10,366 | 6,002 | 4,364 |
| 1923-24 | 11,288 | 6,398 | 4,890 |
| 1924-25 | 12,003 | 6,559 | 5,444 |
| 1925-26 | 12,415 | 6,812 | 5,603 |

[1] Includes wages for hired labor, purchases of food, seed, binder twine, harness, etc., and estimates of cost of operating farm machinery, automobiles, and trucks, upkeep of farm buildings, taxes, rent, and interest paid to nonoperators.

What do the above net incomes available for capital, labor, and management mean, (1) as to the rate of return on investment and capital, and (2), as to the reward for the farmer's labor?

### Reward for Capital and Management

There is no adequate way of determining the exact shares of the net income which may be taken separately as the rewards for each of the three factors in production—capital, labor, and management. We can, however, assume that the average farmer is entitled to a reward for his labor equivalent at least to what he pays for hired labor without board. If we make this allowance for all the farmers engaged in agricultural production, and deduct it from the total net income available, after meeting current expenses of production, the balance may be taken as the reward for the capital invested, including reward for management. Table 13 presents the results of such allowances and deductions, with the balance expressed as percentages of the net capital investment of all farm operators. The negative figures for 1920–21 and 1921–22 mean that after paying current expenses, interest, rent, and taxes, the balance not only fell short by $1,720,000,000 in 1920–21 and $797,000,000 in 1921–22 of providing a current wage for the labor of the farmer and his family, but left nothing for return on the capital investment. During the past two years the return for both capital and mangaement has exceeded 3 per cent, but even these returns are considerably below the commercial interest returns and managerial rewards in other enterprises.

In computing the foregoing data on gross and net income, and the rates of return on capital and management, no account was taken of the declining value of capital invested in agriculture shown in Table 13. If allowances were made for the losses sustained by those farmers who were forced to sell on declining land values, the net income for the industry as a whole would show still greater losses during 1920–21 and 1921–22.

TABLE 13.—*The value of capital invested in agriculture and the reward for the operator's capital and management*

| Year | Current value of all capital invested in agricultural production [1] | Current value of operator's net investment in agricultural production [2] | Income available for operators [3] | | Reward for capital and management as percentage of operator's net investment [5] |
|---|---|---|---|---|---|
| | | | Capital, management, and labor | Capital and management [4] | |
| | *Million dollars* | *Million dollars* | *Million dollars* | *Million dollars* | *Per cent* |
| 1919–20 | 79,459 | 47,065 | 8,034 | 2,675 | 5.7 |
| 1920–21 | 73,139 | 41,172 | 4,406 | −1,720 | −4.2 |
| 1921–22 | 63,811 | 34,711 | 3,297 | −797 | −2.3 |
| 1922–23 | 62,549 | 34,321 | 4,364 | 419 | 1.2 |
| 1923–24 | 60,472 | 33,046 | 4,890 | 520 | 1.6 |
| 1924–25 | 59,743 | 32,574 | 5,444 | 1,039 | 3.2 |
| 1925–26 | 59,778 | 32,793 | 5,603 | 1,137 | 3.5 |

[1] As of Jan. 1 in the period indicated values include land, buildings (dwellings and other), livestock, implements, machinery, motor vehicles, and an allowance for cash working capital.
[2] Total capital investment less property rented from nonoperators and debts owed to nonoperators.
[3] Exclusive of residential value of buildings.
[4] Obtained by deducting a wage allowance for the labor of the farm operator and his family.
[5] Column 4 divided by column 2.

It is to be noted further that the difference between columns 1 and 2 in Table 13 represents the estimated value of property rented from and debts owed to nonoperators, and that the rates of interest paid on this borrowed capital have been at least between 6 and 7 per cent, considerably more than farm operators have earned for their own capital and management. This illustrates the fact that periods of prosperity and depression do not affect all owners of farm property to the same degree. The return on capital invested in farm mortgages, or in farms rented out on a share or cash basis to farm operators, is fairly constant, and, being a primary obligation, is fairly certain compared with the uncertain fluctuations in earnings on the farmer's own capital. It is therefore highly important to observe how agricultural conditions of the past seven years have affected the earnings on the farm operators' own capital as distinguished from the rates they paid on borrowed capital or on rented farms. In making this distinction farm operators may be likened to the stockholders of the farm industry, while the inactive city owners of rented farms and the holders of farm mortgages may be considered the preferred stock and bondholders.

### Reward for the Farmer's Labor and Management

The reward for the farmer's labor and management may be computed by deducting from the net income available for capital labor and management, shown in Table 13, a current conservative interest return on the capital investment. The results of this computation, using 4.5 per cent as a reasonable return for the farm operator's capital investment, are shown in Table 14 reduced to a per farm basis.

TABLE 14.—*Reward, per farm family, for labor and management*

| Year | Income available for capital, labor, and management [1] | Interest allowance on net capital investment per farm [2] | Reward for labor and management |
|---|---|---|---|
| | *Dollars* | *Dollars* | *Dollars* |
| 1919–20 | 1,246 | 329 | 917 |
| 1920–21 | 684 | 287 | 397 |
| 1921–22 | 514 | 244 | 270 |
| 1922–23 | 682 | 242 | 440 |
| 1923–24 | 766 | 233 | 533 |
| 1924–25 | 854 | 230 | 624 |
| 1925–26 | 879 | 231 | 648 |

[1] Net income available for operators' capital, labor, and management calculated on the basis of the number of farms interpolated between 6,448,000 in 1920 and 6,372,000 in 1925.

[2] Interest allowed on operators' net capital investment at 4.5 per cent.

In 1919–20 the income per farm for capital, labor, and management amounted to $1,246, of which $917 represents reward for the farmer's physical and managerial efforts. During the depression these returns were greatly reduced, but in 1925–26 the former amounted to $879 and the reward for labor and management $648.

For a proper interpretation of these earnings per farm operator it is necessary to consider at least the following questions:

How do these earnings compare with wages of hired labor?

How do they compare with wages earned by factory workers?

How have the recent changes in cost of living affected the buying power of the farm operator, farm laborer, and factory worker, and their ability to maintain their separate standards of living of 1919–20?

The answers to these questions appear in Table 15, where the net income (for labor and management) per farm family are compared with farm wages and factory wage earnings by expressing each of these as indexes or percentages of their earnings in 1919–20 (columns 1, 2, and 3), and where each of these series is adjusted for changes in the cost of living (see columns 4, 5, and 6).

TABLE 15.—*Indexes of net income per farm family, farm and factory wage earnings, and of their relative purchasing power*

[1919–20=100]

| Year | Net income per farm family [1] | Farm wages without board [2] | Factory wage earnings per person employed | Relative purchasing power [3] of — Net income per farm family | Relative purchasing power [3] of — Farm wages | Relative purchasing power [3] of — Factory wage earnings per employee |
|---|---|---|---|---|---|---|
| 1919–20 | 100 | 100 | 100 | 100 | 100 | 100 |
| 1920–21 | 47 | 115 | 104 | 47 | 114 | 103 |
| 1921–22 | 34 | 77 | 88 | 39 | 89 | 101 |
| 1922–23 | 51 | 74 | 95 | 60 | 87 | 112 |
| 1923–24 | 61 | 82 | 100 | 70 | 94 | 115 |
| 1924–25 | 70 | 83 | 100 | 81 | 97 | 116 |
| 1925–26 | 72 | 84 | 103 | 81 | 94 | 116 |

[1] Net income for labor and management plus an allowance ($60) for residential value of farm dwellings.

[2] Calendar year averages, 1919=100.

[3] The first 3 columns of this table adjusted for the following changes in the cost of living in the United States for December of each year: 1919, 100; 1920 101; 1921, 87; 1922, 85; 1923, 87; 1924, 86; 1925, 89.

It appears from this comparison that the farmer's money income was affected by the postwar depression a year earlier and more seriously than either farm or factory wage earnings, that the recovery has been much slower, and that it is still incomplete. Factory wage earnings per person employed fell in 1921-22 to 88 per cent of the 1919–20 figure, equaled the 1919–20 earnings in 1923, and were maintained at that level for the past three years. Income per farm family in 1921–22 dropped to one-third of the predepression income and during the past year, after four years of gradual improvement, reached 72 per cent of the 1919–20 earnings.

### Comparison with Other Industries

If these earnings are adjusted for the changes in cost of living in the United States since 1919, it is found that the purchasing power of the average farmer's income during 1920 and 1921 dropped to less than half of what it was in 1919–20, and during the recent recovery, gradually reached 81 per cent of the predepression purchasing power. Farm wages dropped less and can now buy about 94 per cent of the amount of goods and services they were able to buy in 1919. The purchasing power of employed factory workers, on the other hand, has throughout the past six years remained greater than in 1919–20, and during the past three years has averaged 16 per cent above. In other words, the farmer with his net income during the past two years could buy 81 per cent of the things he was able to buy before the depression, while employed factory workers could buy 116 per cent of a comparable amount.

---

**INCOME Data Show Earnings Vary Widely** Farm business records available to the United States Department of Agriculture and the agricultural colleges and experiment stations show that some farms in every locality return larger incomes than others from a year's operations. This holds true whatever the type of farming, and whether the year be a good one or a poor one. It is true whether the income be expressed in terms of farm receipts, farm income, or labor income. Farm income, in this connection, means farm receipts less expenses, and labor income means farm income less an interest charge for use of the farm capital.

In all, data are on file in the Bureau of Agricultural Economics from 70,516 farm business records from 450 localities in 45 States and they cover the years 1907 to 1924. Figures 124 and 125 illustrate how labor incomes vary from farm to farm in two localities.

Comparisons should not be made between these two localities as to highest, lowest, or average labor incomes, because unlike economic conditions prevailed during the periods represented. One locality was selected to show variations from farm to farm in a single year; the other, over a period of several years.

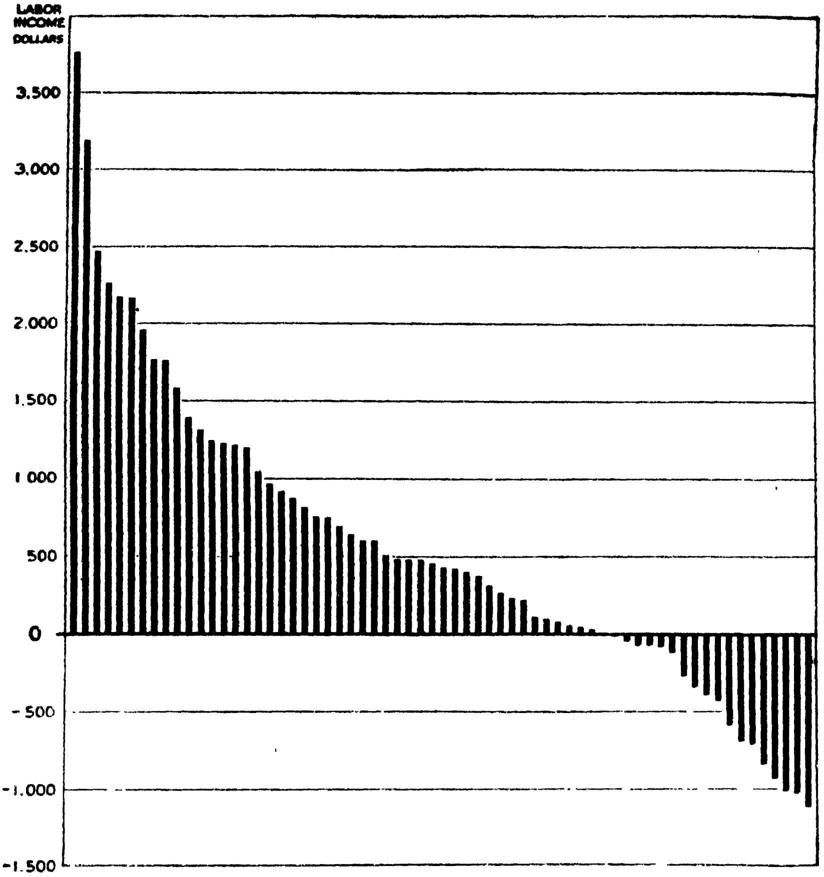

FIG. 124.—How the labor incomes from 65 wheat and dairy farms near Middletown, Del., varied in 1924. The highest labor income was $3,761, the lowest – $1,122, and the average $554

## Results by Groups

By grouping a large number of the farm business records by labor incomes and into periods of different economic conditions, the labor incomes were:

Over $2,000 from—
  4.5 per cent of the farms from 1910 to 1915,
  15.8 per cent of the farms from 1916 to 1919, and
  6.6 per cent of the farms from 1920 to 1922,
From $1 to $2,000 from—
  67.2 per cent of the farms from 1910 to 1915,
  66.0 per cent of the farms from 1916 to 1919, and
  36.9 per cent of the farms from 1920 to 1922.
Zero or less from—
  28.3 per cent of the farms from 1910 to 1915,
  18.2 per cent of the farms from 1916 to 1919, and
  56.5 per cent of the farms from 1920 to 1922.

From these figures it may be observed that: While most of the farms during the first and second periods returned from $1 to $2,000 in labor income, a much larger percentage of them returned over $2,000 from 1916 to 1919 than from 1910 to 1915, and a much smaller percentage of them returned zero or less.

Although about as many of the farms returned over $2,000 for the labor and management of the operator from 1920 to 1922 as from 1910 to 1915, just about twice as many of them returned zero or less.

To present the variation in incomes in another way, the records were grouped by periods as before, but with one-fifth of the farms highest in labor incomes in each locality in one group, the one-fifth second highest in another group, etc.

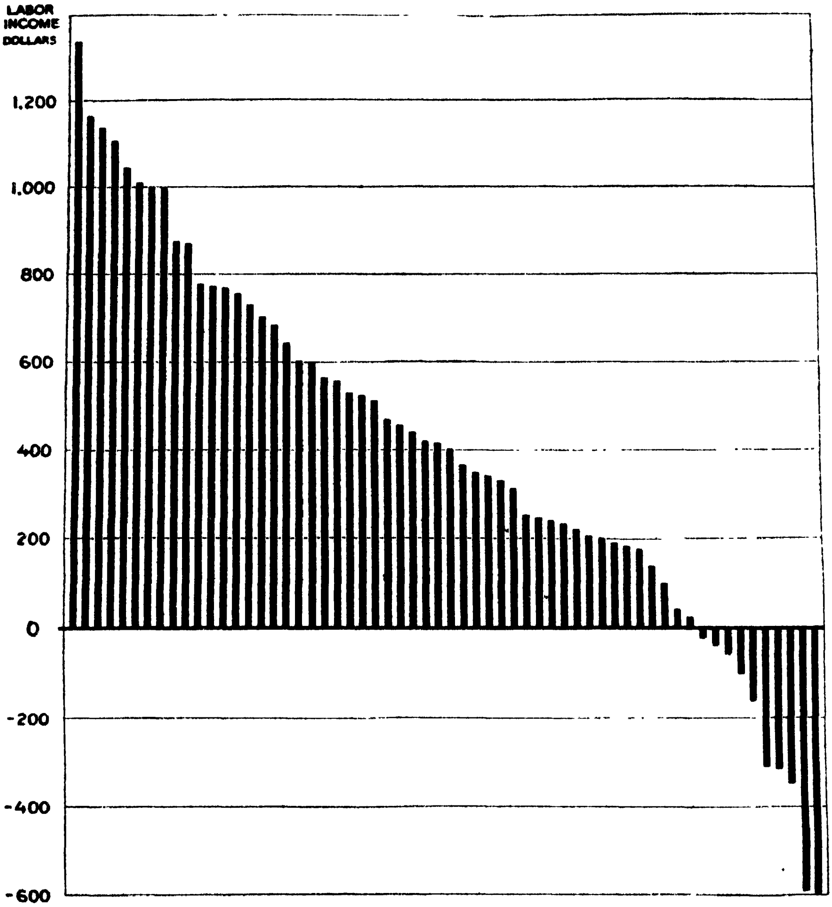

FIG. 125.—How the labor incomes from 60 dairy and hog farms near Verona, Wis., varied over the period 1913 to 1917, the income for each farm being a five year average. The highest labor income was $1.337, the lowest —$598, and the average $408

There was over $2,000 difference between the average labor incomes of the highest and lowest fifths during the first period; over $3,000 during the second period; and over $4,000 during the third.

The group highest in labor income in the first and last periods averaged about as much as the group second highest in 1916 to 1919, whereas the group highest in 1916 to 1919 stood out with an average about twice as much as the highest in the two other periods.

The group third highest in 1910 to 1915 averaged about as much as the group fourth highest in 1916 to 1919, and as the group second highest in 1920 to 1922.

Only the group lowest in labor incomes averaged less than zero in both the periods 1910 to 1915 and 1916 to 1919, whereas all but the groups which were highest and second highest, averaged less than zero in 1920 to 1922.

H. W. HAWTHORNE.

## INFERTILITY in Cattle and Vitamin Diet

The dairy-cattle industry is suffering a constant economic drain and loss of valuable hereditary material because of uncertain breeding ability, delayed conception, and temporary sterility of both males and females. These conditions are found in heifers as well as in older cows and are causing much concern to dairy farmers and breeders of dairy cattle. In ordinary practice a cow is expected to calve once in each period of 12 to 14 months and is bred accordingly. Failure to conceive to the first or second service seriously interferes with the regularity of herd management and frequently results in an extended period of low or unprofitable production between calvings, thereby reducing the average earnings of the herd.

### Effect on Rats Is Clue

The discovery by other investigators of the effects on the reproductive powers of white rats of feeding a ration deficient in vitamin E led to the conclusion that this shy breeding trouble in cattle might be similarly caused, particularly since it prevails in herds where management and feeding are highly specialized and also in herds where natural feeding conditions vary from one extreme to the other.

Sprouted oats have been reported to be one of the abundant carriers of vitamin E. For this reason this feed was selected for trial to determine its effect on the uncertain breeding condition in cattle.

During 1923 a limited trial was conducted in the Government dairy herd at Beltsville, Md. The favorable results which followed led to preparations for more extensive feeding of sprouted oats. From this later trial, thirteen animals have already been pronounced pregnant after receiving sprouted oats for periods varying from 10 to 122 days. These cases fall naturally into two distinct groups of 6 cows and 7 heifers.

### Results of Sprouted-Oats Ration

Space does not permit a detailed discussion of each case, but the 6 cows varied in age from 8 to 3½ years. The number of services before oats were fed ranged from 5 to 17, and the average length of time from last previous calving to the first oats feeding was 14 months. Two of these cows conceived at the first service after receiving oats, two at the second, one at the third, and the other at the sixth service. The intervals from first oats feeding to conception ranged from 19 to 132 days, the latter in the case of the cow requiring six services.

Six of the seven heifers on this trial were being bred for first calf, the other for second after an abortion. Two were bred four times, two three times, and the others were unbred previous to oats feeding. The object of this work was to determine whether sprouted oats would be effective in reducing the number of services per initial conception. Four of the heifers conceived at the first service subsequent to oats feeding, the interval ranging from 10 to 19 days. The others required 3, 4, and 5 services before settling, and were fed 91, 113, and 114 days, respectively. This heifer group includes one animal which had shown no signs of heat up to 18 months of age but came in season 10 days after receiving the first oats, and conceived at the fourth service. Although there are no direct checks on these heifer trials, it is significant that conception after oats feeding required an average of two and two-sevenths services, whereas the average for all heifers in the herd is approximately four services for initial conception.

Additional heifers are now receiving oats before first breeding in order to obtain further data on this subject.

M. H. FOHRMAN.

## INSECTICIDE and Fungicide Board's Work

The insecticide act of 1910 is a Federal enactment designed to prevent the manufacture, sale or transportation, in interstate commerce, of adulterated or misbranded insecticides, fungicides (including disinfectants), lead arsenate, and Paris green; to prevent the importation of such misbranded or adulterated articles into the United States, and the exportation of such articles out of the United States.

Under the provisions of the act the Government is empowered to proceed criminally against persons who make interstate shipments of misbranded or adulterated goods, or against those who offer for sale adulterated or misbranded goods in the Territories or the District of Columbia. The Government is further empowered to make seizures of misbranded or adulterated articles shipped in interstate commerce and remove same from the channels of trade. The act also authorizes the Government to refuse entry into the country of misbranded or adulterated goods.

Penalties are provided, consisting of fines for a first offense and fines or imprisonment, or both, for a second offense.

Some of the principal features of the law are: (1) Definite standards for lead arsenate and paris green; (2) a requirement that a statement be made on the label relative to the active and inert ingredients; (3) a requirement that the total and water-soluble arsenic be stated; (4) a requirement that no false statement, design or device regarding the article or the ingredients or substances contained therein shall appear upon the label; (5) a requirement that a product shall be up to the standard under which it is sold and that it shall not be injurious to vegetation when used as directed by the manufacturers.

### Organization

In the enforcement of the act, the Secretary of Agriculture is aided by a board composed of four scientists, one each from the Bureaus of Chemistry, Entomology, Animal Industry, and Plant Industry.

Working under the direction of these four scientists in the bureaus involved is a corps of chemists, bacteriologists, microscopists, entomologists, plant pathologists, and veterinarians, who analyze and test the various insecticides and fungicides appearing on the market. In addition to the various scientists actually employed by the board, various experts in the four bureaus involved are freely consulted and aid the board in determining whether or not the various products which come under the act will do what is claimed for them.

The board maintains a central executive office which directs the activities of a corps of inspectors, attends to all fiscal and business affairs of the board, arranges for hearings, collects evidence and prepares cases for reference to the solicitor of the department.

### Enforcement of the Act

A force of inspectors is distributed over the United States for the purpose of inspecting shipments, collecting official samples, and getting evidence of violation of the law. Special attention is given to the collection of samples of insecticides and fungicides which are suspected of being adulterated or misbranded and to new preparations as they appear on the market. The samples collected are transmitted to the board under seal with complete records to show interstate shipment. The samples are assigned by the board to one or more of the four groups mentioned above and are analyzed and tested by the proper scientists.

If upon examination any sample is found to be in violation of the act, charges are prepared and if there has been substantial violation of the law the shipper is cited to a hearing. If no violation of the law is shown the case is placed in permanent abeyance. If a nonflagrant violation of the law is shown the matter is taken up with the shipper by correspondence.

After a shipper has answered citation, a full report of the hearing, accompanied by all the records, is submitted to the board. If prosecution is decided upon the case is transmitted to the solicitor of the department with the recommendation of the board. The solicitor prepares the case for the Department of Justice to which department it is forwarded by the Secretary of Agriculture. From the Department of Justice the case is forwarded to the proper United States attorney for prosecution. Notices of court judgment are prepared and published for the information of the public. In some cases the manufacturer makes such answer to citation that the board takes the case up with him by correspondence rather than court action.

In case of seizure action the procedure is quite similar to that outlined above, except that a seizure is made without previous citation of the shipper and the case is referred by the Secretary of Agriculture directly to the United States attorney in whose jurisdiction the goods are found.

Some of the more important articles covered by the act are insecticides and fungicides for general agricultural use, such as calcium arsenate, lead arsenate, bordeaux mixture, fish oil soaps, kerosene emulsions, lice and mite killers, lime-sulphur solutions, Paris green, dips, fly repellents, mange preparations, insecticides used in the household, disinfectants, etc.

The law has been actively enforced since January 1, 1910, and up to July 1, 1926, samples from 16,242 domestic and import shipments have been collected and examined; 1,539 cases having been reported to the courts to institute criminal action or seizure proceedings. Disposition has been made of 2,801 cases by correspondence with the manufacturers.

Various investigations have been made relative to basic facts which it was necessary to determine in order to enforce the provisions of the act, most of which have been published for the benefit of the consuming public and manufacturers.

Thousands of investigations have been made by the entomologists and the plant pathologists of the board to determine whether certain ingredients were active or inert and whether they were injurious to vegetation. Chemists of the board have investigated and devised many new analytical methods for examining insecticides and fungicides.

### Board's Work Far Reaching

The activities of the board have been very far-reaching. When it is considered that all food-producing crops, all fruit-producing crops, all food-producing animals, the great cotton and tobacco crops, and wool-producing animals are all subject to the ravages of destructive insects or fungous diseases, and that growers are dependent to a large extent for their control upon the use of proper insecticides and fungicides, it will be realized that the enforcement of this act affects every individual in the Nation. The disinfectants and insecticides used in the home and public places are also subject to the provisions of the act. It has been estimated that the total annual losses from insects and fungi in the United States is in excess of $1,500,000,000. A considerable part of this loss can be avoided by the use of high-grade insecticides and fungicides.

Unless high-grade insecticides and fungicides of standard strength are used, which will do what is claimed for them, the treatment of crops and animals will be a partial or total failure and the grower will not only suffer the loss in price he paid for his insecticide or fungicide but will suffer the much more serious and enormous losses caused by insects and fungi (including bacteria).

### Most Labeling True

As a result of the enforcement of the insecticide act, it is probable that about 80 per cent or more of the labels now used on interstate shipments of standard agricultural insecticides and fungicides bear statements that are absolutely true or only slightly faulty. It is unusual to find on the market at the present time samples of lead arsenate and Paris green which are not in conformity with the standards required for such products. Yet some 10 to 15 years ago it was a common occurrence to find on the market samples of lead arsenate adulterated with water, samples of Paris green adulterated with sand and sodium sulphate, and even in some cases samples of Paris green which did not contain any of this material. The labels of hundreds of agricultural and other insecticides and fungicides have been corrected so as to give proper dilutions for use; the adulteration of pyrethrum powder has been greatly reduced; the selling of lime-

*sulphur solution, Bordeaux mixture, tobacco extract, dips, etc., under false claims relative to composition and efficacy have been greatly* reduced. Finally, and of extreme importance to the country, the activities of the board, carried out by seizure, prosecution, and education, have been of great service in protecting the cotton planters of the South against the purchase of low-grade calcium arsenate.

J. K. HAYWOOD.

**INSURANCE Against Fire and Storms** The insurance needs of the farmers are numerous and varied. Few if any industrial groups are subject to losses from a wider range of hazards. The farmer's buildings, equipment, and livestock are subject to loss or destruction by fire, lightning, and windstorm to quite as great an extent as are improvements and personal property in the city. His livestock is also subject to loss from disease or accident. His crops are subject to a variety of climatic and other hazards. He is as much in need of life insurance and various forms of accident and casualty insurance as is the man in most lines of commerce or industry.

For many of his insurance needs the farmer, so far as he provides for them at all, relies largely upon commercial agencies intended to serve all economic groups. A large percentage of farmers, however, have found it possible to meet certain of their insurance needs at a marked saving in cost by means of specialized agencies or organizations under their own management and control. This is particularly true in the field of fire and windstorm insurance.

Farmers' mutual fire insurance companies constitute an increasingly important source of insurance protection to the farmer. The number of such companies has not materially increased in recent years. The organization of new mutuals of this type has been largely offset by consolidations of smaller companies. The business territory of existing organizations has, however, been considerably extended in numerous cases, and the total volume of insurance carried shows a steady and substantial growth. Farmers' mutual fire insurance is by no means a new and untried experiment. The oldest companies in this class have passed the century mark. But the most rapid increase in number of such organizations took place in the last quarter of the past century.

### Two Thousand Farmers' Fire Mutuals

The present number of farmers' mutual fire insurance companies in the United States is nearly 2,000, and the total amount of insurance carried by them exceeds $9,500,000,000. The average annual cost of insurance during the past five years has been approximately 26 cents per $100. This average cost is about 2 cents per $100 greater than the average annual cost during the preceding five-year period. This slight increase in cost is by no means surprising. The postwar depression in agriculture, like most such experiences, has had a decided tendency to increase fire losses on the farm. Maintenance, upkeep, and replacements of property have in many cases been unavoidably neglected. Many of the commercial companies, in spite of rates materially higher than the cost charges in the farmers' mutuals, have found it necessary to restrict their activities in the field of farm fire insurance, and a few such companies have entirely discontinued their farm departments.

About 15 per cent of the farmers' mutual fire insurance companies write so-called combined protection, covering against windstorm as well as fire and lightning. These are in general the larger companies operating in a number of counties or in an entire State. Those with more restricted business territory very properly leave the wind hazard to specialized windstorm companies operating on a state-wide basis or at any rate covering a considerable number of counties. In about a dozen States of the Middle West these windstorm mutuals are closely allied with the more local fire insurance mutuals, to the marked advantage of both classes of companies.

### Scope of Mutual Insurance

Farmers' mutual insurance is now rather generally available to all farmers of good standing among their fellows, in all States outside of the Cotton Belt and certain of the Mountain States. In the Southern and Mountain States only a relatively small number of such companies are in operation, and these fall far short of covering the field.

Few, if any, attempts at cooperation among farmers have proved so generally successful as have their efforts to provide themselves with fire insurance by means of mutual companies owned and controlled by themselves. Essentially the same can be said of farmers' windstorm insurance, where companies for this purpose have been so organized as to cover a substantial territory and have been operated in close contact with the local fire insurance mutuals.

V. N. Valgren.

---

## IRRIGATION and Its Cost to the Farmer

A fertile soil, a persistently industrious summer sun, and moisture when it is needed, make the ideal combination upon which the agriculture of the West is founded. Given a dependable water supply, the irrigation farmer carries his crops to a bountiful harvest, free from the worry of drought and storms which besets his eastern competitors. Hence his has been called an easy way to farm, and his lot has been envied.

It is far from being easy. Several seasons must elapse and a multitude of operations must be performed before a new irrigated farm is at its best. That is true of any farm, of course; but there are things to do preceding the actual use of water which are costly in time, strength, and money, and which are not necessary in the humid climates.

Even after dams and canals, for which the farmer eventually must pay, have provided the means by which water is brought to the land, the stubborn desert shrubs and bushes must be uprooted and removed, the fields must be leveled so that the water may be sent to every part of them, and farm ditches and irrigation structures must be installed to effect that distribution. Special tools and apparatus must be bought or made with which to do these things. The operations themselves are tedious and must be done carefully at the very start if later exasperations and expense are to be avoided.

Moreover, the periodic application of the water to the growing crops is not automatic. When the farmer's turn for water has come, he must take it or lose it altogether. Often he must do the work at night. When it is remembered that he has also to cultivate his fields and harvest his crops as does any other farmer, it will be realized that irrigation is not at all a cheap and easy mode of farming.

### Cost of Irrigation Farming

If not cheap, just what does farming under irrigation cost? Any answer must be qualified, because the West is large and its agriculture is shaped by many factors besides the prevalence of irrigation. However, some significant averages have been derived by the division of agricultural engineering, Bureau of Public Roads, and the division of land economics, Bureau of Agricultural Economics, from the results of a cooperative study made to determine how much irrigation farmers can afford to pay for water.[8]

Of course, cost of water is only one item in the farmer's cost of producing crops, and permissible cost of production depends upon receipts; hence it is not possible to make a definite statement as to permissible cost of water for any type of farming. It is possible, however, to get comprehensive data as to costs and returns from farming under irrigation, and on the basis of the data as to other costs and as to returns, to determine approximately how much net return is available for paying for water. The study was made on that basis with the incidental purpose of getting information on the cost of clearing and leveling land and building farm ditches.

### Representative Enterprises Canvassed

To make the averages fairly representative, enterprises were selected for canvass which it was thought would reflect the principal interests upon which the agriculture of various sections of the West has centered. The largest community canvassed was that served by the Twin Falls Canal Co., an enterprise now owned and operated by the farmers near Twin Falls, Idaho, and one of the first of the many irrigation developments undertaken under the terms of the Carey Act. Its agriculture is extremely diverse. The Wenatchee reclamation district, of Washington, was selected to represent the fruit-growing industry, almost the entire revenue of the farmers being derived from the sale of apples.

Several enterprises in northern Colorado, central Wyoming, and western Nebraska were included to represent communities specializing in the production of sugar beets, grain and hay, and the feeding of stock. A small district in western Texas, where almost the only crop was choice alfalfa grown for shipment to eastern markets, represented another specialty. The Carlsbad, N. Mex., project and parts of the Rio Grande, Tex., project of the Federal Bureau of Reclamation were included not only to represent the development fostered by the Government but also to permit a study of the costs and profits of farmers in the Southwest whose principal crop is cotton. Similarly the land settlement at Durham, Calif., was included because of its inception by the State of California. In all, nearly 6,000 farms were canvassed, and more than 4,200 individual reports, from both owner-operators and tenants, were retained for study because of their evident dependability.

---

[8] A series of preliminary mimeographed reports on "Economic Limits of Cost of Water for Irrigation," by R. P. Teele and P. A. Ewing, has been issued.

### Average Cost in Cases Studied

Only a portion of these schedules represented irrigators who had occupied the farms since their reclamation; hence data on cost of clearing, grading and leveling, and of farm ditches and farm-irrigation structures were obtained from only a comparatively few of the farmers, some of whom, moreover, could supply estimates on only one or two of those expenditures. The average cost of these operations, which are a necessary part of preparing a farm for irrigation, from all the enterprises canvassed except those of the Bureau of Reclamation, was $27.55 per acre.

Such expenditures as those enumerated enter into the farmers' permanent investment. The nearly 2,600 owners who were operating their own farms reported farm land, improvements, equipment, stock, and cash worth on the average $16,714 per farm against which they owed debts amounting to $4,506, their equity therefore, being nearly three-fourths the total farm valuations. The average farm comprised 81 acres, of which 59 acres were covered by water rights. Hence the average irrigated farm had a value of $206 per acre. The land alone was valued at $11,392 per farm, or $141 per acre.

This included the value of the water right for the portion of the farm on which water was used. Water rights often are sold separately from the land, especially in the case of new enterprises, but since the canvass included many farms which had changed hands several times since the original cost of water rights had been absorbed, it was not feasible to show separately the investments in land and water. It was true, however, that most of the farms canvassed could not have produced crops without irrigation. Therefore the average farmer's investment was considered as dependent upon irrigation for its success. His yearly operating expenses, based on the record for 1924 (1923 in a few enterprises) were as follows: Feed, $221; fertilizer, $15; hired labor, $570; interest on debts, $294; taxes, $212; annual charge for water, $101; automobile truck and tractor upkeep and operation, $122; miscellaneous items, $319; a total of $1,854. Interest on net investment was calculated at $912, and depreciation on buildings and machinery at $235.

### Outlay for Fixed Charges

Of especial interest in these accounts was the fact that, while the annual water charge was only about one-twentieth of the total actual expenditures for farm purposes, water, taxes, and interest on debts—outlays more or less fixed in amount—together were almost one-third the entire expenditures for farm purposes, not taking into account depreciation and interest on net investment.

Perhaps a more significant way to examine the expense of farming under irrigation is to compare expenditures with returns. For instance, the three items just referred to—taxes, interest, and water—were slightly less than one-fifth the average farmer's receipts from farm products. The average farm operated by its owner had receipts from farm products totaling $41 per acre, $18 per acre more than expenditures not including depreciation and interest on net investment. The excess of receipts over expenditures per farm was $1,405. Inasmuch as the survey did not undertake to ascertain the worth of the labor of the farmer and his family, it appears that the average owner-operator received $1,405 in addition to the part of his living obtained directly from the farm, the value of which was also disregarded. This amount was available to meet the expense of operating his farm, cover depreciation, and pay himself interest on his net investment. In 1924 he had a balance of $258, after making those deductions.

### Average Farm Had Profit

Although the average irrigated farm showed a favorable balance in the year of the survey, a few more than one-fifth of the farms canvassed were operated at a loss, and an additional third showed net returns of less than $1,000, their balance being, in fact, less than enough to absorb depreciation and interest on net investment. If $1,000 be taken as fair return for the labor of the farmer and his family, more than half the farms failed to make wages for them, disregarding the part of the family living obtained from the farm, with nothing for interest and depreciation. However, the remaining half showed comfortable balances depending somewhat upon the size of the farm, the larger farms, as a rule, being the more profitable, except in such communities as that near Wenatchee where many farms, although representing large investments, were of relatively small acreage.

Moreover, as might be expected, the larger the proportionate area under water rights the greater were the returns from farm produce. On the other hand, the annual charge for water was a smaller proportion of the year's total, operating expenses for the farms showing highest net returns than for the average farm on the farms showing losses or small profits. This was true also as regards taxes and interest on debts. Going even further to emphasize the benefits of careful management, while the farmers receiving highest net returns reported almost insignificant sums paid them for labor off their farms, their outlays for labor were higher in the scale of total operating expenses than those of any other group.

Remembering the undeniable success of many farmers whose investments far exceeded the averages derived from the entire canvass, nevertheless it must be concluded that, if the farms were truly representative of irrigation farming generally and the survey year was a normal one, farmers can not afford to pay even as much as $141 per acre for water rights and land prepared for water unless some financing plan is available, such, for instance, as that offered by the Federal Government, which charges no interest to settlers on the projects of the Bureau of Reclamation, or unless some crop of high value especially suited to the climate or having particularly advantageous markets can be relied upon to augment the steadier but less liberal returns to be expected from diversified farming.

PAUL A. EWING.

**JAPANESE Beetle Control** Since the Japanese beetle (*Popillia japonica* Newman) was found to occur in the United States, in 1916, at a point near Riverton, N. J., it has increased its numbers and area of distribution until at the close of the summer of 1926 it occupied an area of approximately 13,919 square miles. The States of New Jersey, Pennsylvania, and Delaware are cooperating with the Federal Government in supporting this project, and large appropriations are being made for the further study, control, and prevention of spread of this insect.

The Japanese beetle became established in a territory particularly suited to its requirements. Here were large areas of sod land where it could breed in almost unlimited numbers, together with a variety of crops and plants on which it could feed, in many cases without restriction. The temperature and moisture conditions were favorable for its development, and these, together with an almost total absence of parasitic or predacious insect enemies, have enabled it to reproduce and multiply in unbelievable numbers. The density of infestation in the vicinity of Riverton, N. J., where the beetle has occurred for the longest time, has increased from year to year. This increase was marked by corresponding increase in damage to various crops, such as apples, peaches, cherries, grapes, and ornamental plants. It is only within the last year that the density of infestation apparently has reached its maximum.

### Life History of the Insect

The color of the Japanese beetle is bright metallic green, except the greater part of the wing covers which are coppery brown. The wing covers do not entirely hide the abdomen, and expose a row of five lateral and two posterior spots composed of white hairs. The under surface of the body is covered with short grayish hairs; the legs are dark metallic green, varying in tint in different positions. The adult beetles are about one-half inch long. The Japanese beetle has an annual life cycle. The adults begin to emerge between the 10th and 15th of June and are present until the middle of October. Each adult female beetle lays between 40 and 50 eggs in the soil. These are deposited at various times, usually at the rate of 3 to 5 eggs per day during a period of four or five weeks. When hatched the tiny grubs are about one-sixteenth inch long. They become full grown in about six weeks, at which time they reach a length of approximately 1 inch. The larvæ resemble our native white grubs in appearance, although they are considerably smaller than the larvæ of the common June beetle. As cold weather approaches in the fall they enter the soil to an average depth of about 7 inches, where they pass the winter in a quiescent condition. In the spring the larvæ become active again and move upward near the surface of the soil, where they feed for about a month, and by the latter part of May or early June transform to pupæ, and appear as adults two to four weeks later.

### Feeding Habits

Over 200 species of plants have been recorded as furnishing food for the Japanese beetle in New Jersey. Practically all of the economic crops grown in the infested territory are represented in the list. The more favored food plants include apple, sweet cherry, plum, grape, blackberry, clover, soy bean, and corn; shade trees, including linden, birch, elm, horse-chestnut, sassafras, willow, white oak; and many ornamental shrubs, particularly althea and rose. Flowering plants and weeds of many kinds are also attacked. Besides attacking the foliage (fig. 126), the adult Japanese beetles are especially partial to the fruit and are often found clustered on both apples and peaches in large numbers (fig. 127). As many as 278 beetles have been collected at one time on a single apple. The feeding is characteristic and resembles that done by the native rose chafers.

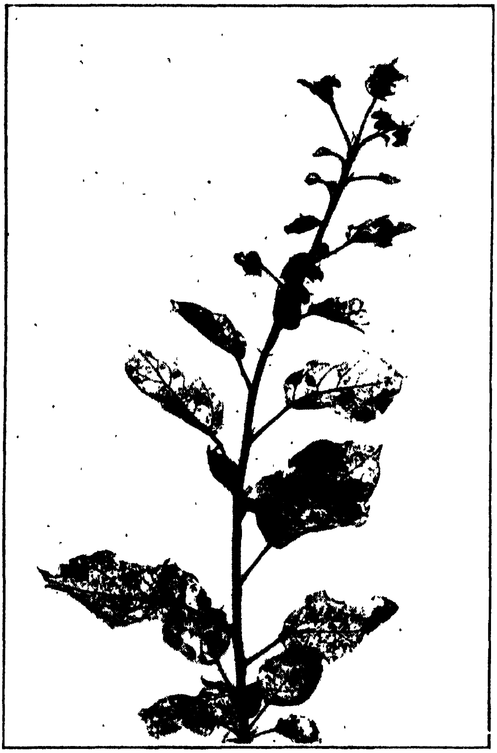

FIG. 126.—Japanese beetles feeding on apple foliage

When abundant, the larvæ or grubs of the Japanese beetle have become a serious pest in lawns, golf courses, and pastures. The rich soil in the heavy turf of golf courses has offered attractive places for the beetles to lay their eggs. The larvæ feed on the grass roots, cutting them off immediately below the surface of the ground.

The quarantine on farm products is intended to prevent the carrying of the adult beetle from the infested area to points outside on such articles as experience has shown as likely to harbor the adult beetle. At the present time the movement of the following articles is restricted: Sweet corn, beans or peas in the pod, cabbage, parsley, carrots with tops, beets with tops, onions with tops, lettuce, outdoor-grown flowers, hay, straw, unthreshed grain, and forage crops. The restrictions on these articles are effective during the time the beetles are on the wing; namely, between June 15 and October 15.

### Quarantine on Nursery Stock and Soil

The quarantine on nursery stock and soil is to prevent the carriage of any of the immature stages of the Japanese beetle to points outside the infested area. Since one or more of the immature stages are to be found in soil at all times, the regulations affecting the shipment of sand, soil, earth, peat, compost, and manure are effective throughout the year.

The absence of any natural or parasitic enemies of the Japanese beetle became apparent soon after its discovery in New Jersey. Therefore, two experts were sent to Japan in 1920 for the purpose of studying the insect in its native home and of finding, rearing, and shipping to this country any of its natural enemies which seemed desirable.

Large shipments of parasites have been received from Japan, many of which have been reared and released in the heavily infested area near Riverton and Moorestown, N. J. During the summer of 1924 the tachinid fly *Centeter cinerea*, which lays its eggs on the adult beetle and kills it within about five days, was found to be established near Moorestown. In 1925, during the first two weeks of beetle emergence, an average of 8 per cent of the beetles were parasitized by the Centeter, and before the end of the season it was found that the parasite had extended its range to include approximately 40 square miles. A large number of dexiid flies of the species *Prosena siberita* have been imported and released in the Moorestown district, and likewise a large number of solitary wasps of the genus Tiphia have been imported.

FIG. 127.—Japanese beetles feeding on apples

### Control of the Larvæ

A method has been developed for the control of the larvæ in lawns, contemplating the use of a 71 per cent emulsion of carbon disulphide diluted at the rate of 1 quart of concentrated emulsion to 50 gallons of water. The dilute emulsion is applied to the sod at the rate of 2 or 3 pints to the square foot.

As the beetles became more numerous the usual sprays applied for the control of many of our native pests were not effective. Therefore, a large amount of work and study has been devoted to the working out of measures whereby apples, peaches, grapes, and ornamental plants could be protected from their attacks.

On ornamental plants, the best control was obtained with a spray consisting of a mixture of lead arsenate and lead oleate, at the rate of 4 pounds of the paste to 50 gallons of water. A mixture of lead arsenate and flour, used at the rate of 3 pounds of lead arsenate and 2 pounds of flour to 50 gallons of water, gives good control on apples, cherries, grapes, and plums. It was found that lime gave very good protection as long as it remained on the foliage or fruit. However, lime does not have good sticking qualities and is easily washed off by rains.

It is anticipated that a pyrethrum soap developed at the laboratory may be extremely useful for the householder who wishes to destroy the beetles on rose bushes and other flowering plants. Additional investigational work is continuing along the lines of developing a substitute for arsenate of lead which can be used in obtaining effective control of the Japanese beetle. Several materials have been developed which are showing promise, although it is not expected that they can be recommended until much further work has been done.

## JERUSALEM Artichoke an Inulin Source

The Jerusalem artichoke (*Helianthus tuberosus* L.) grows as a native plant over a large part of the United States, being most abundant in the Corn Belt. It is usually found in the most fertile soils, especially in the alluvial soils bordering streams, and occurs from Alabama to Ontario and from the Atlantic coast to Kansas and Nebraska. It was introduced into Europe, probably by the French, in the early part of the seventeenth century. It was erroneously credited to Brazil, and this mistake was not corrected by botanists until the decade between 1880 and 1890. As a crop plant it is new, having had little improvement at human hands. The present varieties in the United States have all been wild-

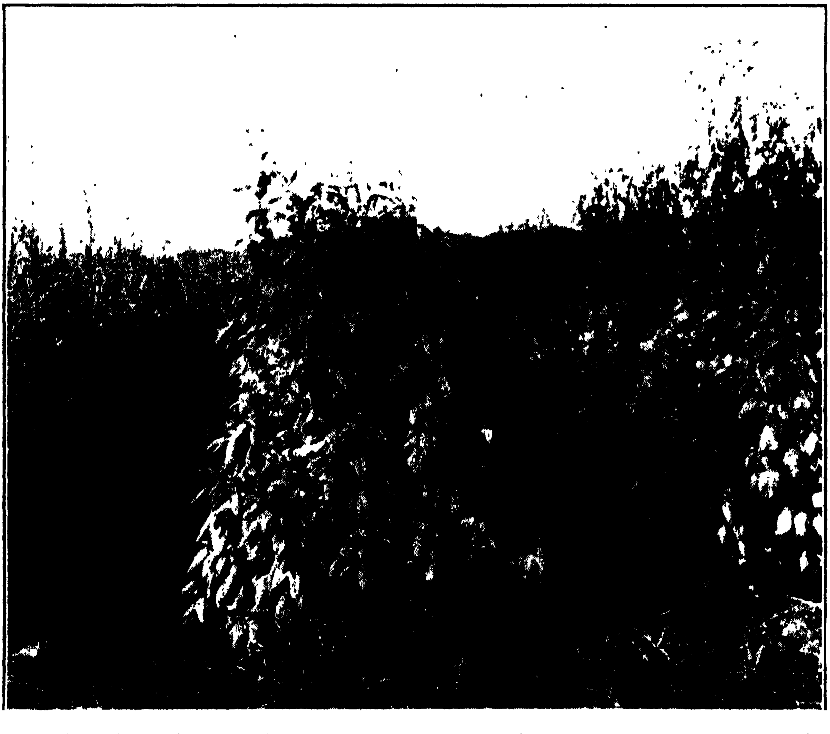

FIG. 128.—Jerusalem artichoke varieties. Left to right, from San Faucisco, Calif., Toronto, Canada, and Norfolk, Va.

lings. It thus forms an interesting study in the origin of cultivated crops.

The Jerusalem artichoke has a varied usefulness. It is peculiar among our cultivated field crops in that it stores its carbohydrates as inulin rather than as starch. This character is connected with much of its interest and usefulness.

At present it is most extensively grown in France, where about 300,000 acres are planted annually. The tubers there are largely used for feeding cattle and sheep, though part of the crop is fed to swine and horses. It is very widely grown in both the Northern and Southern Hemispheres, being quoted by seedsmen from Sweden to New Zealand. Outside of France, however, it is nowhere an important crop. In the United States, where it is native, it is known to many people but is not extensively planted.

This plant is very productive and its culture is not expensive. But there are difficulties in storing the tubers, on account of shriveling and decay, and the plant has a considerable reputation as a weed.

### Uses as Human Food and Stock Feed

As a human food it gives a pleasant variation to potatoes and garden roots. Probably its widest use at present is in the form of home-made pickles. When boiled it is much more watery than potatoes or the ordinary roots. It has a decidedly sweet flavor in all types of cooking. Probably the best mode of preparation is as chips, made by frying thin slices in deep fat. These are very crisp and are much sweeter than potato chips. They may also be prepared by baking in a slow oven, thus becoming less watery.

Recent experiments have shown that the Jerusalem artichoke may be used by diabetic persons to a much greater extent than any foods containing starch. This fact has given it great interest to a large and apparently increasing group of people who are subject to this disease. Thus it appears to be on the way to wider use as a human food generally, since if used extensively as a food for diabetic patients its use will doubtless spread to other people.

Its greatest usefulness in the past has been as a stock feed. The tubers have been fed to all kinds of livestock. In France, as above stated, they are mostly used for sheep and cattle, and in this country they are most frequently grown for hogs. They have been highly recommended for this purpose, but have never superseded corn. The leaves and branches are also good stock feed and are extensively used abroad. The stalks may be cured in the same way as corn stover, or they may be made into silage. Judging by the past, it is not probable that the Jerusalem artichoke will make much headway against corn for fattening livestock or for forage or silage. In France it is grown outside of the limited maize-growing region, and in the United States it is most extensively grown in the South and in the Pacific Northwest where corn is not a very certain crop.

### Industrial Use

It has been investigated in Europe as a source of industrial alcohol and is apparently about as useful for that purpose as the beet. Some of the French crop of tubers is worked into alcohol.

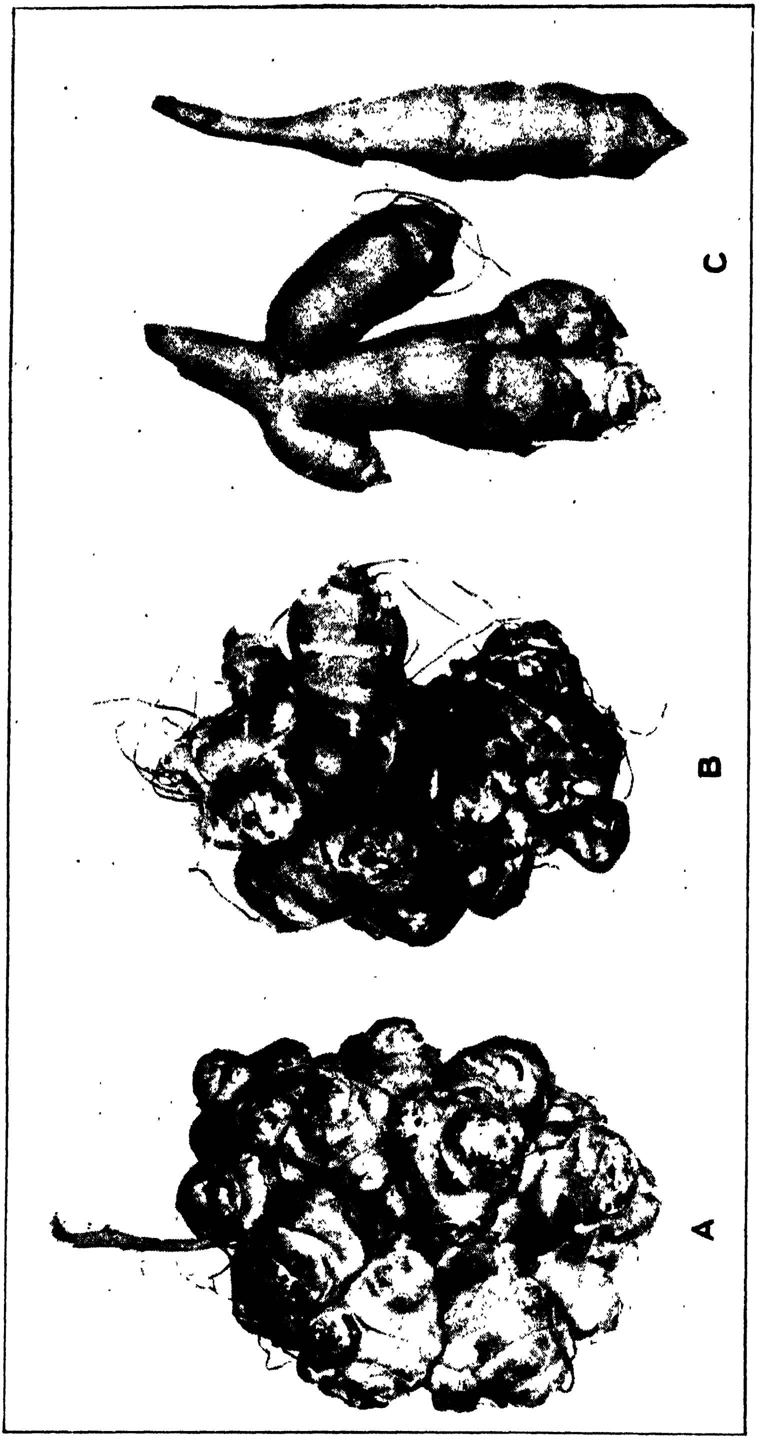

FIG. 129.—Three varieties of Jerusalem artichoke tubers. A, White; B, Ordinary; C, Spindle

At present it has promise as a source of levulose or fruit sugar,[19] which is obtained from the inulin contained in its tubers. Levulose has a sweetening power much greater than that of sucrose or cane sugar, which is the sugar most widely known. Levulose bears the same relation to inulin that dextrose (corn sugar) does to starch. Inulin is fairly widely distributed in the plant kingdom. The most promising producers are all members of the composite family, to which the sunflowers belong and which includes the Jerusalem artichoke, the dahlia, and chicory. Of the three, Jerusalem artichoke seems to offer the greatest promise as a source of levulose.

The tubers of different varieties tested at the Arlington Experiment Farm at Rosslyn, Va., vary in levulose-producing ability from 10 to 16 per cent, moist weight. They also vary greatly in productiveness and in adaptability to harvesting with machinery. Some 50 or more distinct types have been studied to some extent at the Arlington farm. There are probably many hundreds of varieties to be found in various parts of the United States east of the Rocky Mountains. Canada can also furnish many types. If the Jerusalem artichoke is to become important as a source of inulin it is important that as wide search as possible be made for the best producers, also that seedlings be grown and that crosses be made. The important characters on which to base selection are (1) short runners, so that the crop may be harvested by machinery; (2) productiveness; (3) high inulin content, and (4) earliness of maturity.

### First Native Field Crop

The subject may be summarized as follows:

The Jerusalem artichoke is the first plant native to what is now the United States to obtain a status as a field crop. It is most extensively grown at present in France, where the 1925 crop was grown on about 300,000 acres.

It stores its carbohydrates as inulin instead of starch.

As a human food it offers a variation from potatoes and has promise of increase in usefulness through its suitability for the diet of persons affected with diabetes.

As a forage crop, as either tubers or plants, it must compete with maize and will probably find its expansion outside the maize region.

As a source of levulose it has no competitors any better developed than itself, and it is here that its greatest present interest lies.

Its varieties are very numerous and are scattered over the United States and Canada, east of the Rocky Mountains and north of Georgia. Wide search is needed to find the varieties best adapted for inulin production.

D. N. SHOEMAKER.

---

[19] Levulose has been known for many years, but it has been very difficult to crystallize, and the pure crystalline form has been very expensive. The sugar laboratory of the Bureau of Standards has recently developed a method of crystallizing this sugar from a water solution. JACKSON, R. F., SILSBEE, C. G., and PROFFITT, M. J. A METHOD FOR THE MANUFACTURE OF LEVULOSE. Ind. and Eng. Chem. 16, 1924; p. 1250; FACTS ABOUT SUGAR 19: p. 586, 1924; THE PLANTER AND SUGAR MANUFACTURER 73: 1924, p. 469; Sugar 27: (1925), p. 9.

**LABOR Requirements Measured for Principal Crops** Farm crops may be divided into three broad groups with reference to the amount of man labor used in producing them. Tobacco, cotton, sugar beets, potatoes, fruit, and truck crops absorb relatively large quantities of labor. Corn, the grain sorghums, peanuts, and like crops need less labor than the more intensely cultivated crops, but more than most hay and small-grain crops which are usually produced with the least labor. This classification with respect to labor used is only relative. More labor may be used on a particular crop in some sections than is usually needed to produce some other crop of a more intensive nature in another part of the country.

Ordinarly, tobacco requires more labor per acre than any other major crop. Requirements for producing different types of tobacco differ, largely because of the different methods of harvesting, curing, and preparing the leaf for market. An acre of burley tobacco yielding from 800 to 1,000 pounds requires for growing, preparing for market, and marketing from 350 to 400 hours of labor. An acre of bright tobacco, the principal cigarette type, as grown in south-central Virginia and yielding 600 to 700 pounds requires about 400 to 500 hours of labor. In the same district 300 to 350 hours of labor will produce an acre of Virginia dark fire-cured tobacco yielding 800 to 900 pounds, and 250 to 275 hours of labor will produce an acre of Kentucky dark tobacco of the same yield. Labor required for producing a pound of tobacco of these types ranges from about 0.7 hour for Virginia bright to about 0.3 hour for Kentucky dark tobacco.

### Cotton's Labor Requirements

In the eastern cotton States (the old Cotton Belt), on farms where the yield of lint is 150 to 200 pounds per acre, 100 to 125 hours of labor are usually necessary to prepare, cultivate, harvest, and market an acre of cotton. In the black belt of Texas 50 to 60 hours of labor are utilized in producing an acre of cotton yielding 140 to 160 pounds of lint, while in the western district of the same State growers with similar yields normally expend only 35 to 40 hours of labor per acre. Requirements for producing a pound of lint cotton for the above districts range from about 0.7 hour of man labor in the Eastern States to about 0.2 hour in the western district of Texas.

Large level fields which permit the use of larger machinery for preparing the land and for cultivating the crop, together with seasonal conditions which make control of weeds easier are the chief reasons why western cotton growers produce cotton with less labor than do the growers in other districts.

The use of large machines also makes it possible to grow more cotton per man. In parts of Texas and Oklahoma growers frequently plant as much as 100 acres of cotton per man with extra labor for hoeing, thinning, and harvesting. Growers in the eastern cotton States usually plant from 10 to 20 acres per man.

From 65 to 100 hours of labor are normally used in producing an acre of potatoes. Average requirements for producing a bushel of late potatoes are about 0.4 hour in the Northern States, while 0.6 to 0.7 hour of labor is usually needed in producing a bushel of early potatoes in southern districts. In the New England States more labor is used on an acre of potatoes than in other late-potato districts, but the higher yields make it possible to produce a bushel of potatoes with about the same quantity of labor as is used in some of the other late-potato districts.

### Much Variation on Corn

In the production of corn, requirements in various districts differ largely because of different methods of harvesting, size of machines used, and yield per acre. In the Corn Belt where good-sized implements are used for preparing the land and cultivating the crop, and where the crop is harvested by hand from the standing stalk, from 15 to 20 hours of labor per acre are usually adequate with yields of 35 to 45 bushels. In some of the Southern States from 50 to 70 hours of labor per acre are ordinarily required for corn yielding 20 to 30 bushels when the stalks are cut and shocked and the ears are harvested by hand from the shock. In the North Atlantic States corn is usually harvested in this way and the requirements per acre are similar, though yields are higher.

Requirements for producing a bushel of corn in the various districts differ even more than do requirements per acre. Usually about 2.5 hours of labor are required for producing a bushel of corn and caring for the stover in certain Southern States as compared with about 0.5 hour in the Corn Belt when the ears are husked from the standing stalk and large level fields and large machines make it possible for one man to grow more acres of corn than in other producing districts.

Small-grain crops require relatively little labor. Size of machines used, size of fields, lay of land, and climatic conditions affect labor requirements for producing these crops to a greater extent than does yield. Requirements for producing a bushel of wheat range from about 2.5 hours in the Southern States to about 0.3 hour in the Pacific Northwest. In the Western States combines are frequently used for harvesting and large teams or tractors are utilized for preparing land and for seeding, whereas in the southern and eastern districts relatively small machines and crews are used for all operations.

But little labor is usually required for producing an acre of most hay crops and practically all of this labor is required during the harvesting season. Requirements on a ton basis vary from 4.5 hours for clover hay to 7.2 hours for alfalfa on irrigated land. For annuals, such as cowpeas or soy beans, which are seeded for hay and cultivated during the growing season requirements are much higher than for other hay crops.

A. P. Brodell.

**LAND Settlement Policies** Returns from agriculture in recent years have been such that special inducements are necessary to attract men to the land. Restricted immigration and the general movement of labor into the industries have tended to intensify the customary shortage of settlers. The additional land still available for settlement far exceeds the present demand for agricultural expansion. This land is largely in private ownership, and a considerable portion of it must be cleared, drained, or irrigated before it can be cultivated or pastured. Individual settlers or colonization and settlement companies need liberal and specialized forms of credit to develop this type of land. The land is not of uniform productive value, and many large areas of poor land will have to be administered with great care if the settlers are not to suffer undue hardships.

The economic situation of agriculture and other factors not here discussed resulted in conditions that have demanded changes in land-settlement policies.

Among the most striking changes in these policies is the attitude of State officials and the general public toward practices used to attract settlers. Many private companies and many States now find their most successful forms of advertising to be offers of reasonable and workable terms of land sale and credit, the protection of settlers against exploitation either in the type of land sold or in other business transactions, and in the general supervision of the settlers' welfare by directing him to advantageous locations and by giving him advice or putting him in touch with State institutions that are able to assist him in adjusting himself to his new environment.

### Better Methods Adopted

The old practices of extravagant display advertising have been supplanted in many cases by a sober statement of facts in the form of official publications, crop and livestock reports, exhibits of bona fide products, and classified advertisements in the public press.

Various State agencies have been created to disseminate information tending to assist the people who contemplate settling in the State and to look after the incoming settlers after they are located. The work of these agencies includes selecting locations for colonization projects or for individual settlers, offering ready-made plans for colonization, keeping the settlers in touch with State and Federal agencies, controlling the sale of real estate by licensing real estate dealers, and personal follow-up work with the settlers who need advice in establishing themselves.

Several States through their State land-settlement boards have attempted to attract and establish settlers by selecting land for group settlements or for individual settlers, preparing the land for occupancy and cultivation and then selling it direct to settlers. This plan has operated with varying degrees of success.

In California and Washington the settlement boards purchased tracts of land, subdivided it into farm units, erected the necessary buildings and installed other improvements, constructed irrigation systems, prepared the land for irrigation, and planted some of it to crops. Sales contracts were adjusted to the financial standing of the settlers and the earning capacity of the land. Personal loans were granted for the purchase of livestock, necessary implements, and operating expenses. Community centers were established and a paid manager directed each colony. Settlers were required to be personally fitted to work their farms and to have a specified amount of capital. After the usual ups and downs three State groups were established under these plans: One of 52 settled farm units near White Bluffs and Hanford, Wash.; one of about 140 farms at Durham, Calif.; and one of about 230 farms at Delhi, Calif.

The settlement board of Oregon purchases individual farm units in different parts of the State. These units, under the direction of the Oregon Agricultural College, are improved, equipped, and operated until they are on a paying basis. They are then sold to farmers under special credit arrangements with the understanding that they will be operated somewhat as demonstration farms.

### Settlement Promotion Work

The constantly increasing areas of idle cut-over land in the Great Lakes States have led private owners and State officials to formulate policies to induce economic development of these lands.

In 1917 Minnesota inaugurated a plan to promote development on State-owned land. A revolving fund of $300,000 was appropriated for clearing unsold school and swamp land, but not more than $300 might be expended on each 40-acre tract. The State improvement board selected 600 tracts classified as agricultural land, cleared and plowed 5 acres on each tract and then offered them for sale at public auction. The purchasers were required to occupy the land and continue its improvement. Less than 200 tracts were sold, and the continuance of the plan necessarily awaits a revival of the demand for farms.

Under the Wisconsin farm mortgage association act, settlement and colonization companies are enabled to keep their credit in a liquid condition and to expedite the development of the individual farms in their projects, while the State is given considerable regulatory power over the companies. The mortgage associations may issue loans on first mortgage on improved or partially improved real estate up to 65 per cent of its appraised value; they may purchase first mortgages of like kind, and they may issue bonds secured by the pledge of the mortgages taken or purchased. Before a colonization company may take advantage of this law the plans of settlement and the land for the project, the terms of loans to the individual settlers, and the farms offered for security must be inspected and approved by the commissioner of immigration. The mortgage associations of the State have issued approximately $1,200,000 worth of bonds on a security of over 600 mortgages.

Michigan offers protection to settlers against the purchase of worthless land through the land certification act and detailed information as to the economic possibilities of idle land through the work of the land economic survey. State land certification is confined to land in private ownership and all expenses are paid by the owners. The land is examined by experts selected by the State and the certificates as to its agricultural possibilities are issued on the basis of the examiner's reports. The owners contract with the State to sell for agriculture only certified land. The cost to date has been about 16 cents per acre. The State is attempting to place before the public the advantages of certification in such a way that the demand for certified land will induce all private holders to take advantage of the act.

The Michigan Land Economic Survey is making a detailed scientific inventory of the land resources of underdeveloped counties for the purpose of formulating a policy for the economic use of the land. The survey is supported by State funds and works on a county basis regardless of ownership. To date the field work and mapping have cost less than 5 cents per acre.

### Loans to Ex-Service Men

Oregon, California, and South Dakota have attracted ex-service men to the land by granting them special loans for buying farms. In South Dakota the loans are granted jointly with loans from the rural credit board, and are secured by second mortgages. In Oregon the ex-service men borrow direct from the soldiers' welfare board up to 75 per cent of the purchase price of the farm, provided the loan does not exceed $3,000. The loans are granted only on improved land and are secured by first mortgage, payable on the amortization plan for a period of 28 years at 6 per cent interest. In August, 1923, over 1,500 ex-service men had used the loan system in buying farms. In California the loans are granted on land, which must be under ditch, with drainage provided but otherwise not improved, and must not exceed $7,500 in value. The soldiers' welfare board purchases the land and resells it to the ex-service men. In August, 1923, 12 men had bought farms with this loan.

Some of the irrigation States have adopted policies to attract both capital and settlers to their irrigation districts. A large number of States certify irrigation district bonds. In Washington the director of conservation is authorized to use portions of the revolving reclamation fund to purchase irrigation district bonds. Since the districts must conform to the regulations of the director before he will purchase their bonds he is able to exercise considerable latitude in governing the terms of sale for the land and other activities of the districts. Settlers in irrigation districts in Oregon are relieved from paying interest on the district bonds during the early stages of development, since the State is legally authorized to meet the interest charges during any or all of the first five years of the bonded period. No definite well-rounded program for directing and controlling land settlement has been adopted by any one State, but a few fundamental policies such as controlling the sale of real estate, land examination and certification, and specialized credit facilities have been inaugurated in several States.

B. Henderson.

## LAND Value Changes from 1920 to 1926

The value of farm real estate, which includes from two-thirds to four-fifths of the value of the farmer's capital investment, has since the peak of 1920 shown an apparently steady approach toward stability, but considerable regional variation both in the amount of change since 1920 and in the rate at which the change is still taking place.

As indicated in Figure 130, the course of the department's preliminary annual estimates of the value of all farm lands with improvements averaged for the United States has shown a steadily lessening rate of decline, although there is as yet no assurance that the bottom has been reached. On March 1, 1926, the index stood at a point slightly greater than 70 per cent of its 1920 high point. Reports of the recent census of agriculture as of January 1, 1925, recorded a drop of approximately a fourth during the five-year period since January 1, 1920.

Although other factors enter, the value of farms is obviously in large measure dependent upon current income and future prospects of income. Available net farm income data and the prices of farm products, as also indicated in Figure 130, have all shown a steady upward trend since the low point of the depression period. This has been reflected in an apparently progressive checking of the rate of decline in land values. When this declining curve of average values for the United States will be fully checked obviously depends in large measure upon the future course of the prices and yields of farm products, and of the various elements that enter into costs, including possible changes in methods or in products grown.

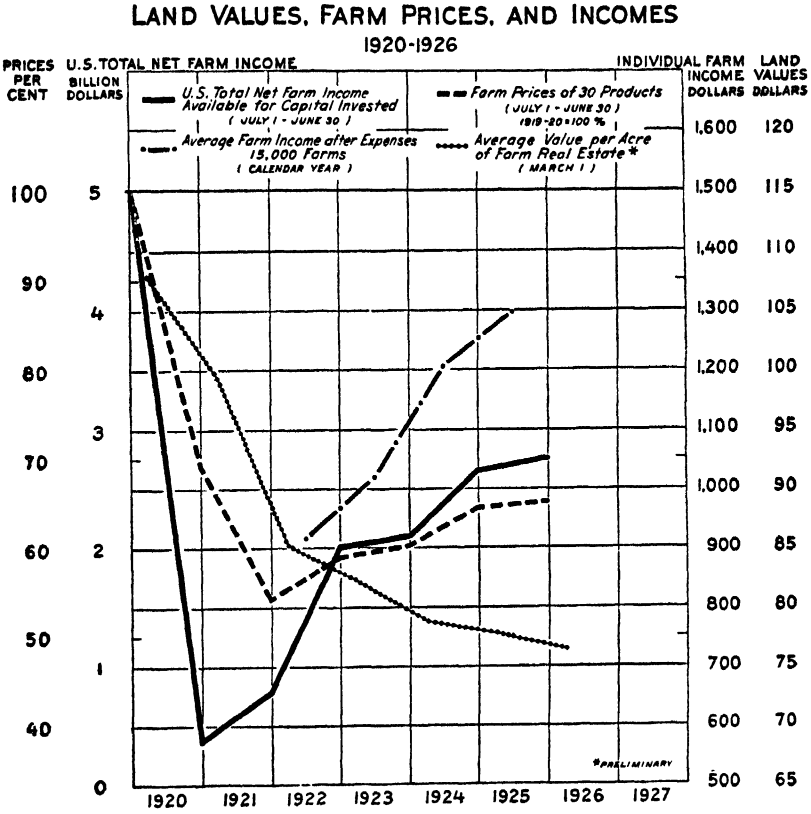

FIG. 130.—Land values, farm prices, and incomes, 1920–1926

Two other factors which will assist stability in values in many cases are:

(1) In a number of areas the foreclosures and other forced liquidations of the depression have probably already exerted most of their influence upon values, and their depressing effect may be expected to be progressively less as market absorption thereof gains momentum.

(2) Reductions in mortgage rates of interest have already been announced in a number of regions and an easing of the credit situation elsewhere appears to be underway with an improvement in country banking conditions and an apparently increasing general supply of funds seeking investment.

### Relationship to Commodity Prices

With respect to this adjustment of the value level it may be noted that, in relation to a dollar now worth in purchasing power but two-thirds of pre-war, farm real estate values (that is, land including buildings and other improvements) as returned by the 1925 census were really worth 11 per cent less per acre than in the census of 1910, although in current dollars averaging 35 per cent more. In 1925 on the basis of comparative total values, however, the aggregate value was in current dollars 42 per cent above 1910, but in unchanging dollars of a constant purchasing power, 6 per cent below. Comparison of the Bureau of Agricultural Economics' annual per-acre index of the value of all farm lands with improvements as of March 1 indicates the value (in current dollars) reached in 1926 to be slightly above that recorded for 1917, or about 25 per cent above the 1912, 1913, 1914 average; in terms of pre-war dollars as of 1912, 1913, 1914, approximately 20 per cent below the base period.

From this comparison, however, it can not be inferred that land values will necessarily readjust themselves to the general price level in the same relationship as existed before the war. That is to say, values expressed in dollars of a constant purchasing power may tend to reach stability at less than the 100 per cent which denotes pre-war parity. The general price level, for example, as measured by the United States Bureau of Labor Statistics' index of wholesale prices of all commodities has for the last four years fluctuated within relatively narrow limits about a horizontal trend about 50 per cent above pre-war. The index of average land values, on the other hand, is still declining and, as elsewhere mentioned, stood at about 25 per cent above pre-war (1912, 1913, 1914) early in the year.

### Taxes a Factor in Land Values

That this inference does not necessarily follow rests in the first place on the obvious basis that a general price index is not a net farm-income index, and the 50 per cent higher general price level of the last few years has by no means been coincident with a net income 50 per cent above pre-war, as farmers well know. In particular, the rise in farm taxes has been seriously out of proportion to the movement in the prices of farm products. Since taxes form one of the principal costs in farm ownership, the proportion of income required for their payment under postwar price levels has been and will continue to be a factor of no small importance in determining the level at which farm-land values will reach adjustment.

In the second place, it is not altogether improbable that land values in relation to income may reach stability in a changed relationship over that earlier obtaining, at least in certain regions. Studies made by the Bureau of Agricultural Economics[9] indicate that the ratio of current land income, as measured by cash rents, to current land value declined steadily from the opening of the century to 1920. In Iowa, for example, in which cash renting is fairly common, the ratio of gross cash rent to value fell from 7.7 per cent in 1900 to 4.3 per cent in 1910 and to 3.6 per cent in 1920. The subsequent sharp break in land values which for a generation "had never gone down" may serve for a time, at least, to check this apparently increasing capitalization of anticipated future increases and result in a higher ratio of current income to current value. Likewise, the disastrous experience of many "boom-year" purchasers of lands in which gross income ratios after deduction of taxes, depreciation, and upkeep of buildings netted in some areas of the Middle West less than 2.5 per cent upon value may have served to emphasize the importance of a more ample income ratio than had previously been accepted.

### Regional Variations

Although farm real estate values as returned by the agricultural census of January 1, 1925, showed an average decline from the 1920 peak of about a fourth, differences between regions in extent of the change were marked. Also, the year-to-year trends and turning points as indicated by this bureau's annual per-acre index have shown considerable regional variation.

Figures 131 and 132 present the percentages of change from 1920 to 1925, by States, as returned by the census.[10] Figure 131 shows the change in acre value; Figure 132, the change in total value. The latter, particularly in some of the Mountain States, may give a somewhat truer picture of the change in the value level because of the downward influence upon the per-acre average caused by large additions to the farming area of land of a relatively low average grade and value. The truth, at least, probably lies somewhere between. Conversely, considerable declines in total farm acreage in some of the Southern and Eastern States, presumably owing to the poorer grades going temporarily or otherwise out of agricultural use, had the opposite effect upon percentage change measured in terms of values per acre.

That values in a general northeastern group comprising primarily the North Atlantic States but extending westward into Michigan and Wisconsin and southward into Delaware, Maryland, and the Virginias should have declined little relatively to the country at large, or have actually increased, is owing in part to the fact that farm prices of dairy, poultry, fruit, and vegetable products so largely grown in these States maintained the highest levels during

---

[9] CHAMBERS, CLYDE R. RELATION OF LAND INCOME TO LAND VALUE. U. S. Dept. Agr. Bul. No. 1224; 132 p., illus., 1924.

[10] 1925 figures preliminary. Comparisons with available final figures, however, indicate the differences to be negligible.

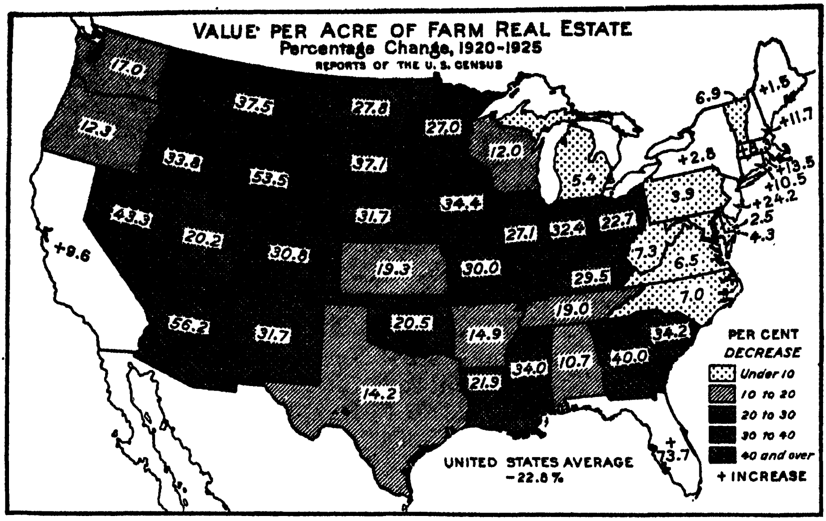

FIG. 131.—The extent to which farm real estate values changed from 1920 to 1925 varied considerably in different sections of the country. In some of the Mountain States large additions to the farming area of lands of relatively low value tended to exaggerate the declines in terms of value per acre. Conversely, the elimination of presumably poorer lands in portions of the South and East tended to minimize the per-acre declines

depression of any of the major farm-product groups. In some of the densely populated industrial sections of the East sustained or rising values were partially attributable to an apparently active demand on the part of urban workers for small farms easily accessible to city employment by motor bus or automobile. Although not directly entering into the census enumerations, considerable demand for farms for use as summer homes, camps, country estates, etc., probably exerted a sustaining influence in areas where farms had potential use as such.

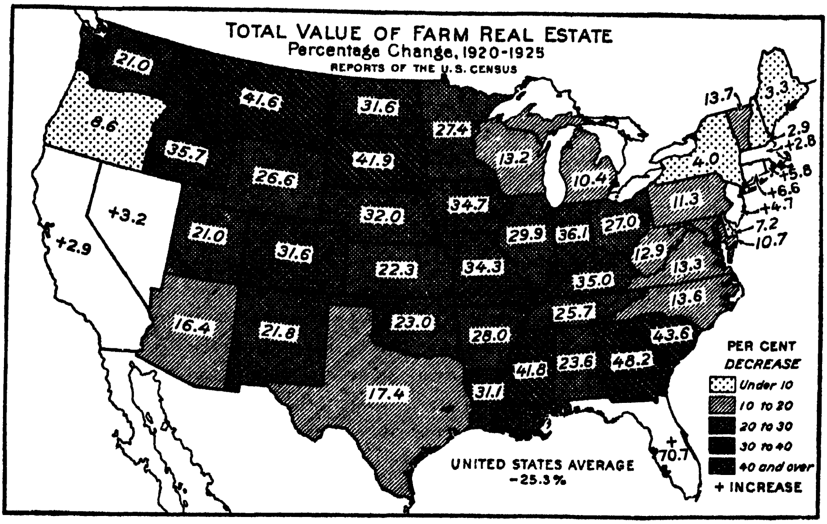

FIG. 132.—Changes in total value of farm real estate, 1920–1925

Similarly in Florida and the Pacific Coast States residential influences, as well as relatively well-sustained prices for some of the specialized products there grown, aided in supporting the values returned by the census. Residential development consequent upon population growth also widens local demand, particularly for dairy, poultry, and truck products.

### Causes of Relative Stability

That values in the cut-over country of northern Minnesota, northern Wisconsin, and the Upper Peninsula of Michigan should have declined relatively little or should have actually increased may be accounted for in part by the considerations that agriculture here is more self-sufficient and hence perhaps less price-sensitive than elsewhere; that clearing and other improvement is a more or less continuous process among those who stay; that settlement promotion by land companies often to city prospects and often with various methods of financial aid is a more or less continuous process; that sales of timber products and the opportunity to work in lumber camps, mines, etc., aids in maintaining an income; that prevailing values are in some areas dominated by the price policies of land companies; and that in some areas, particularly near lakes and streams, the uses of land for recreational purposes have been accelerated with the improved highway program of recent years. In some of these counties an increase in the number of farms is indicated by the 1925 agricultural census.

In the cotton States the exceptionally severe declines in Georgia and South Carolina are primarily the result of several years of unparalleled damage by the boll weevil. The exodus of negro farm labor, both because of virtual ruin of his income, as in Georgia, and because of the attraction of relatively high industrial wages, constituted another important factor, especially in the plantation area. A combined average of farm real estate values in the principal cotton States,[11] however, though showing a greater percentage decline than in the northeastern dairy-poultry-truck group,[12] fell less than a similar combined average for the grain and livestock-raising States of the Middle West.[13] This is largely because cotton prices and cotton incomes, though in 1920 and 1921 declining the most severely of all of the major product groups, thereafter recovered to levels lower than for dairy, poultry, fruit, and vegetable products, but appreciably higher than for the grain and meat-animal group.

### Increases in Mountain Counties

The increases in value to be observed in the mountain counties of western North Carolina and eastern Tennessee appear to have been associated in part with active development of the territory for residential and recreational purposes.

Sharp increases in the Texas Panhandle are largely an accompaniment of the rapid conversion of the former extensive cattle ranches into smaller cotton farms. So adapted to raising this product cheaply has the area been found that activity in farm real estate took on the proportions of a boom. Increases in the southernmost group of Texas counties were associated with a considerable acreage cleared and made suitable for crops, by an increase in acreage planted to cotton, and in some sections by considerable expansion in the growing of fruits and vegetables.

---

[11] North Carolina, Tennessee, Arkansas, Oklahoma, and all States south thereof, Florida excepted.

[12] North Atlantic States, Michigan, and Wisconsin.

[13] West North Central States, Illinois, Indiana, and Ohio.

On an average, apparently uniformly the most severe declines were recorded in the grain and livestock-raising States of the Middle West. Farm prices for the major products of this region and incomes therefrom held to the lowest levels of the country's major product groups. Severe declines in value in several of the Mountain States, even when total rather than per-acre changes are compared, are likewise largely traceable to the drastic decline in cattle and grain prices, particularly in wheat, and to droughts. In an area in western Kansas, however, values either held up relatively well or increased. At the same time the acreage in wheat increased. Cutting of costs by use of the combine and other power machinery was a large factor. This, together with the even more depressed conditions in the cattle industry, stimulated the breaking of former grazing lands and planting them to wheat as the better alternative.

A relationship between the change in land values and in the prices of products was observable during both the war and postwar period. For example, of the three groups, cotton, meat animals and grains (combined), and dairy and poultry products (combined), relative to pre-war prices, the first increased most in the war period, the second somewhat less, the last considerably the least of all. Farm real estate value averages for the Cotton Belt, the midwestern grain and livestock States, and the northeast dairy States increased in the same way. Taking 1919–20 prices as a base of comparison, dairy and poultry products thereafter fell least, cotton more, but the meat-animal and grain group most. Farm real estate values in the respective regions in which these provide the principal sources of income, moved likewise.

### Declining Downward Trend

With respect not to extent of change, but to the year-to-year trend, it is significant to note that for only two of the nine geographical divisions of the country did the averages up to March 1, 1926, still show a pronounced downward trend. These two were the East North Central and the West North Central sections. In the remaining seven divisions, the averages in the New England, Middle Atlantic, South Atlantic, and West South Central sections had for several years shown a tendency to go no lower and, with the possible exception of the South Atlantic, had even shown some tendency to move into higher ground. In the East South Central, Mountain, and Pacific divisions, the trend of the averages, as far as can be told now, appears to have nearly reached stability in adjustment to prevailing conditions.

E. H. WIECKING.

**LAW of Diminishing Returns in Farm Business** A given amount of labor and fertilizer will produce some kind of a yield of practically all crops. But if the amount of labor or fertilizer, or both, be doubled, the yield will in general be increased, but not in proportion to the increase in expenditure of labor and material. In general, each additional unit of fertilizer applied causes an increase in yield which is a certain percentage of the increase caused by the preceding unit.

For instance, in the case illustrated in Table 16, an application of 30 pounds of bone meal per acre for wheat in southeastern Kansas raised the yield from 10.6 to 14.9 bushels, an increase of 4.3 bushels. The addition of another 30 pounds of bone meal produced an additional increase in yield amounting to 56.53 per cent of 4.3 bushels, or 2.4 bushels. An application of an additional 30 pounds produced an increase amounting to 56.53 per cent of that due to the second 30 pounds, and so on. The sixth 30-pound application caused an increase in yield amounting to only 0.3 bushel.

TABLE 16.—*The effect of bone meal upon the yield of wheat in southeastern Kansas*

| Pounds of bone meal | Yield | Increase | Value of increase at-- | | |
|---|---|---|---|---|---|
| | | | $1.00 | $1.20 | $1.40 |
| | *Bushels* | *Bushels* | | | |
| 0 | 10. 6 | | | | |
| 30 | 14. 9 | 4. 3 | $4. 30 | $5. 16 | $6. 02 |
| 60 | 17. 3 | 2. 4 | 2. 40 | 2. 88 | 3. 36 |
| 90 | 18. 7 | 1. 4 | 1. 40 | 1. 68 | 1. 96 |
| 120 | 19. 5 | . 8 | . 80 | . 96 | 1. 12 |
| 150 | 19. 9 | . 4 | . 40 | . 48 | . 56 |
| 180 | 20. 2 | . 3 | . 30 | . 36 | . 42 |
| Optimum pounds of bone meal | | | 106 | 116 | 124 |

The increments in yield given in the third column of Table 16 constitute a decreasing geometric series, each term after the first being 56.53 per cent of the preceding term. This is the general result that has been found in experimental work both with plants and animals, though the percentage of the increase caused by a given unit application, as compared with the preceding unit, varies widely with conditions.

The last three columns of Table 16 give the financial results. The value of wheat given in the headings of these columns take no account of the increase in cost of harvesting and marketing due to increase in yield. But this discrepancy in the case of wheat is a small one. The cost of 30 pounds of bone meal is estimated to be 75 cents. The third column from the last shows that increasing the application from 90 to 120 pounds will produce an additional 80 cents worth of wheat, which shows a profit of 5 cents from the increased application. But the profit is made from the first half of this extra 30 pounds, and there is a loss on the second half. The profit stops at an application of 106 pounds per acre. With wheat at $1.20 a bushel the most profitable application is 116 pounds, and with wheat $1.40 it is 124 pounds of bone meal under the conditions of this experiment.

### Applies to Livestock Feeding

The same law applies to the feeding of animals. Table 17 and Figure 133 illustrate the results with hogs. The calculations in this table are based on Henry and Morrison's summary of experiment station work with hog feeding. It is assumed that the hogs are fed a ration of corn and tankage, the tankage constituting 10 per cent of the ration. The second and third columns of the table show respectively the bushels of corn and pounds of tankage consumed by hogs after reaching a weight of 100 pounds in attaining the weights given in the first column of the table. The fourth column shows the cost of the pig and the feed consumed in attaining each of these weights. The fifth column shows the market price of the animal per pound. It is assumed that the 100-pound pig is worth 10 cents a pound and that as he increases in weight the price per pound increases until at a weight of 200 pounds the pig is worth 12 cents a pound. As the weight increases beyond this the price is assumed to fall, as indicated in column 5. Column 7 gives the income over cost of pig and of feed. The maximum income over cost occurs at about 200 to 225 pounds weight.

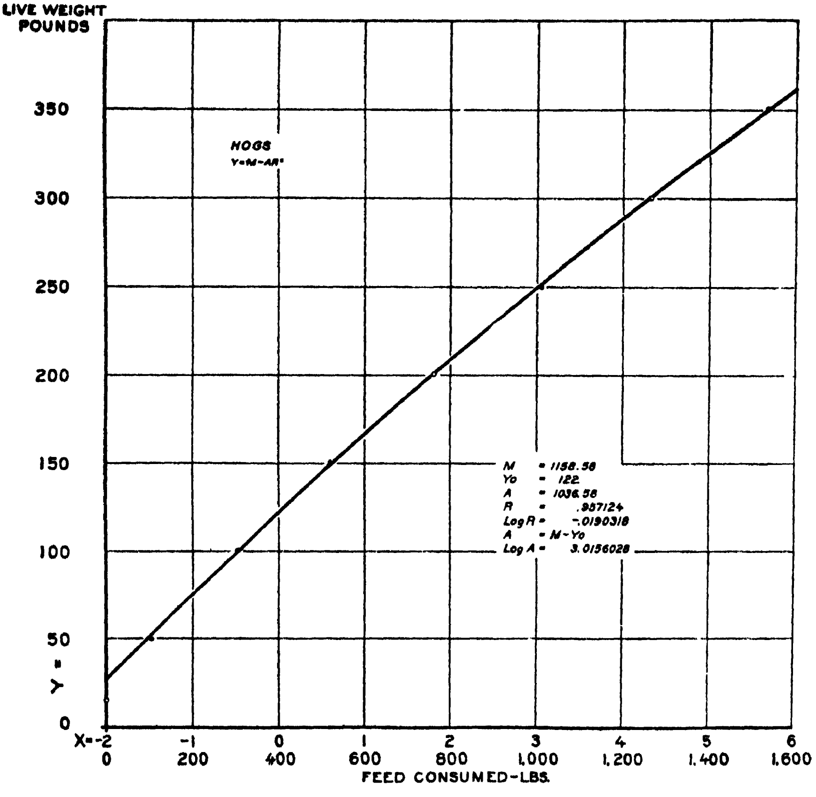

FIG. 133.—Gains in hog feeding calculated from the formula for the law of diminishing returns

TABLE 17.—*The cost and profit of feeding 100-pound hogs to given weights*

[Conditions: Pigs weighing 100 pounds at start, and worth $10; corn on hand—20 bushels per head, worth 84 cents a bushel; tankage, 10 per cent of ration, cost 3½ cents a pound]

| Weight of hog | Feed consumed to date |  | Cost of pig and feed to date | Value of hog per pound | Value of hog | Income over cost pig and of feed | Received for 20 bushels of corn |  |  | Received per bushel |
|---|---|---|---|---|---|---|---|---|---|---|
|  | Corn | Tankage |  |  |  |  | Fed | Not fed | Total |  |
| *Lbs.* | *Bus.* | *Lbs.* | *Dolls.* | *Dolls.* | *Dolls.* | *Dolls.* | *Dolls.* | *Dolls.* | *Dolls.* | *Dolls.* |
| 100 |  |  | 10.00 | 0.10 | 10.00 | 0.00 | 0.00 | 16.80 | 16.80 | 0.840 |
| 125 | 1.75 | 10.872 | 11.63 | .105 | 13.12 | 1.49 | 2.77 | 15.33 | 18.10 | .905 |
| 150 | 3.55 | 22.092 | 13.31 | .11 | 16.50 | 3.19 | 5.78 | 13.82 | 19.60 | .980 |
| 175 | 5.39 | 33.552 | 15.03 | .115 | 20.12 | 5.09 | 9.02 | 12.27 | 21.30 | 1.065 |
| 200 | 7.28 | 45.308 | 16.80 | .12 | 24.00 | 7.20 | 12.53 | 10.68 | 23.21 | 1.1605 |
| 225 | 9.22 | 57.376 | 18.61 | .115 | 25.87 | 7.26 | 14.01 | 9.06 | 23.07 | 1.1535 |
| 250 | 11.21 | 69.770 | 20.47 | .11 | 27.50 | 7.03 | 15.23 | 7.38 | 22.61 | 1.1305 |
| 275 | 13.26 | 82.510 | 22.38 | .105 | 28.87 | 6.49 | 16.19 | 5.66 | 21.85 | 1.0925 |
| 300 | 15.37 | 95.616 | 24.34 | .10 | 30.00 | 5.66 | 16.89 | 3.89 | 20.78 | 1.039 |
| 325 | 17.54 | 109.110 | 26.37 | .095 | 30.87 | 4.50 | 17.32 | 2.07 | 19.39 | .9695 |
| 350 | 19.77 | 123.016 | 28.45 | .09 | 31.50 | 3.05 | 17.65 | .19 | 17.84 | .892 |

In making the computations in the last four columns of the table it is assumed that the feeder has 20 bushels of corn for each hog on feed. These columns show the amount that would be received for this 20 bushels of corn if the feeding operations were stopped at the various weights given in the first column of the table. Here, again, the largest income from the corn is obtained by feeding the pig to a weight of from 200 to 225 bushels.

### Price Changes a Factor

A change in the prices in column 5 would, of course, change this most profitable weight to which to carry the fattening hog. But the first three columns of the table would remain as they are, and anyone proficient in arithmetic could figure the remaining columns for any price data inserted in column 5.

Figure 133 shows the rate of gain of the hogs. The small dots represent the figures given by Henry and Morrison. The graph shows the gains calculated from the formula for the law of diminishing returns. It is seen after the pig reaches a weight of about 50 pounds his actual gains conform very closely to this law. Below 50 pounds the gains are more rapid than called for by the curve, a fact to be attributed to the milk the pig obtains at that time.

W. J. SPILLMAN.

## LAW and the Farmer's Business

It was recognized at an early date that aid should be given to agriculture by law. Prior to 1862 some laws beneficial to the farmer were passed by Congress, but not until that year was a law passed creating a distinct organization known as the Department of Agriculture, the general design and duties of which were to acquire and diffuse among the people of the United States useful information on subjects connected with agriculture and to procure and distribute seeds and plants. Since that time a vast amount of legislation has been enacted having for its aim the betterment of agricultural conditions. Many of these laws, regulatory in nature, have led to numerous legal controversies. The activities of the department have grown immensely, and the variety of legal questions which are constantly arising relating to the enforcement of the laws, regulations, and the management of the property of the United States entrusted to the department is astounding to the uninitiated.

The appropriation act of 1911 provided for the conduct of the legal work of the department. A corps of lawyers is maintained to carry out the work under the supervision of the solicitor. The organization is divided into sections, each of which specializes in certain activities of the department. In this manner the office seeks to be in a position to give expert advice on any legal question which may arise. Some of the assistants to the solicitor are located permanently away from Washington in order that they may be in personal contact with those representatives of the department who may need their aid. In certain sections of the country large areas of land are purchased by the United States through the agency of the Department of Agriculture. To facilitate these transactions title attorneys are stationed at convenient points.

### Court Aid Must Be Invoked

The greater percentage of matters such as the construction of statutes administered by the department and the preparation of legal papers submitted to the office are disposed of within the organization. In many instances, however, it is necessary to seek the aid of the courts in enforcing the rights of the Government, in which event the cases are prepared for prosecution by the department's legal force and assistance is given to the various United States attorneys in their presentation to the courts.

Generally speaking, corrective or regulatory laws are not passed by Congress unless conditions warrant their enactment and there is a demand for relief. Such situations are not born over night but ordinarily grow during a span of years, due to the failure of persons concerned to adopt measures to remedy unfair or undesirable conditions. As time passes, these conditions one by one are dealt with by Congress. It is of interest to observe some of these efforts to assist the agricultural interests and the results attained in a legal sense.

In 1916 it was recognized by treaty between the United States and Great Britain that many species of birds, in their annual migrations, traversed parts both of the United States and Canada, and that they were of great value, among other things, in destroying insects injurious to vegetation. These birds were declared to be in danger of extermination through lack of adequate protection. Provision for their protection was made by the treaty and the migratory bird treaty act passed by Congress on July 3, 1918. The right of the Federal Government so to act was questioned by the State of Missouri on the ground that the treaty and the legislation were contrary to the Constitution of the United States, in that they invaded the sovereign rights of the State. The Supreme Court of the United States upheld the treaty and the act of Congress passed in aid thereof and stated that it saw nothing in the Constitution which would compel the Government to sit by while a food supply is cut off and the protectors of our forests and crops destroyed. (Missouri *v.* Holland, 252 U. S. 416.)

### Grain Futures Decision

It was very generally considered that numerous transactions involving the future delivery of grain as conducted on boards of trade caused sudden and unreasonable fluctuations in prices, detrimental to both the producers and consumers of grain. By the grain futures act of 1922, Congress recognized this to be a fact and provided for the regulation of transactions in grain futures in such a manner as to remedy the undesirable conditions. This action was taken under the commerce clause of the Federal Constitution. Immediately efforts were made to defeat the purposes of the legislation by enjoining the Secretary of Agriculture and other officers from carrying out the provisions of the act. The Supreme Court of the United States, however, stated that Congress had reasonably declared the fluctuation in prices of grain due to transactions in futures a burden on interstate commerce, and held that the act was clearly within the regulatory powers of Congress. (Chicago Board of Trade *v.* Olsen, 262 U. S. 1.)

Legislation relating to foods and drugs is general in the States. The Federal legislation on this subject is administered by the United States Department of Agriculture. It condemns every statement, design and device which may mislead or deceive. The law was enacted to enable purchasers to buy articles for what they really are. An interesting example exists in the case of vinegar labeled as "Apple Cider Vinegar Made From Selected Apples," the fact being that the product was made from evaporated apples. The Supreme Court of the United States held that the label was misleading to the public, and a misbranding under the act. It was said that an article must be the identical thing which the branding indicates it to be, irrespective of its merit. (United States *v.* 95 Barrels of Vinegar, 265 U. S. 438.)

The administration of the packers and stockyards act of 1921 is of considerable interest. This act was passed to secure the free and unburdened flow of livestock from the ranges and farms to the consumers of meat and meat products, or still as livestock to other parts of the country.

### Packing Monopoly Feared

The monopoly of the packing industry was the chief evil feared by Congress, since such monopoly enabled them unduly and arbitrarily to lower prices to the shipper who sold or to increase the price to the consumer who bought. Then it was desired to provide against the exorbitant charges, duplication of commissions, and deceptive practices in the passage of livestock through the stockyards, made possible by collusion between the stockyards, the commission men, the packers, and the dealers. It is readily seen that any expenses incurred in the handling of the stock necessarily reduces the price paid the shipper or farmer and increases the price to be paid by the consumer. It was realized by Congress that the shipper of livestock, being generally far away, was not in a position to protect his interests, being dependent upon the commission men.

The packers and stockyards act treats the stockyards of the country as great national public utilities, and regulates their conduct under the commerce clause of the Federal Constitution. As is often the case in instances of national progress, the constitutional authority of Congress so to legislate was questioned on the ground that the business conducted was not a part of interstate commerce and therefore not subject to regulation by Congress. But the Supreme Court of the United States called attention to the fact that the stockyards are not a place of rest or final destination of the livestock. Thousands of head of cattle arrive each day and must be promptly disposed of to give place to the constantly flowing traffic. The court likened the stockyards to a throat through which the current flows, and held that the transactions which occur therein are only incident to this current from the West to the East and from one State to another, and that such transactions can not be separated from the movement to which they contribute, and necessarily take on its character—that is to say, the character of interstate commerce. The constitutionality of the law was upheld. (Stafford *v.* Wallace, 258 U. S. 495.)

### Grain Grading Practices

For a number of years prior to 1916 the farmers of the West were dissatisfied with the practices attending the grading of grain at the great terminal markets. This condition led to the passage of the Unied States grain standards act, which had for its object the grading of grain in interstate or foreign commerce under Federal supervision. This law has been of exceptional help to producers and consumers of grain. In 1922 the State of North Dakota passed a law which prevented the buying of wheat by grade except under certain prescribed conditions. This act was attacked in the courts by grain buyers on the ground that it burdened interstate commerce and was in conflict with the United States grain standards act. The court found that 90 per cent of the wheat produced in the State was shipped in interstate commerce, rendering the control of the business of concern to the people of other States as well as to those of North Dakota. The State law was held unconstitutional. (Shafer *v.* Farmers Grain Co., of Embden, 268 U. S. 189.)

The department has encountered more or less difficulty in cattle-tick eradication. At times the dipping of cattle in vats has been opposed to such an extent by the owners as to result in the most serious consequences. In Echols County, Ga., where members of the Bureau of Animal Industry were engaged in supervising the dipping by State officials of tick-infested cattle, the opposition resulted in the violent death of one employee of the department and the wounding of others. Certain persons were indicted for conspiracy to assault or interfere with Government officers, and their conviction was upheld by the Supreme Court of the United States. Among other things, the defendants urged that no showing had been made that the cattle involved were the subject-matter of interstate commerce and liable to supervision by the Secretary of Agriculture. The court said, however, that the pertinent laws and regulations were intended to prevent the spread of cattle disease from one State to another, which necessarily meant the interstate movement of diseased cattle; so that the duties interfered with were a part of the quarantine measures reasonably adopted to prevent the spread of animal disease in interstate commerce. (Thornton et al. *v.* United States, 46 Supreme Court Reporter 585.)

### Cases Cited Are Examples Only

Only a brief idea of the problems confronting the legal force of the department is possible in the limited space here allotted. Those above are referred to not because they are exceptional, but because they offer fine examples of the importance of the questions considered. The Department of Agriculture is a large organization and controls considerable property, the protection of which involves the United States in a varied assortment of legal actions. The files of the solicitor's office are rich in records relating to a variety of matters unusual in any one legal organization, dealing, as they do, with questions of statutory construction, constitutional law, criminal law, regulatory law, and property rights in general.

H. N. Foss.

**LEATHER Damaged by Impure Air** Leather bookbindings, leather upholstery, and leather bags and cases last longer in some parts of the country than in others. Research studies recently conducted by the Bureau of Chemistry have shown that the chemicals which pollute the air about our large industrial centers hasten the deterioration of certain kinds of leather.

In the course of this investigation a large number of worn leather bookbindings were examined and analyzed chemically. The leather of each binding was divided in accordance with the plan given in Figure 134, which shows a book lying face downward. A and B are the side portions of the cover and C is the back.

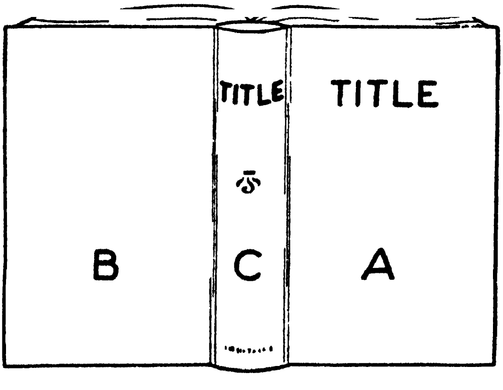

FIG. 134.—Book cover lying face down. A, right side cover; B, left side cover; C, back of cover

Many cases of rapid decay were found. Often the leather in the back, C, was in a powdery condition and could be easily rubbed off, torn, or cracked, while the sides, A and B, of the same binding showed very little decay. Figure 135 shows typical instances of this condition.

Now, the cover of a leather-bound book is one continuous piece of leather, practically uniform throughout when new. The marked differences developing with time in the condition and composition of different parts of this piece of leather must be the result of unequal service conditions of one kind or another. In the case of books kept on shelves the most decided inequality is exposure. The back of the binding is very much more exposed to the light and the air than the sides. A comparison of the deterioration of these two

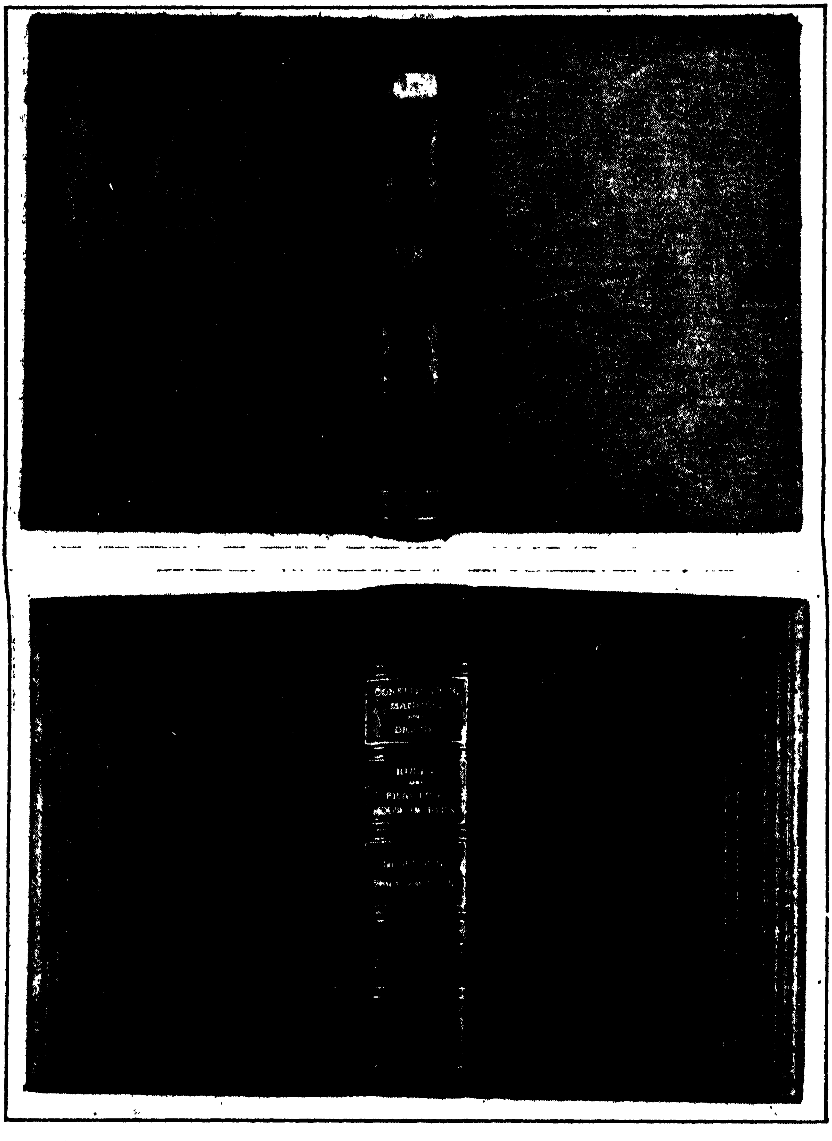

FIG. 135.—Shelf-filed books, showing advanced stage of deterioration of the leather in the back of the binding

parts, then, should throw some light on the effect of the degree of exposure.

Examination showed that the back, C, the most exposed part, had deteriorated most. Chemical analysis showed that it also had the highest acidity, the highest sulphate content, and the greatest modification of originally insoluble leather substance into water-soluble nitrogen compounds, or decomposition products of leather.

Both light and atmosphere are involved in deterioration from exposure. It is difficult to determine the exact rôle played by each.

Daylight, although known to be harmful to leather, can not alone be held responsible for the increase of certain constituents of the leather, notably acid and sulphates, in the more deteriorated part of the binding. This increase must be due to the absorption of something from the air. There can be but little doubt from the data obtained that harmful sulphurous and acidic impurities, taken up in destructive quantities from a polluted atmosphere, are responsible for part of the deterioration. This is but a natural expansion of the old " gas-light " theory of the famous scientist Michael Faraday, who as early as 1842 developed a theory pointing to the sulphur products from incomplete burning of illuminating gas, coupled with poor ventilation, as the cause of rapid deterioration. The adherents of this theory, however, limited the corrosive air to the space lighted by gas. It has now been shown that the space must be enlarged to include our usually polluted atmosphere.

The pollution of the atmosphere is often greater than is generally appreciated. W. F. M. Goss says: "Gaseous compounds of sulphur are products of combustion * * *. Sulphur compounds eventually are converted into sulphuric acid * * *. Sulphuric acid tends to exert an important influence in the disintegration of building materials of all kinds and produces deleterious effects upon furnishings, clothing, and merchandise." R. E. Swain states that "coal, on the one hand, and sulphur-containing ores, on the other, are easily foremost as ultimate sources of the substances which concern us most in atmospheric pollution. Loss of fuel from incomplete combustion represents much more of an economic loss than simply one of energy, for it clouds the atmosphere over our great cities, does extensive damage to buildings, furnishings, and merchandise, and leads to widespread personal loss and discomfort." The sanitary commission on air pollution, of Manchester, England, states: "If we draw a circle of a mile in radius with the town hall (Manchester) as center, about 195 tons of impurities would be collected during the month (July) from this area."

Atmospheric pollution is not the only cause of rapid deterioration of leather. Other factors, such as the tannage, the original composition of the leather, particularly its acidity, the oiling and greasing, and finishing undoubtedly play a part also.

The results of the research work done in the Bureau of Chemistry show that one way to prolong the life of leather is to prevent the absorption of atmospheric impurities. Coatings and finishes will help in proportion to their impermeability, permanence, and effect upon the leather. Many oils and greases, especially castor and neat's-foot oils, alone or mixed with tallow or lanolin, and many waxes are useful for this purpose because they counteract to some extent the gaseous impurities of the air and help to keep them from penetrating into the leather fibers. At the same time they provide "nourishment" for the leather.

The results of this work do not apply to bookbinding leathers alone but to all other leathers of a similar nature intended for long service, such as upholstery leather and bag and case leathers. They should bring about a better appreciation of the rôle of atmospheric corrosion in the deterioration of leather and, as a consequence, the further development and application of treatments, either during the manufacture of the leather or during its service, that will aid materially in its preservation against such corrosion.

## LEGUME Inoculation and Fixation of Air Nitrogen

Nearly 2,000 years ago historians recorded the observation that better crops of grain were obtained when the seed was planted in soil which had just previously borne a crop of legumes. Here began our written knowledge of crop rotation. Although at this time and for many years afterwards nothing was known about bacteria or nitrogen gas, the beneficial effect of nitrogen fixation of legumes in a rotation (vetches, beans, lupines, clovers, etc.) was early recognized. It is only within the last century that the agents concerned with legume plants in the utilization of atmospheric nitrogen have been discovered and are now known to be minute soil-inhabiting plants which are called bacteria. When these bacteria come in contact with suitable legume roots in the soil they enter and cause the plant to form growths in the course of their multiplication which are commonly referred to as nodules or tubercles. These growths are very characteristic in outward appearance, varying mainly on account of the plant on which they occur, although their external appearance is sometimes modified by soil conditions. Nodules being the evidence of nitrogen-fixation and of the presence of certain kinds of legume bacteria in a soil, are growths with which every farmer should make himself familiar.

Nature has distributed the legumes and their bacteria very liberally to the various soils throughout the world, but since the bacteria which will produce nodules on a particular legume will not necessarily produce them on another species, it does not always happen that the proper kind of nodule-forming bacteria are in the soil. Legumes are therefore classified on the basis of their ability to accommodate the same organisms in their roots. Thus, the nodule bacteria of the plants within each of the following four groups of legumes are considered the same for practical purposes: (1) Alfalfa, bur clover, and sweet clover; (2) crimson, red, and alsike clover; (3) cowpea, velvet bean, peanut and Lima bean; (4) vetch, garden pea, and sweet pea. The soy bean requires its own special nodule bacteria. With the modern interchange of legume seed between widely separated parts of the world and the development of conditions detrimental to nodule bacteria it is often necessary to bring them into a soil.

### Acidity Should Be Corrected

If legume bacteria are lacking in a soil on account of soil conditions, as, for instance, soil acidity, this condition should be corrected before replenishing the supply of bacteria in this soil. The process of introducing nodule bacteria into the soil is commonly called inoculation. The material for this purpose is obtainable from two general sources: (1) artificially prepared cultures and (2) field soil in which the proper bacteria are known to be present. It is possible by careful laboratory work to take the bacteria from nodules and to propagate them on sterilized artificial food in the absence of other bacteria. Inoculating material prepared in this manner is obtainable from various governmental and commercial agencies. On the other hand, soil known to contain the proper bacteria and free from diseases and pests, makes an excellent source of inoculating material for the farmer. At times it may be advisable to establish a source of bacteria on the farm by growing seed treated with pure culture on a small plot of soil. With this source at hand, the soil may be transferred to other fields as it is needed. When a soil is once seeded with the proper bacteria and it is maintained favorable to their growth with necessary additions of lime, fertilizers, and organic matter and an occasional growth of the legume on which they function, they should continue to live indefinitely in this soil.

After legume bacteria penetrate the roots they begin to draw nitrogen from the air and so alter it that the plant may absorb and utilize it in the building of tissues. While the bacteria are fixing nitrogen they draw on the plant roots for the carbohydrates, moisture, and minerals necessary for their growth. Through the work of these bacteria greater legume crops are produced, uniformly higher in nitrogen than most nonlegumes or legumes which do not have the benefit of this bacterial association.

### Amount of Nitrogen Fixation Varies

The amount of nitrogen fixed by legumes and their bacteria varies with the species, the conditions, and the time of growth. Under favorable conditions a single crop of legumes may fix as much as 200 pounds nitrogen per acre in a year and a crop put on the soil to fill a gap for a short time may only add from 40 to 60 pounds per acre in a season. In the choice of legumes for planting, those which grow vigorously under the existing conditions and which meet the needs of the type of farming practiced should be considered.

The main part of the nitrogen fixed by legumes stays in the plant until it dies and decays, although in a dormant period of the plant or in extremely dry weather, a small amount of it may pass into the soil by the "sloughing off" of the nodules. The fate of the nitrogen in the legume crop is entirely dependent upon its utilization. The nitrogenous organic matter in the stubble as a rule remains in the soil where it rots and is thereby made available for subsequent nonlegume crops. The greater part of the nitrogen in legumes is usually in the part that is cut for hay or seed.

Lewis T. Leonard.

## LIMEQUAT: A New Hardy Ade Fruit

The peculiar zest of the juice of the West Indian lime makes it desirable that fruits of this type be grown over a much wider range than at present. Those familiar with citrus fruits know that the lime is the tenderest of all the commonly grown species of this group. It is frequently frozen severely even in southern

Florida, so that its culture is chiefly restricted to the keys along the Florida coast. It is not grown commercially in California at all.

In 1909, the senior writer originated a new type of citrus fruit by crossing the West Indian lime with the kumquat orange. The kumquat is one of the hardiest of the evergreen citrus fruit trees, and is also highly resistant to some of the diseases affecting the lime and other citrus varieties. The fruit, however, has little commercial value and is used chiefly for preserves, or for decorative purposes. These crosses resulted in a number of hybrids varying in character, but all producing fruits much like the lime in their acid quality.

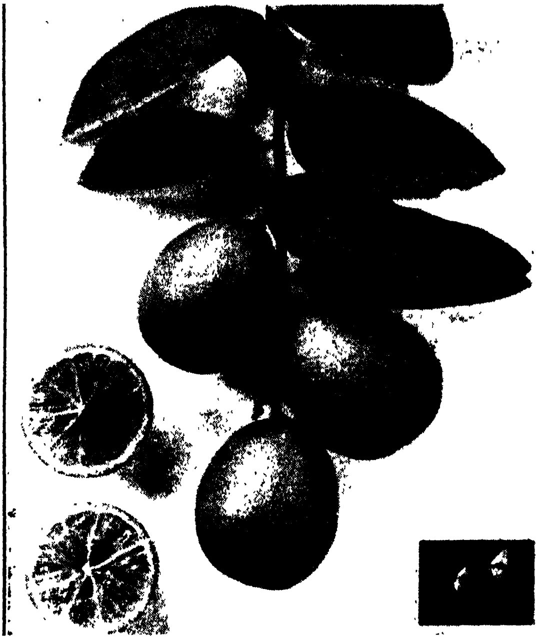

FIG. 136.—The Eustis limequat, natural size

The hybrid selected from among these as the most promising was the result of fertilizing the flowers of the common or West Indian lime with pollen of the round or Marumi kumquat. Since the cross was made at Eustis, Fla., the fruit has been named the Eustis limequat. It is strikingly beautiful in appearance, resembling the lime in size and texture, but with a light yellow color like that of the grapefruit. (Fig. 136.) It is thin-skinned but firm, very juicy, has few seeds, and the flavor, except when dead ripe, can scarcely be distinguished, even by an expert, from that of the true lime. The fruit develops its juice content while still green, so that, like the lime, it can and should be used while still partially green. The tree is evergreen, of rapid, upright growth, and with small, pointed leaves. The spines on the bearing twigs are very inconspicuous, a decided point in favor of this hybrid, contrasting with the viciously spiny character of the lime. The limequat is more or less everbearing, so that fruit is usually available for nearly six months of the year. It has proved itself adaptable over a wide range of territory, withstanding temperatures in northern Florida and Alabama as low as 17° F. without serious injury. Even where frozen back severely it usually makes a quick recovery and has the ability, like its kumquat parent, to produce fruit on new sprouts, so that a fair crop may be obtained even following a damaging freeze. While thus proven quite hardy, it also fruits well in warmer regions, being quite at home in southern Florida and even in tropical Honduras, where its vigor and freedom from disease furnishes a striking contrast to the true lime. It is entirely immune from "lime wither tip," a disease very destructive to the common lime crop. For budding, it has proved adapted to all the common citrus stocks except the sour orange; and it may be grown by rooting cuttings. Although it does not come true from seed, selected seedlings may produce very excellent trees. Nursery propagation is confined largely to the rough lemon stock for the warmer sections and the trifoliate orange for colder areas. Most of the larger citrus nurseries have undertaken the propagation of the limequat within the last few years.

Aside from its use in making ades, the limequat is excellent for marmalade, for preserves, and in the crystallized form, since the rind, like that of the kumquat, is edible. California lemons are not to be had in Florida, owing to quarantine restrictions to prevent the possible introduction of brown rot, while Sicilian lemons are expensive and obtainable only in the larger towns. Thus it often happens that a good acid citrus fruit for ade making, salads, or for flavoring is actually a scarcity even in citrus-growing territory. A more extended planting of the limequat in home gardens and small groves will supply this deficiency to a large extent, and may lead to the development of a moderate demand in more distant markets.

WALTER T. SWINGLE.
T. RALPH ROBINSON.

---

**LIVESTOCK Estimating Work Much Enlarged** The activities of the department in estimating livestock production have been greatly enlarged during the last four years. Prior to 1922 the principal estimates were of the numbers of animals on farms January 1 each year, number of brood sows April 1, number of stock hogs September 1, a partial estimate of livestock losses in April, and an estimate of wool production.

No attempt was made to estimate actual annual livestock production. The only measure was the change in inventory numbers as of January 1—admittedly a very inadequate basis. No official information was available to producers or to the trade in advance of the marketing period as to the size of the pig or lamb crops, number of cattle and sheep on feed for market, probable market supplies over seasonal periods, or condition of livestock to be marketed. Practically the only information as to these items was that coming through trade sources; this was fragmentary, unorganized, often conflicting and based largely on biased opinion evidence.

The following list of livestock reports now being issued or to be issued indicates the progress that has been made in furnishing needed information as to various phases of livestock production. Chronologically arranged, these reports are:

### January

Annual inventory of numbers of livestock on farms by species, showing class and age separation.

Estimate of the amount and value of livestock production during the preceding year, with annual balance sheets showing items of increase and decrease.

Report of the December 1 pig survey for the United States, showing the size of the fall pig crop and number of sows bred to farrow in the following spring.

Estimate of cattle and sheep on feed for market as of January 1. This to be preceded by reports in October, November, and December on conditions influencing the feeding situation.

Estimate of the calf crop and revised estimate of the lamb crop of the preceeding year.

Revised estimate of wool production and weight per fleece of preceding year.

Estimate of livestock losses from all causes for preceding year.

Condition of range cattle and sheep in western range States. This is a regular monthly report throughout the year.

Weekly movement of fed lambs to market in Western States, continued until May.

### March

Estimate of early lamb crop and market movement of spring lambs from early-lamb States, including prospective movement of grass-fat sheep from Texas.

### April

Estimate of cattle on feed for market in the Corn Belt States on April 1.

Estimate of supply of cattle to be marketed during the spring months from Texas, New Mexico, and Arizona.

Report on pasture conditions in the Flint Hills and Osage pastures.

Report on the development of the early lamb crop during March.

### May

Final report on development of early-lamb crop and estimate of market movement.

### June

Report of the June 1 pig survey for the Corn-Belt States showing size of the spring pig crop and the number of sows bred to farrow the following fall.

Estimate of the movement of cattle into the Flint Hills and Osage pastures.

### July

Report of the June 1 pig survey for the United States.

Estimate of the size of the total lamb crop in the United States and of sheep losses during first six months of the year in the range States.

Preliminary estimate of wool production, with sheep shorn and weight per fleece.

### August

Estimate of number of sheep and lambs to be shipped from range States during the fall and early winter.

Report on conditions in the range States that will affect the number of cattle to be marketed during the fall and early winter.

### October and November

Reports giving movement of feeder cattle and sheep into feeding States, corn, and other feed prospects, prices of cattle and feed, preliminary to the January 1 feeding estimates.

### December

Report of the December 1 pig survey for the Corn-Belt States.

Report on the feeding situation similar to that in October and November.

C. L. HARLAN.

## LIVESTOCK Judging Aided by Use of Camera

Type in dairy cattle is a much discussed topic wherever breeders assemble. The climax of these discussions is reached in the show ring, which is the arena of final decision. It is there that the keenest interest abounds when representative cattle from many herds are gathered in competition for the awards of the judges. These men are trained to weigh and consider those points which make up the type desired in the animals of the various breeds.

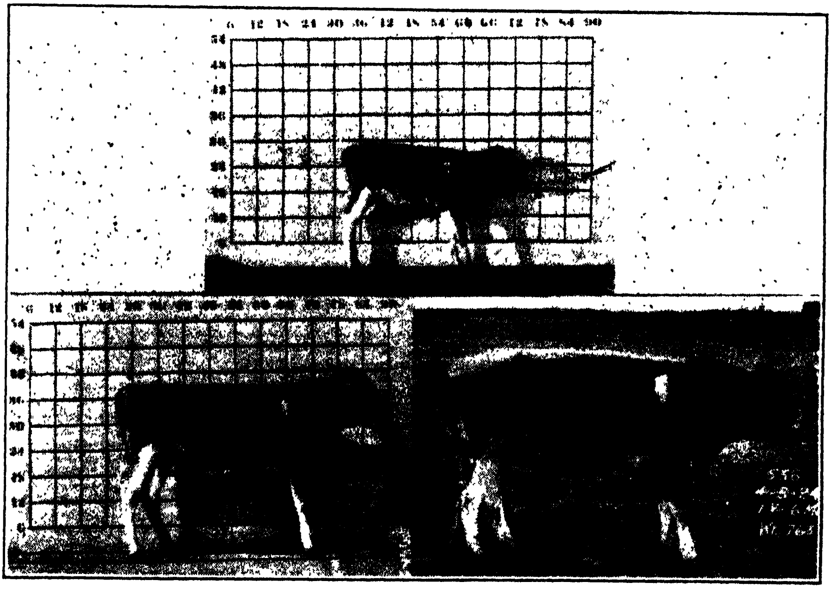

FIG. 137.—Changes in levelness of rump at different stages of development

Official judging of dairy cattle is nearly all done during the two months of late summer and early fall. Great reputations are frequently made by winnings during a single show season, and now and then young animals reach the heights of fame by entering the championship classes.

One interesting feature of type in dairy cattle which is not brought out by present show methods is the fact that some of these points which make up desirable type are subject to change during relatively short periods of time. Men's memories are faulty, and then, too, new favorites are crowding to the fore and blotting out mental pictures of former champions.

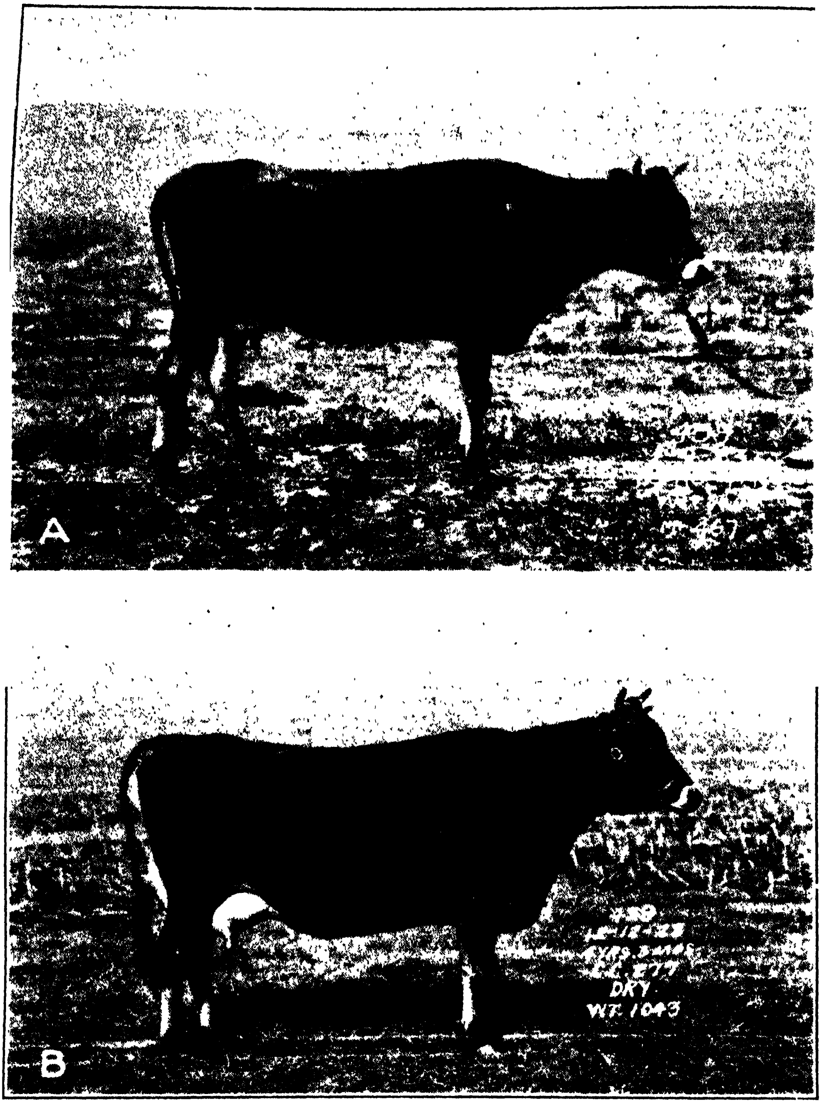

FIG. 138.—Effect of physical condition of cow on general appearance

The camera is serving the useful purpose of recording those changes in a permanent way. By systematic photography it is possible to place these variations in type beyond the vagaries of the human memory.

One point which is strongly emphasized by show-ring judges and cattle fanciers is the levelness of the rump. No one seems to know why a rump is level except that it grew that way. The fact is, however, that the level rump may become sloping and that the opposite may also occur.

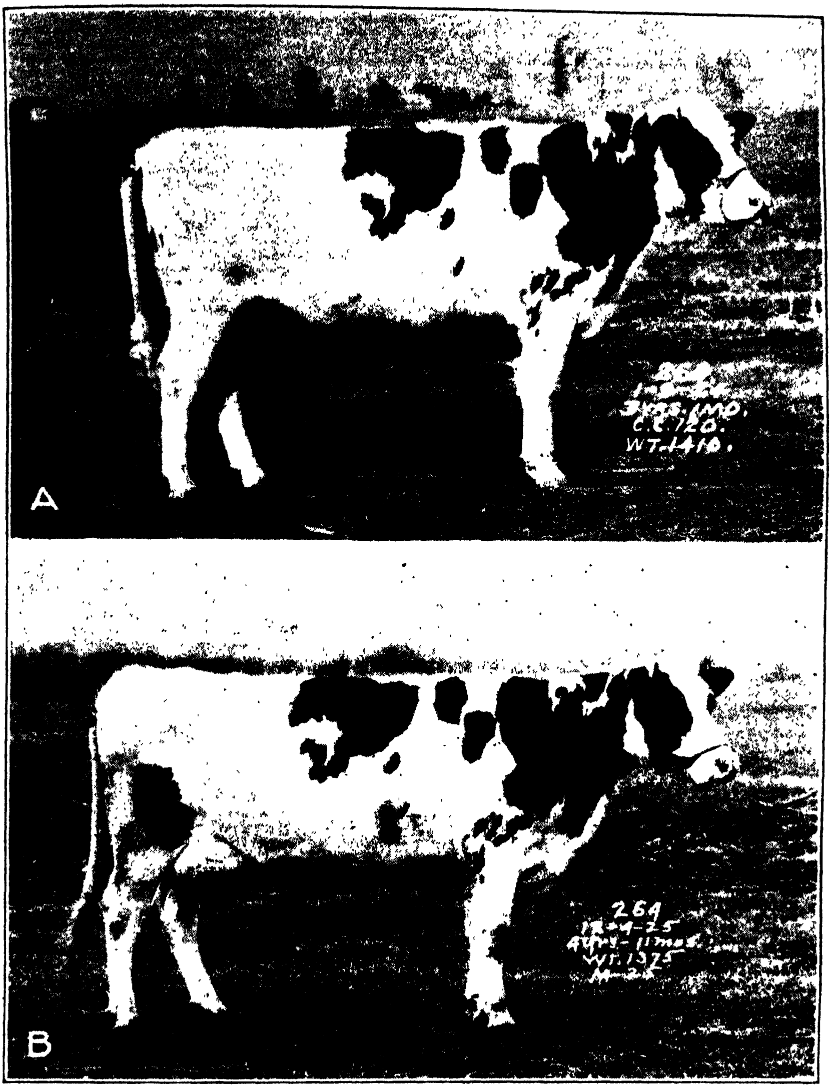

FIG. 139.—Change in appearance of animal produced by breeding

Figure 137 illustrates the changes which have occurred during the growth of an animal at the department's dairy farm at Beltsville, Md. The physical condition of cows also has a bearing on appearance or type, as is shown in Figure 138. Levelness of the udder is often considered in judging cattle, and here again time and condition work their changes. Tilted udders sometimes become level, and the opposite also occurs. Delayed breeding has been known to alter the appearance of heifers. This condition may correct itself after normal calving, as is shown in Figure 139.

Aside from the foregoing uses, the camera has a far wider field of usefulness when employed in conjunction with studies in dairy-cattle breeding. By taking photographs at regular intervals and according to a plan which makes all pictures comparable, it is possible to make comparisons of animals in various generations at the same ages, between individuals of the same generation at the same age, and also to study the changes which occur during the development of each animal.

Comparability and uniformity are attained by using the same camera in a fixed place and posing the animals in a standard position at a uniform distance from the camera.

M. H. FOHRMAN.

## LIVESTOCK Market News Distribution

With the active cooperation of State departments of agriculture at nine markets, the Federal market news service on livestock, meats, and wool to-day embraces 30 markets. Livestock markets covered in this service are Atlanta, Boston (Brighton market), Buffalo, Chicago, Cincinnati, Cleveland, Denver, Fort Worth, Indianapolis, Jersey City, Kansas City, Lancaster, Pa., Los Angeles, National Stock Yards, Ill., New York City (Sixtieth Street market), Ogden, Pittsburgh, Portland, Richmond, Salt Lake City, San Francisco, South Omaha, South St. Joseph, South St. Paul, and Wichita. Meat markets are Boston, Chicago, New York City, and Philadelphia. The wool market is Boston.

Through cooperative arrangements with commercial agencies, considerable livestock market information is also obtained daily from Baltimore and Sioux City. Extension of the service during the current fiscal year included the opening of livestock offices at Buffalo, Cincinnati, Cleveland, Indianapolis, Pittsburgh, and St. Joseph.

Designed to meet demands for timely, thorough, accurate, and unbiased market news, gathered and disseminated by a neutral agency, the service inaugurated on meats at the three largest meat-consuming centers, in 1917, and speedily expanded to embrace service on livestock and meats at Chicago and on livestock at other important midwestern markets, has reached the point where it may be truly said to be nationwide in scope.

In furtherance of its efforts to provide prompt, reliable, and properly interpretable market information on these important commodities, the Bureau of Agricultural Economics, under which the market news service is conducted, adopted, at the inception of the service, tentative class and grade standards by means of which markets in all sections of the country could be reported in a uniform manner. Through persistent investigation, research, and demonstration and through constant use, the tentative standards have been refined and improved from time to time, and during the fiscal year 1926 those covering slaughter cattle, beef, and wool were promulgated by the Secretary of Agriculture as official United States standards.

Through this means a slow, though steady, elimination of indeterminate grading, misleading or confusing classifications, and conflicting phraseology is being brought about.

### Quick Dissemination Important

Next to accuracy, speed in dissemination is one of the most important features of this market news service. The backbone of the service, which provides for prompt interchange of market information between markets, is the leased telegraphic wire system, extending some 7,700 miles in length and connecting the majority of the market centers and Washington, where the headquarters of the service are located. Markets at which offices are maintained that are not at this time directly connected with the leased wire circuits are Buffalo, Cincinnati, Cleveland, Indianapolis, Los Angeles, Ogden, and Portland. Through cooperative arrangements with State and commercial agencies, the leased wire service covering livestock, meats, and wool market information is also provided at Ames, Iowa; Columbus, Ohio; Hastings, Nebr.; Jefferson City, Mo.; Oklahoma City, Okla.; San Antonio, Tex.; and Stephens Point, Wis. At all of these points the information is made immediately available to the public by radio, telephone, the press, and by mail.

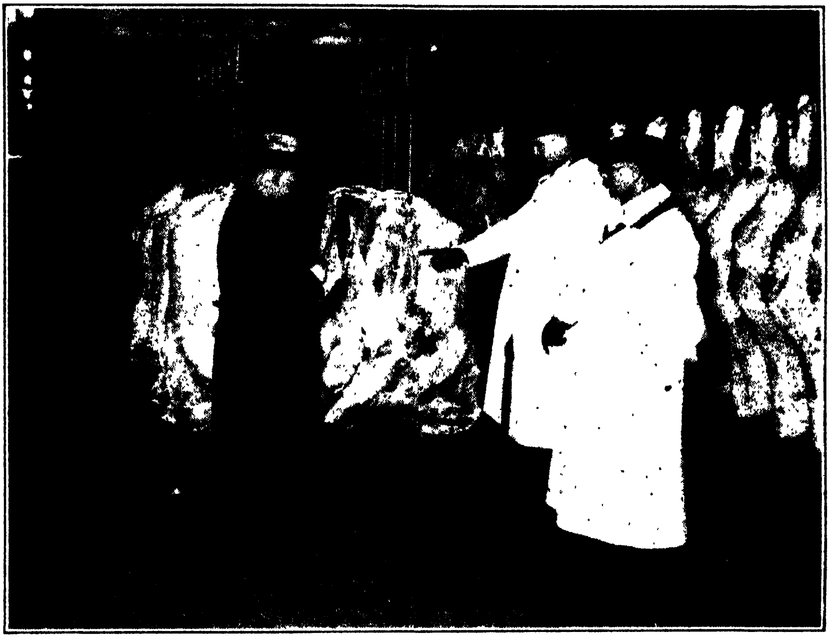

FIG. 140.—Checking beef prices and grades. Beef salesman (center) and branch house manager (right) discussing a sale with reporter (left)

Market news by radio is becoming an increasingly important feature of the service. With three exceptions, reports of livestock, meat, and wool markets covered by the service are now being released by at least one local broadcasting station, some of the more important markets by several local stations and by a number of stations other than those located at points where reporting offices are maintained.

The value of this method of news distribution, not only from the standpoint of furnishing prompt, dependable information but in actual dollars-and-cents savings, is being manifested daily. Wide and prompt dissemination of the market information is also obtained through daily and increasing use of it by the C. N. D. (commercial news despatch) service of the commercial telegraph companies, by the Associated Press, International News Service, United Press Associations, the daily, weekly and periodical news, trade, and agricultural press, and by mail from the various field stations.

### Reports Sent Almost Hourly

In accordance with the urgent demands of the trade, and fully realizing the special value of quick service, reports are sent out almost hourly from the larger centers, particularly in the case of livestock. Beginning with estimates of supplies at the various markets early in the morning, these releases are continued throughout the day, keeping in close touch with the many phases and developments of the market until the final close of trade. To permit of careful and valuable analyses of market trends, supply, and demand conditions, etc., voluminous statistical records embracing the fundamental facts at all markets are compiled and released.

FIG. 141.—Watching a hog transaction. Seller (middle) argues over price and sort with buyer (right), while reporter (left) is silent observer

Only a trained personnel can meet the strict requirements of this work. Accordingly, the division of livestock, meats, and wool has acquired for the market news service technical men who have practical experience. They have been carefully and uniformly trained for their special duties in accordance with plans having far-reaching benefits to the industry.

E. W. BAKER.

**LIVESTOCK Market Statistics** The need of accurate data was early recognized by the Department of Agriculture as a prerequisite to a careful study of the marketing of livestock and meats. It was hoped, as a result of this study, to devise better methods of marketing, which would tend to regulate market supplies, insure stable markets, and help the producer to determine in advance of shipment the kind and grade of stock in demand at the various markets and the exact times at which this demand was greatest and when it was the least urgent.

To this end records have been kept: (1) Of daily, weekly, and monthly livestock movements, including receipts, shipments, and slaughter at each of the livestock markets and the shipments by classes and weight groups of stockers and feeders from the central markets to the individual States; (2) of receipts of western dressed meats at the eastern markets, of stocks held in storage, and of imports and exports; and (3) of the number, average weight, and yield of livestock, by classes, slaughtered in the United States by months and years.

These data are the basis for estimating production and consumption and for determining the regions and seasons of greatest and least supplies.

Prior to the organization of this work by the Department of Agriculture, studies in comparative prices of livestock and meats were impracticable, for uniform grades did not exist and therefore the available price series were not comparable. For instance, prices quoted on beef cattle or butcher steers might apply to choice grade at one market and to common grade at another market.

### Statements Published Daily

Since the establishment of the department's livestock and meat market news service, however, statements have been published daily showing price quotations by classes and grades of livestock at the principal livestock markets and of meats at Chicago and at three eastern markets. A careful record has been kept of these daily quotations and from them weekly and monthly averages have been computed by grades. These prices are now available for all of the more important markets over a period of years.

With the completion and general adoption of these standard classifications, making possible intensive studies of market preferences and net returns by grades, together with the livestock movements and supply, much has been accomplished toward determining, in advance, where and when the producer should sell his stock, and where, when, and what the feeder should buy.

E. M. Jordan.

**LIVESTOCK Problems That Have Been Solved** In reporting from year to year on livestock conditions surrounding the production, feeding, care, diseases, and parasites of animals, there sometimes appear to be but minor changes. But in contrasting the situation to-day with that of 10, 20, or 30 years ago, the real progress is plainly evident.

Stock raising is less hazardous and more of a substantial business than at any time in the past. Scientific and practical achievements have made it so.

The present definite knowledge concerning cattle-fever ticks and the systematic method of eradicating them are in striking contrast to "shotgun quarantine" methods of a generation ago on the part of northern cattlemen seeking to protect themselves against the "bloody murrain," as tick fever was called at the time. Hog cholera, though still a formidable disease, lacks the terror that it once had for swine growers. The most serious problem in that field now is some method of stabilizing production and use of serum. One remedy for such a condition in the future lies in a more general immunization of pigs, especially while they are young, for at that time the preventive treatment is most economical.

FIG. 142.—Swine raising is less hazardous than in former years. Though heavy losses still occur, hog men can readily control them by suitable precautions, such as immunizing pigs to prevent cholera and practicing swine sanitation to protect pigs from parasites

## Sanitation Asserts Its Importance

Another current development is a more definite knowledge and utilization of sanitary methods than was prevalent a decade or more ago. Present-day stockmen are realizing that sanitation is more than visible cleanliness. It means the suppression by tested methods of infection by bacteria and parasites too small to be seen with the unaided eye. The newer system of swine sanitation, which has proved to be so helpful in reducing losses, illustrates the practical value of the few hours of care and of the additional equipment that so greatly enhances net returns.

Our knowledge of stock-poisoning plants and methods of management and prevention has increased remarkably in recent years. Persons who now suffer losses from stock-poisoning plants do so largely through failure to obtain the information that is available.

There is a large quantity of sound information now at hand on the value of improved breeding in increasing the sale value of animals raised. Heredity is a force constantly in operation but moving slowly. For that reason its effects are seldom observed or attract slight attention unless the results are presented more forcefully by suitable demonstrations.

From the few examples cited it is clear that the livestock industry is much better equipped to meet future problems that may arise than at any time in the past. Moreover, the advances made have consisted largely in the solution of fundamental problems and not merely in the adjustment of temporary troubles.

### A Million Reactors Removed from Herds

Satisfactory as the outlook appears to be, a still more encouraging development is the current trend toward better teamwork among the various branches dealing with the production, handling, and sale of domestic animals. As the result of such teamwork more than a million tuberculous cattle have been sent to the shambles in less than 10 years. Even the most visionary optimist probably would not have ventured to predict such a result when cooperative tuberculosis-eradication work was undertaken in 1917.

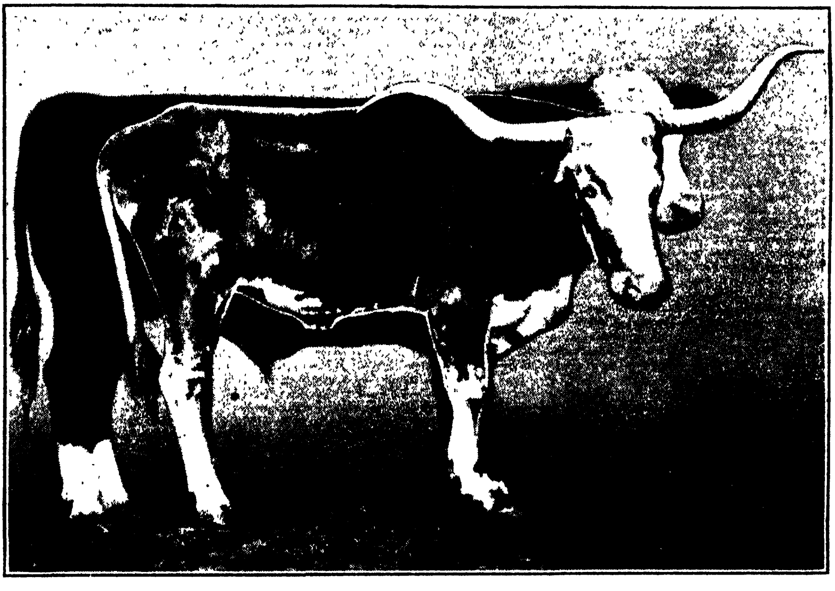

FIG. 143.—A study of the progress the cattle industry has made in improving the type of animals raised for beef

Several other important cooperative projects relating to the betterment of our animal industry have developed in the last few years. One of these is the cooperative meat project to study factors influencing the quality and palatability of meat. Nineteen State experiment stations, representatives of the livestock and meat industries, and several bureaus of the United States Department of Agriculture are engaged in this important study. A similar, though less extensive project, is the study, now in its seventh year, of factors causing the production of soft pork.

In various ways the department has gradually come into the possession of several experiment farms and field stations at which regional problems are being studied. In some cases the land was donated; in others it was made available by State officials for cooperative Federal and State projects. In the case of the extensive range livestock experiment station comprising 57,000 acres at Miles City, Mont. (fig. 144), the land, buildings, and equipment were transferred to the Department of Agriculture by the War Department. In other instances, as in Moultrie, Ga., where studies of livestock parasites began during the last fiscal year, many facilities were supplied by a cooperating commercial organization. Members of Congress have shown keen personal interest in the establishment of many of the cooperative stations and farms. All such facilities make possible a greater number and range of experiments.

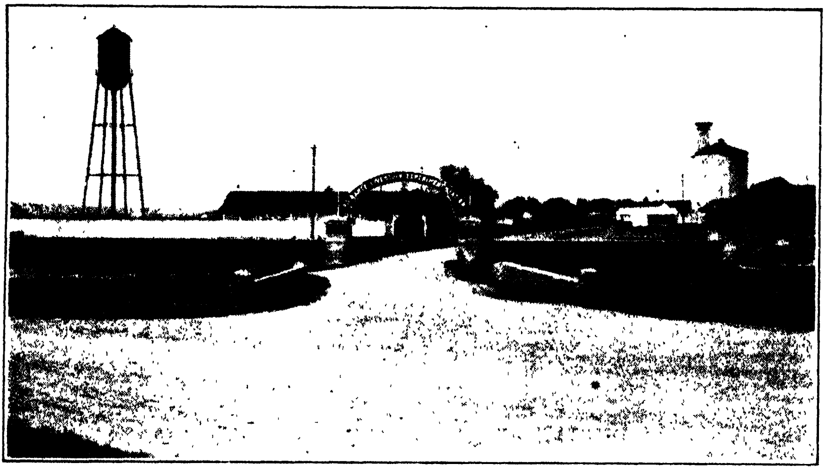

FIG. 144.--Entrance and part of the equipment at the U. S. Range Livestock Experiment Station at Miles City, Mont. Visitors are welcome at the various experiment farms and experiment stations of the Bureau of Animal Industry, many of which are operated in cooperation with State experiment stations

## Credit Enough for All

In all this work there has been an effective combination of scientific training, practical experience, executive ability, funds, and other necessary factors. This diversity of resources naturally hastens progress and by reason of the contacts of each of the different interests there has arisen also a wider public interest in the work.

The benefits of mutual effort have brought about likewise an increasing willingness among the workers to share the credit for achievement, and in some cases even to let credit fall where it may. Cooperative investigations quickly show that the effort of any one group is too small to carry any given piece of work through to completion. Even the research worker, whose efforts are perhaps most intensive and are basically important, must depend on his colleagues for certain parts of his work, on livestock owners for the demonstration of results under farm conditions, and on field men and the press for making the final results sufficiently well known to benefit the industry, which is the ultimate objective. Briefly, there is a growing and unselfish willingness to admit that "there is credit enough for all."

From the foregoing discussion the outlook for the animal industry of the United States is plainly favorable. Conflict of effort and strife among the various branches of the industry has been rapidly giving way to mutual efforts for a common goal. Hazards are fewer, and knowledge of means for reducing them and increasing net returns has been increasing gradually. In fact, the supply of useful information appears to have accumulated faster than the industry has absorbed it and used it for practical purposes. The intimate relation between the livestock industry and the country's food habits and its demands for leather, wool, and other products is obviously a complex economic study. But with population growing somewhat more rapidly than the number of animals in the country, the position of the industry with respect to demand for its products is well established.

John R. Mohler.

**LIVESTOCK Reports Issued Weekly to Country Bankers** A weekly livestock market review, prepared primarily for the use of country bankers and their patrons in the Corn Belt States, is one of the features of the market news service conducted by the Bureau of Agricultural Economics. At the present time approximately 400 banks are receiving such reports weekly from either the Chicago or the East St. Louis offices of the division of livestock, meats, and wool of the bureau.

Prior to the inauguration of this service several years ago, requests had come from several bankers, whose funds were used largely in financing livestock producers and feeders, for concise, readable, and dependable reviews of the livestock market which would keep them in touch, not only with the day-to-day developments but which would provide an authoritative source of information regarding supply, demand, and price conditions over a longer period, thereby indicating broad movements and general trends. In response to this demand, letters were sent to a large number of banks in livestock-producing areas, to determine whether or not there was a real need for a service of this kind. The response was prompt and showed beyond question that there was a widespread demand for such reports.

These "bankers special" livestock reviews, consisting of between 800 and 1,000 words, analyze and cover the principal features of the week's trading in cattle, hogs, and sheep. They are mimeographed and mailed each Thursday afternoon, in order that they may be received by the banks not later than Saturday morning. In most instances the reports are posted on bulletin boards or elsewhere and are consulted regularly by large numbers of stockmen and other patrons of the banks.

These reports are intended to supplement rather than supplant other and more timely reports prepared in the division, such as those disseminated every market day by radio, telegraph, the press, and the mail. In thus reviewing the market for an entire week a more comprehensive idea of underlying conditions can be obtained by the readers than is possible through the medium of a record of each day's trading, with its frequent temporary fluctuations up and down the price scale, which often appear to have no definite trend in any direction.

J. A. Burgess.

## LONG-RANGE or Seasonal Weather Forecast Methods

The principles underlying seasonal forecasts and those upon which daily forecasts are based, differ radically. The seasonal forecast does not, as many persons might suppose, involve simply an extension of the time covered by the daily forecast. Being based on different premises, it is itself totally different. We are confronted on the very threshold of the problem with the need of a full knowledge of the effects, over a period of months, which physical laws exert upon the atmosphere, of the sequences of world-wide weather they produce, and so on.

Such perfect knowledge, very far as yet from being within our grasp, would enable us, for example, to forecast seasonal rainfall; that is to compute the quantity and trace the course of the water vapor which is carried by the winds to the uttermost parts of the earth.

In the absence of perfect knowledge, seasonal forecasts must be based on such empirical rules (admittedly imperfect) as can be deduced from world-wide weather statistics. These rules may be considered under several groups:

Efforts have been made to predict the weather of the coming months from that of the month just past. Thus in 1904 the last third of May was unusually cold, giving rise to a belief that the remainder of the year would be like 1816, the "year without a summer." But statistical test showed that out of 156 Mays (long records at two stations), only 58 per cent preceded years of like character as to temperature. Nevertheless C. D. Reed of the Iowa climatological service has shown that the June mean temperature of Iowa can with considerable success be used to forecast that of the next following July, August, and September. European meteorologists have found that temperature tends to persist in the same sense; for example, there is more than an even chance that a " warm " month will be followed by a " warm " month, etc., but the relation is not sufficiently definite to be of much use in seasonal forecasting.

Immense effort has been devoted to search for periodicities in the weather. The search has thus far, however, not produced convincing results, because many of the so-called periods seem to be discernible only when changes in the weather so slight as to be of no practical importance are taken into consideration. Moreover, the claim is made that the length of the period varies systematically—and this would further increase the complications of seasonal forecasting.

### The Geographical Method

The method of geographical relations, so named for convenience, is based on the fact that weather travels from west to east. Through it, many students have tried to find a definite relation between the weather of a certain region at a certain time, and that of a distant place two to six months later. This, in substance, the Indian meteorologists do in forecasting the summer monsoon rains—one of the few even fairly successful attempts at long-range prediction.

The method of the Indian meteorologists is apparently not applicable elsewhere. No other areas have India's favorable situation—open on both sides to a flow of moist air that has traversed several thousand miles of tropical waters, and backed along its whole northern boundary by a high mountain range, the Himalaya, which deflects the rain-bearing winds along its southern slopes and causes them to precipitate their moisture there and over the plains of India.

If there were on the Mexican border of the United States a similar indraught of southerly winds, there still would be no monsoon rains; that border is separated from the equatorial waters of the Pacific by the highlands of Mexico and Central America, wherefore southwest winds would be descending, and thus warm and dry. This and other reasons preclude applying the Indian methods of forecasting to North America.

The recognized influence of the ocean upon the temperature of adjacent lands probably gave rise to the thought that the weather of a season might be forecast on the assumption that high or low temperature in some part of the oceanic areas would later be brought by ocean currents into close proximity with the lands for which it is desired to forecast.

There are weak links in this chain of reasoning: Suppose the water of the Gulf Stream, for example, to be several degrees warmer than the average as it passes through Florida Strait; what is the probability of its retaining its excess warmth until it arrives off the coast of Europe? Helland-Hansen and Fridtjof Nansen, after studying extensive data for the North Atlantic between the English Channel and New York, say that "in the middle of the North Atlantic the wind is the principal direct cause of the observed variations in the winter temperature of the surface of the ocean." They also point out that no causal relation exists between the variation of the surface-water temperature on the Norwegian coast and the variations of air temperature in Scandinavia, but rather both must have the same cause, the effect being noticeable a little earlier in the air than in the water.

Certain studies have demonstrated that pronounced changes in temperature sometimes occur almost simultaneously over both continents and oceans; if oceanic temperatures were the controlling factor, the changes should be recorded first over the oceans.

### Solar Radiation Theory

Public attention has recently been directed to the work of the astrophysical observatory of the Smithsonian Institution in measuring the amount of heat received at the outer limit of the atmosphere and to the possibility of applying these measurements to weather forecasting. When the sun is most spotted, which is precisely when it is hottest, terrestrial temperatures the world over suffer a slight diminution (paradoxical as this may seem), and vice versa. How this remarkable result is brought about is not known with certainty.

The significance of the astrophysical observatory's work for weather forecasting is not yet clear. It would, therefore, be premature and unscientific to base a program of forecasting on it, before the intensive and sympathetic study which the Weather Bureau is making of the daily measurements sent to it by the observatory is further advanced.

One may, of course, finally resort to forecasting on the laws of chance. If an event can happen in but two ways, for example, the coming winter may be either warm or cold, the probability of either occurring is expressed by the fraction ½, indicating the even chance that either may occur. In an area the size of the United States, the temperature rarely varies from the normal in the same sense everywhere. One may therefore predict "a cold winter" with the assurance that in some part of the country his prediction will be verified. Rainfall is still more patchy in its distribution. In the 42 years, 1884–1925, no single month had a rainfall above the normal throughout the entire country, and but one month in the 504 showed even a close approach to that condition. A prediction of deficient rainfall which discreetly avoids specifying time and place, would, therefore, have better than an even chance of verification.

### The Outlook for Seasonal Forecasting in the United States

It is manifest that every scientific effort put forth by organized weather services or other agency to increase knowledge of the physical laws of the atmosphere, must contribute to a better understanding of the problem. The writer has elsewhere pointed out the application of this subject to the United States:

> The most important variable involved is without doubt the variations in north Pacific pressure one-quarter year in advance and the influence of such variations upon the weather of the continent of North America. . . . Atlantic pressure is important but must take a subordinate place to that of the Pacific. The hope of the future so far as seasonal forecasting for the United States is concerned lies in the Pacific.

There is but one sound point of view as to the outlook for long-range forecasting: To make such forecasting widely successful will tax the ingenuity of the scientist, and certainly, meanwhile, the patience of the public. Since the beginning of recorded history, man has sown at seedtime, with the expectation of reaping at harvest, and, pending realization of his hopes for long-range forecasting, he must so continue.

ALFRED J. HENRY.

### MAGNESIA in Fertilizer for Tobacco Plant

At least 10 elements are essential to normal plant growth, namely, carbon, hydrogen, oxygen, nitrogen, sulphur, phosphorus, potassium, calcium, magnesium, and iron. Some investigators believe that certain other elements need to be taken into consideration. In ordinary fertilizer practice, heretofore, only three of the above have been taken into account as follows: Phosphorus, as phosphoric acid ($P_2O_5$); nitrogen, as ammonia ($NH_3$); and potassium, as potash ($K_2O$). In recent years it has been shown that on some soils another element, namely, magnesium, is a necessary constituent of the fertilizer for tobacco. It has been found that some tobacco soils, especially those containing considerable sand, have a very low content of magnesia, and a marked increase in the yield and quality of product usually results when this element is supplied in addition to the three commonly used.

The growing tobacco plant exhibits characterstic symptoms when magnesia is deficient in the soil and not supplied in the fertilizer, as shown in Figure 145. The first sign of magnesia deficiency is the loss of the green color at the tips of the lower leaves of the plant. This loss of green progresses inwardly on the leaf toward its base, along the margins and between the veins and from the lower leaves of the plant to the upper. The lower leaves may be pale green or almost white, except the veins which usually retain their green color. This type of chlorosis is distinguished from the mottling characteristic of potash deficiency in that the chlorotic areas of the leaf do not break down so readily.

### Show Discolored Areas

Plants manifesting potash-deficiency symptoms show discolored areas of the leaf of a light-yellow color which occur in splotches at the tip and between the veins of the leaf, whereas the discolored areas caused by magnesia deficiency show a light-green or almost white color and progress more regularly from the tip toward the base of the leaf along the margins and between the veins. The magnesia chlorosis also progresses more uniformly from the lower to the upper leaves of the plant. The plant showing magnesia deficiency is not, therefore, as rough as a plant showing potash deficiency, for in case of magnesia deficiency, the leaf has usually reached full size before the translocation of the magnesia takes place.

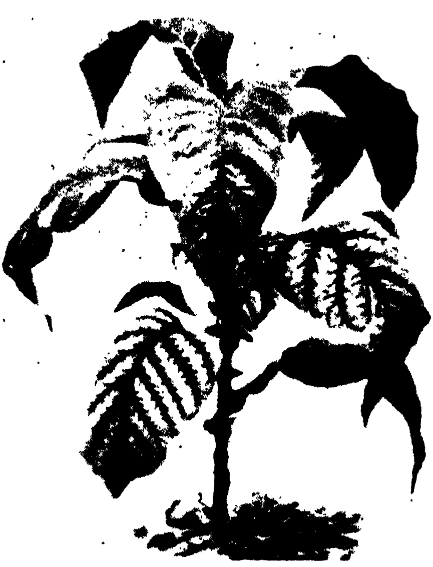

FIG. 145.—Tobacco plant showing characteristic symptoms of magnesia deficiency

Symptoms of magnesia deficiency and its bad effects on quality and yield of tobacco can be prevented by using potash salts carrying magnesia or by applying to the soil light applications of dolomitic limestone. Cottonseed meal, muriate of potash, basic slag, and raw bone meal when used in the fertilizer mixture, also seem to partially control this trouble. Magnesium-deficiency symptoms are more prevalent in wet seasons and on sandy soils, and for this reason this condition is commonly called "sand drown."

J. E. McMurtrey.

**MEASURING Changes in the Prices of Farm Commodities** Changes in the prices of farm products, like changes in other prices, are obviously important to the producers of those products. Not only do the prices received during a season largely determine the farmer's income but they also influence his production for the coming season. Inasmuch as wholesale prices of farm products do not always reflect changes in prices at the farm, it becomes important to measure the changes in the latter. At the wholesale markets price quotations relate to specific grade, quality, or class, but the farmer's marketings for the most part are composed of all classes and grades. Furthermore, in the case of commodities where the market price is considerably higher than the price received by the grower, a given change in each is much more important in terms of the producer's price than of the market price. For instance, with the market price of potatoes at $4, of which the producer may receive $2, a decrease of 40 cents in both the market and farm price means only a 10 per cent drop in the former but 20 per cent in the latter.

Measures of changes in farm prices also serve to answer such questions as the following: Are some prices advancing or declining faster than others? Are certain sections of the farming industry enjoying a price advantage which others are not? Are the prices for agriculture as a whole keeping pace with prices in other industries? What do present prices suggest as to their future course? How do the prices received by farmers compare with prices they have to pay for what they buy?

### Relative Prices

When we are concerned only with comparisons between prices of individual commodities, as between wheat and corn, or hogs and cattle, the simplest method of measuring their changes is to express the actual prices as percentages of their prices in some common previous period. Thus, if wheat before the war sold at the farm for an average price of 88.4 cents per bushel and now sells for 125.1 cents, the present price is 42 per cent higher, or if we take 88.4 cents as 100 per cent, the present price may be represented by a relative price of 142 per cent. If this is done for all the items to be compared, one obviates the difficulty arising from the fact that each commodity price is usually expressed in different units, such as bushels, tons, and crates. By the use of price relatives, an increase of $4 in the price of an $80-horse (5 per cent) is no greater a percentage change than an increase of 4 cents in an 80-cent bushel of corn (5 per cent). In Figures 146 and 147 the prices received by producers in the United States for grains and meat animals from 1910 to date are shown as relative prices; that is, relative to their pre-war averages taken as 100 per cent.

The comparison of the price changes of one group of farm commodities with that of another or between changes in the farmer's prices and nonagricultural prices requires the use of index numbers.

Just as relative prices indicate by what percentage the price of one commodity has changed from some previous price of a stated date, so index numbers of prices show the average percentage that a group of commodity prices has changed from the previous prices.

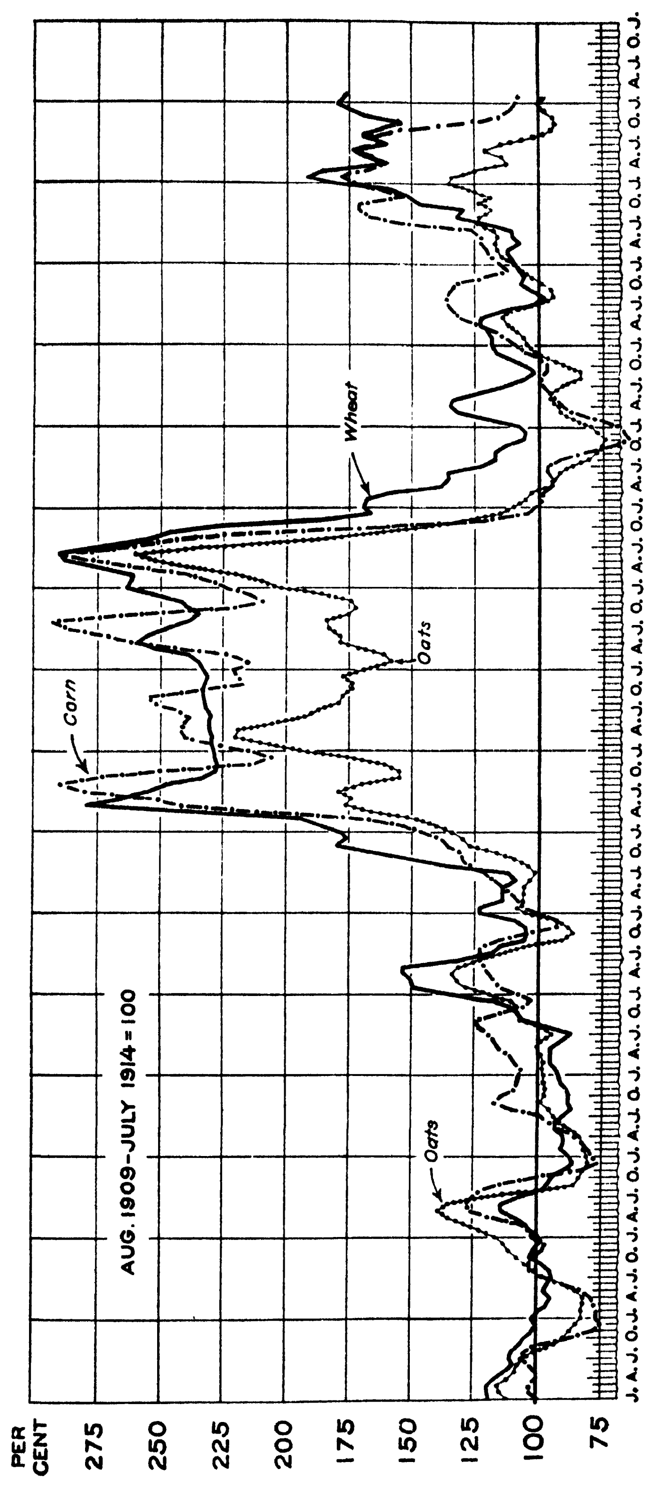

FIG. 146.—Relative farm prices of grains. When grain prices are expressed as percentages of their pre-war average prices, their relationships are more clearly brought out than is possible when dollar-and-cent prices are used

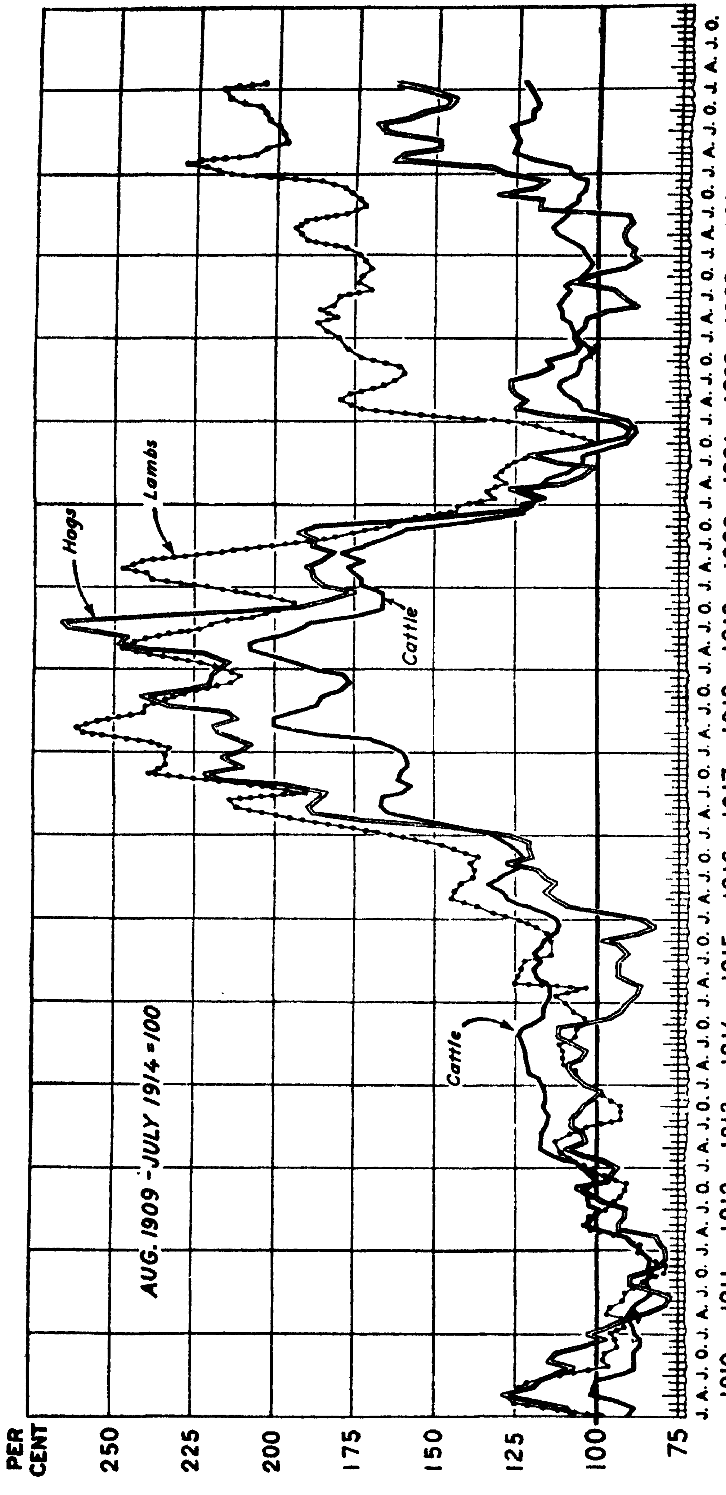

FIG. 147.—Relative farm prices of meat animals. Hog prices have improved materially since 1924. Cattle prices are still relatively low. Lamb prices have been comparatively favorable to producers since 1921

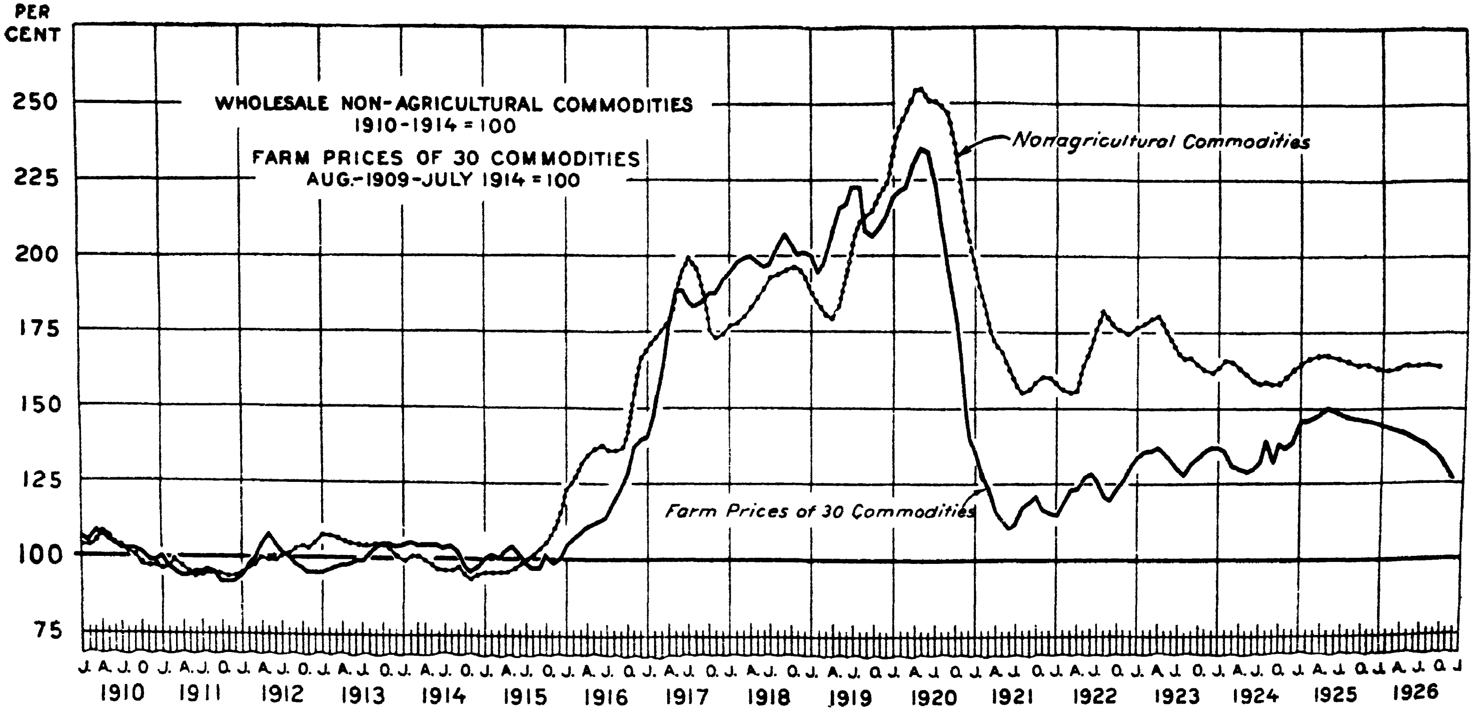

FIG. 148.—Index numbers of farm prices and wholesale prices of nonagricultural products, monthly, 1910–1925. The process of averaging the prices of a large number of commodities, some of which are high and some low, gives a result which shows much less change from date than the changes represented in Figures 146 and 147. Relative prices of farm products have been below those of nonagricultural commodities since 1919 and in 1926 lost part of the gain made in previous years

The general index numbers of the farm prices of major farm products, such as grains, meat animals, dairy and poultry products, and cotton and cottonseed are shown in Figure 148. It also shows the changes that have taken place in the prices of nonagricultural commodities at the wholesale markets.

### Method of Constructing Index Numbers

Several problems need to be considered in the construction of index numbers. The first of these is the question of a base period. In the accompanying charts the base period, or the period during which the average prices are taken as 100 per cent, is the five years before the outbreak of the World War. In the construction of other index numbers, such as those published by the Bureau of Labor Statistics, the prices which prevailed in 1913 are used as 100 per cent. A one-year base for agricultural prices is not entirely satisfactory, because in any one year the prices of one or more farm products may be unusually out of line with the rest. Corn prices, for example, during part of 1913 were unusually low. If those low prices were taken as 100 per cent, it is obvious that present prices when expressed as percentages of those low prices would appear too high. On the other hand, cattle prices in 1913 were high. If they are taken as 100 per cent, present prices when expressed as price relatives would appear too low. Inasmuch as most agricultural prices fluctuate a great deal from year to year, it is safer to adopt a five-year average as the basis for comparison.

Another requirement for a base period is that it should not be too far removed from the present. This would suggest a base period after 1914, but a study of the charts suggests that any period between 1914 and 1919 would be unsatisfactory because of war-time influences on all prices and from 1919 to date because of the great depression of 1920–21, and its after-effect on farm prices.

### Importance of Each Commodity

Another important question that arises in constructing index numbers is the importance that should be given to each commodity. If the index were constructed by merely taking an average of the several price relatives, it would be assuming that each commodity has the same importance, and an unusually high or low price relative for one commodity would then have a disproportionate influence on the final index. For instance, if it were desired by this simple method to construct an index number for the three prices of meat animals shown in Figure 147 for the year 1923, an average of about 175 for lambs, 110 for cattle, and 100 for hogs, would be 128. This average is above 110 because of the high figure for lambs, which is here assumed to be as important as either of the other two. But farmers as a whole derive nearly 10 times as much money income from either cattle or hogs than from lambs. If lamb prices at 175 per cent are given an importance of 1 and the other two 10 each, the average of the three becomes 108 instead of 128.

There are other objections to this method of averaging price relatives, even if they are weighted according to the relative importance of each commodity.[14] In order to obviate these, it has been found both convenient and practical to use not price relatives, but the actual prices in the making of an index. This method involves first determining what quantity farmers sell of each product during an average month or year, and then, as prices change from year to year or month to month, to calculate the total value of these quantities for each month or year. For instance, the value of the average marketings of the major farm products at 1925 prices amounted to $7,900,000,000. The same quantities at pre-war average prices were worth $5,400,000,000, or an increase of 47 per cent. In other words, since the same quantities are used in both values, the increase is due entirely to changes in prices, and if $5,400,000,000 be taken as 100 the 1925 value of $7,900,000,000 becomes 147 or the farm price index for 1925.

This method has been used in constructing the general indexes of farm prices and nonagricultural commodity prices shown in Figure 148.

L. H. Bean.

## MEAT Cooking a Fine Art That Science Assists

Of meat as of pudding "the proof is in the eating." In other words the quality of meat is decided on the table by whether it is palatable as an article of food. The Bureau of Animal Industry and Agricultural Economics are studying the points which are believed to determine the quality of meat and the Bureau of Home Economics is cooperating by cooking cuts from experimental animals to prepare them for palatability tests and also by assisting in the judging of the cooked meat. The aroma of the cooked meat, its texture and tenderness, the flavor of the lean meat and of the fat, and the juiciness of the meat are the points by which palatability is judged. The cooking, it goes almost without saying, must be done by a standard method. Every roast, or steak, or whatever the cut, can then be scored up or down on its own merits. Great care must consequently be taken to preserve the characteristic flavor of the meat, to get it to just the right stage of doneness, and to avoid toughening it unnecessarily. These are of course the same points that home makers have in mind when cooking meat for the family table. But how to achieve them is sometimes another matter. The following points about the cooking of meat for these tests suggest practical methods for the home maker.

The flavor of meat comes chiefly from substances called extractives present in the juices. Holding in the juices is therefore one of the first things to strive for in cooking meat. Baking, roasting, and broiling do this best, because the surface of the meat is seared at the very start of the cooking and juices are conserved. Also other appetizing flavors develop as the high temperature of searing forms a rich brown coating on the surface. Tender cuts should always be cooked in this way. Steaming, simmering, or any other method of moist cooking draws the juices and accordingly the flavor from the meat, but for tough cuts it is necessary. The juices can, however, be saved and served in gravy with the meat.

---

[14] See Irving Fisher, "Making of Index Numbers."

Salt and other seasonings also draw out the juices and mask the meat flavor. When meat is cooked to the judges' taste, no seasoning whatever is added to the meat during cooking. When broiling steaks and chops at home, salt should be sprinkled on just before they are put on the platter for serving. Large roasts are generally salted when they are first put into the oven so that the seasoning will cook through the meat. A better method would be to add the salt when the roast is about half done, and it can not draw out so much juice.

### Cooking Temperature Important

The temperature of cooking also has a great deal to do with the eating quality of meat when it comes to the table. Meat is one of the most important foods from which we get protein to build and repair body tissues. In order to have highest food value, meat protein should be changed as little as possible by cooking. Protein is very sensitive to heat, and high temperatures coagulate, toughen, and modify it. Meats, therefore, should be cooked at as low temperature as possible while at the same time keeping in the juices and getting it done to just the stage desired. After a roast or steak has been seared at high temperature, the heat should be reduced quickly and the meat allowed to finish cooking not far above the boiling point of water (212° F.). This is a slow method of cooking, but the meat is juicy, tender, and done to the same stage throughout. If a tough cut is being cooked, it should be simmered or steamed, using only enough heat to keep it cooking.

FIG. 149. Meat laboratory in the Bureau of Home Economics

Everybody wants his meat done to what he considers a turn. This may be "rare," "medium," or "well done," for certain cuts of beef. All pork must be well done, and most people prefer all cuts of lamb and mutton, except chops, cooked at least to the medium stage. Even experienced meat cooks find it difficult to get large roasts to just the right stage every time. The shape of the cut and the amount of bone have a marked effect on the way heat penetrates.

For it is the temperature that meat reaches at the center as well as on the surface during cooking which determines its "doneness." Thermometers stuck into the center of the roast are the only way to avoid guesswork. Such thermometers may be bought for a comparatively small sum. Meat is considered rare when the thermometer registers between 130° and 150° F., medium rare between 150° and 160° F., and well done between 160° and 180° F. It should be taken from the oven as soon as the desired point is reached, because the temperature of a roast continues to go up several degrees after it is taken from the oven. If allowed to remain longer it may be overdone.

**MEAT Investigations That Help Stockmen** Quality in meat is ultimately measured by its tenderness when cooked and by the consumer's taste. As a result, the more tender kinds and cuts of meat are more popular and command a higher price than those which need more forcible chewing. Juiciness and a full, agreeable flavor are also enjoyed by all, and these combined with a high degree of tenderness largely determine the consumer's preference for the various meats.

The profits of the stockman depend on the difference between the cost of producing his animals and their market value. He is desirous of producing the quality of meat that finds the greatest favor with the consumer, and hence also at livestock markets, if it can be done without prohibitive expense. Given a certain number of home-grown or available feeds, the farmer's problem is to combine them so as to produce the greatest possible tenderness and palatability in the meat. He must consider the kind, age, sex, breeding, and weight of the livestock to be fed; likewise the kind, quality, quantities, and prices of the grain, hay, silage, and pasture which are obtainable. Equipment, labor, time of year, and probable market are other factors which must be studied. Only then can the course be laid and decision made as to whether the product will be cow beef or baby beef, medium beef or prime beef, stockers or feeders.

A most comprehensive and forward step has been recently taken which aims to assist both producer and consumer in answering the questions "What kind of beef shall I raise?" and "What kind of beef shall I eat?" About 30 State agricultural experiment stations and the United States Department of Agriculture have begun a cooperative study of the factors which influence the palatability of meat. The National Livestock and Meat Board is sponsoring the work. What is quality? How can it be distinguished? What is the best way to produce it, and the best way to preserve or improve it?

### Feed-Lot Practices Standardized

The cooperating institutions mentioned have mapped out a program which will help in answering these questions. Feed-lot practices have been standardized so as to make a true comparison between sex, age, breeding, grain, grass, and other factors. An official committee scores each steer as a feeder, a finished animal, and a carcass. Complete slaughter records are combined with the feeding records.

FIG. 150.—Grading committee at work in the Government abattoir

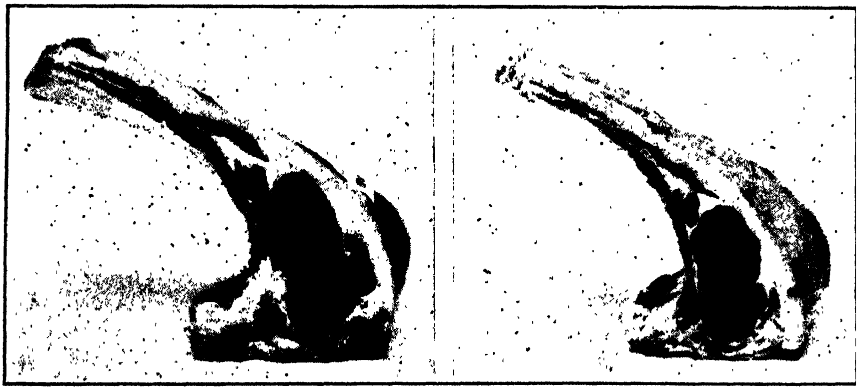

FIG. 151.—Although these beef ribs appear to an inexperienced purchaser to be very similar, the rib at the right was surprisingly superior in tenderness and flavor. The object of these meat investigations is to determine the breeding, feeding, and management practices which cause such variations

Lastly, the meat from these animals is actually measured as to quality. The color, tenderness, chemical composition, and muscle structure are recorded and compared. Samples are also cooked by standard, uniform methods and graded by another official committee.

One thousand cattle were fed in accordance with this program last year. Ribs from 63 head were sent to the Government laboratories for a complete test as to quality. Eleven hundred hogs were slaughtered at the Government abattoir during the last year, most of them being used in the study of factors causing soft pork. Many were experimentally cured to determine the effect of the curing methods on the palatability of the meat.

More than 400 lambs were also slaughtered at the department's experiment farm at Beltsville, Md., for a comparison of various feedlot and management practices.

The work is new, but sufficient progress has already been made to warrant the belief that the factors which influence quality in meat can be more definitely measured and controlled. This will be to the advantage of both the person who raises the livestock and the one who eats the meat.

**MEAT Retailing Methods** A study of the retail meat industry has been made in 20 representative cities and towns in all sections of the country. The cities and towns were selected according to geographic distribution, comparability of general business, density of population, and other comparable characteristics. The purpose of the survey was to determine efficient and inefficient methods of retailing and ascertain the effect different methods had on livestock production.

Conditions in the retail branch of the industry have undergone marked changes during the past two decades. Changes in living conditions have been responsible for greater economies in distribution, while increased competition of a progressive type has largely displaced the old-time butcher. Accordingly, the requirements for success in the operation of a retail meat market to-day are different. Opportunities for initiative and sales ability have been multiplied, and in general the standard has been raised.

The factors studied included type of store, location, character of business, practical knowledge of proprietor, source of supply, methods of buying, selling practices, facilities and equipment, advertising, sanitation, bookkeeping, types of employees, attitude toward customers, salesmanship, misleading practices and deception, frequency of turnover, price determinations, disproportionate demand for cuts of meats, spread between wholesale costs and retail prices, volume of business, wastes and shrinkages, number of stores in relation to population, and numerous factors of lesser importance which exert an influence on the industry.

### Chief Factors in Industry

The major factors which concern the industry most were found to be insufficient knowledge on the part of many operators, adherence to old methods, inadequate equipment, false and misleading advertising, low degree of sanitation in a large percentage of markets, and a total lack of uniform standards of quality in the sale of meats. Of these, probably the effect produced by misrepresentation is the most important. Consumers, for the most part, have little or no knowledge of differences in quality of meats, consequently are not in position to make selections intelligently. Because of this, some dealers did not hesitate to misrepresent their products to their own financial advantage. This was done principally through misleading displays and advertising. For these purposes meats of high quality were stressed and meats of low quality actually sold.

Procedures of this kind have affected producers of better grades of meat animals because meats of poor quality have, in many cases, been sold as meats of high quality with a consequent loss of confidence on the part of consumers. Misrepresentation in the sale of meats has demonstrated clearly the need for uniform grades. The industry in general will not be placed on a fundamentally satisfactory basis until uniform standards have been universally adopted.

The study showed that too many incompetent men were engaged in operating retail markets. Some of these lacked a knowledge of the fundamental principles on which any business is based. Many had little or no knowledge of the retail meat business prior to their entrance into it. They knew practically nothing concerning percentages and yields of cuts, therefore had no means of knowing how to determine selling prices. Many such operators followed price lists of one or more competitors, regardless of quality of meats handled. Consequently they were operating on a "hit or miss" basis, with the result that their period of operations was likely to be short lived and generally unsatisfactory to all concerned.

### Many Without Records

Approximately 50 per cent of the stores studied were found to be operating without adequate bookkeeping records and many of these had no records by which even their operating expenses could be determined. Many admitted their inability to meet competition, yet they failed to appreciate the need for keeping records.

Many dealers were found who were trying to operate with insufficient equipment and inadequate refrigeration. In most such cases waste and shrinkage were factors which could not be controlled satisfactorily.

Despite the fact that conditions in the retail meat industry have changed materially in recent years, necessitating new methods of operating, many operators still cling to antiquated methods and as a consequence they are unable to meet competition of modern progressive dealers satisfactorily.

W. C. DAVIS.

## MEAT Spoilage; Its Prevention

The spoilage of meats in curing, while fortunately the exception and not the rule, is nevertheless a source of serious loss both to commercial establishments and to farmers. The magnitude of commercial meat curing is shown by the fact that about 3,000,000,000 pounds, chiefly pork, were placed in cure in establishments operating under Federal inspection during the last fiscal year.

Scientific study of the spoilage of pork in cure began soon after the inauguration of the Federal meat inspection service under the present law in 1906 and has been continued up to the present time. Twenty years of study and observation have developed some of the causes of spoilage as well as preventive measures.

### Souring of Hams

Spoilage is due to bacteria, and in the preservation of meat the development of bacteria is controlled by the use of low temperatures. Bacteria of one particular type are regularly found in sour hams. This type is characterized by the properties of growing in the absence of air and of forming spores or seeds. All spore-forming bacteria are extremely tenacious of life when in the spore stage and some of them will grow at uncommonly low temperatures. Bacteria of this type are common in nature and are abundant in the dirt and dust of livestock pens and on the skin and hair of the animals themselves. Their presence has been demonstrated repeatedly in hog-scalding equipment.

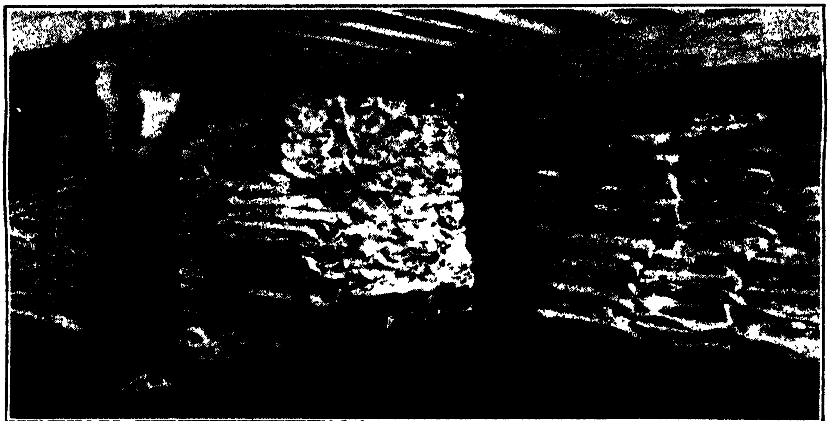

FIG. 152.—Curing meat in dry salt. The quality of the product and success in preventing spoilage depend first on prompt and efficient chilling, and next on salting to prevent growth of the organisms that cause spoilage

Bacteriological study of hams has shown the presence of bacteria of the type responsible for spoilage in such locations as to make it certain that they did not gain access to the carcass during the scalding or dressing processes. The state of present knowledge indicates that the bacteria are present in the blood and tissues of the living animal. They are invariably present in the meat, and no means are now known whereby they can be entirely excluded. It does not follow from this fact that cleanliness and sanitation may be neglected. On the contrary it is of the utmost importance that any further invasion of destructive organisms be avoided. Preventing the development of the bacteria already in the meat is sufficiently difficult without increasing their numbers unnecessarily.

### Methods of Prevention

Experience has shown that the first step in prevention of spoilage is the chilling of the meat. It is necessary to reduce the temperature of the meat below 40° F. as soon as possible. Freedom from spoilage is dependent on quick and efficient chilling.

The next and final check is the common salt used in curing. Salt will not kill the organisms concerned, but when all parts of the meat have taken up as little as 3 per cent of salt it is effective in preventing growth of these organisms.

The prevention of spoilage of meats in cure begins with the live animal. Holding the live animals overnight in clean pens, with plenty of water but no feed, ought to diminish the number of destructive organisms in the flesh. The meat of an animal which has been driven, overheated, excited, roughly handled, or heavily fed shortly before slaughter may be expected to contain more than the normal number of such bacteria. Rapid and efficient handling through the different processes of slaughtering, scalding, dehairing, and evisceration, prompt and effective chilling, and holding the chilled meat at a low temperature until it has taken up salt enough for preservation comprise the means of prevention against spoilage.

FIG. 153.—Federal inspector testing smoked hams for soundness. A steel trier is used for making the tests

Applied to commercial establishments, this means strict adherence to what is generally recognized as sound practice. There is no convenient short cut, but strict attention to every detail is required. The same principle applies to home slaughtering. In the absence of artificial refrigeration it is advisable to wait for clear, cool weather for slaughtering. The hogs should be confined in small pens the day before killing and should be watered, but not fed either the evening before or the day they are killed. Each hog should be scalded, scraped, and eviscerated promptly after killing. The carcass should be thoroughly cleansed with plenty of clean water, and hung where it will cool throughout without freezing. The meat should then be cut and placed in cure as soon as practicable. This procedure is recognized as good practice and is shown to be so by scientific study.

---

**MEAT Standards and the Livestock Producer** One of the outstanding developments in the livestock industry in recent years is the marked increase of interest on the part of livestock producers in the dressed-meat market. Only a few years ago the interest of even the more progressive livestock producers ended at the stockyards when his livestock was turned over to the packer-buyer. In those days the stockman was vitally concerned with production costs, facilities and costs of transportation, and the price his stock brought when it reached market. But there his interest stopped. If the check or draft which he received from his commission man exceeded his production costs by a fairly wide margin he was jubilant; if by a narrow margin he was happy; and if it failed to equal his costs, as frequently happened, he was downcast and sometimes pessimistic.

### Likely to Blame Buyers

Under such circumstances he was likely to charge his losses up to the alleged greed and heartlessness of the buyers on the livestock market. Almost never did he attempt to look through, over, or beyond the purchaser of his livestock. The buyer was the man who took his stock and either did or did not give in exchange what the producer considered a fair price, and that, for the producer, was the end of the matter. Unfortunately there are still some livestock producers who conduct their business in this manner, but the number is growing rapidly smaller.

The up-to-date stockman recognizes the buyer for what he is—a middleman. Although the buyer can by no means shirk all responsibility for the price paid the producer, nevertheless the latter now looks far beyond him to the ultimate consumer of the meat which his livestock produces. He realizes that he is converting grass, hay, and concentrates into meat rather than livestock. He recognizes the fact that he is really producing for the meat consumer and not for the livestock buyer.

### Consumer Must Be Considered

Above all he has come to appreciate the fact that it is the meat consumer who holds the purse and supplies the money—not only that which is divided among the various distributing agencies but also that which ultimately reaches the livestock producer himself. That being the case it becomes obvious that unless the meat produced by the stockman is of a kind, class, weight, and grade which appeals strongly to the consumer, the latter will either refuse to exchange his money for the meat or will take advantage of his position by demanding a relatively larger quantity for a relatively small amount of money. In a word, the producer has come to realize that if he is to obtain a relatively high price for his stock it must ultimately be because that livestock will produce meat for which the consumer is willing to pay a relatively high price. Most livestock producers now appreciate the fact that unless they succeed in producing something that the meat consumer wants and wants badly, they can not hope to find a ready or profitable sale for their stock.

It follows then, as a natural course, that the livestock producer of to-day is studying very carefully the wants and requirements, the likes and dislikes, the peculiarities and preferences of meat consumers and is doing his utmost to meet those requirements. He is doing this, not as a matter of altruism, but purely from the standpoint of an enlightened selfishness.

### A Common Trade Language

In view of the fact that consumer wants are matters of such vital concern to the livestock producer, it would seem essential that some satisfactory means of communication between the two be devised. This is particularly true in view of the fact that frequently anywhere from 1,000 to 3,000 miles separate producer and consumer. Under such circumstances a common trade language capable of being used and understood alike by meat consumers, handlers, and producers would seem to be one of the first essentials. At this point the scheme of standard market grades for both livestock and meat, devised by the United States Department of Agriculture, comes to the assistance of both the producer and consumer. Before the meat consumer can inform the livestock producer as to the kind of meat he wants he must have at his disposal a set of class and grade names which will identify unmistakably to the producer just the kind of meat the consumer wants.

The real purpose of all standardization is identification. The department's plan of setting up fixed standards for grades of both livestock and meats makes this possible. This system of standardization provides ways and means whereby the meat consumer can convey his needs and preferences to the livestock producer, through specifications and obviates the necessity of personal inspection of the commodities involved.

So long as a system of barter served the needs of the industry there was little use for a standard trade language. So soon, however, as buyers and sellers become widely separated one of two courses becomes imperative; either goods had to be shipped to the consumer subject to his inspection and approval, or facilities had to be provided whereby he could describe the thing desired in such a way that there was no likelihood of misunderstanding on the part of the seller. Economy dictated the latter course.

Why should the livestock producer be interested in grade standards for meat and how is he likely to profit from such standards? He should be interested because such a system puts him in almost immediate contact with his real market—the meat consuming public. Because it enables him, the producer, to inform the buyer or consumer regarding the thing he has to offer and makes it possible for the consumer to tell the producer exactly what he wants.

### Use of Grades to Producer

The livestock producer will profit from such standards because, under such a system, if the consumer wants choice steer beef the producer will not send him an animal which will produce medium grade cow beef. Because by knowing in advance what the consumer wants the producer can govern his operations accordingly and avoid much waste in time and effort which frequently occurs from trying to force on the consuming market commodities for which there is little or no demand. Finally the producer will profit by being able intelligently to read and interpret market reports, learning from such reports not only what the consuming market demands, but just what prices it will pay for the various classes and grades of livestock and meat.

C. E. GIBBONS.

## MECHANICAL Corn Picker in the Corn Raising States

In eastern South Dakota and southwestern North Dakota there are more mechanical corn pickers on farms than in any section of similar size located within the States which are commonly referred to as making up the Corn Belt. This situation exists because the picker meets a big demand from farmers for a method of harvesting which will eliminate husking by hand the low-growing varieties of corn which many of them grow. The corn picker does not necessarily eliminate all possible difficulties that may be experienced when the crop is harvested by hand power.

During corn harvesting in the Dakotas, variation in soil and weather conditions affect operation. When the ground is slippery the machine does not work well on account of poor traction, as the drive wheel often becomes clogged with mud and trash. The machine does its best on a firm, dry, or damp soil. In corn that stands up well the picker does a very good job, and in corn that is not too badly lodged it does fairly good work. If corn is lodged crosswise a better job can be done than when it is lodged lengthwise of the row. The picker wastes less corn and does the cleanest job of husking in corn that is slightly damp and the stalks are tough. Under these conditions few ears are left in the field, practically all the husks are removed from the ears, and the stalks do not break loose from the ground when passing through the machine. To some extent the quality of work is dependent upon the operator and his knowledge of the machine and the proper adjustments to make under different conditions.

### Work Done Per Day

The work done per day by a picker depends upon the power used, equipment, soil, weather, topography, yield, and hours of work.

Table 18 shows the rate of work per day for crews of the same size using different methods of unloading and for different sized crews. According to men who use a tractor to pull the picker, a larger acreage can be covered in a day than when horses are used.

Table 18.—*Rate of work per day for mechanical corn picker with different sized crews*

| Picker crew | | Hauling crew | | Method of unloading | Yield per acre | Acres per day | Bushels per day | Hours per day | Bushels per hour | Bushels per man |
|---|---|---|---|---|---|---|---|---|---|---|

From interviewed farmers who own pickers, it is learned that acreage in corn is not the factor which most of them consider first or which influences them in purchasing a machine, but rather the advantages to be gained by its use. The average area in corn on farms where pickers were owned was 105 acres, but only an average of 89 acres was harvested with the machine. Although the present price of a picker, $400 to $425, may seem high, the advantages of ownership may more than offset the first cost.

### Supplants Labor on Farm

Many owners feel that the principal advantage of a picker is that it enables them to do away with high-priced, inefficient, and undependable hired help for husking the corn crop by hand. Others feel that the elimination of hand husking, which they and their families are required to do, is more important. Practically every owner feels that either is of enough importance to warrant the expenditure necessary for the purchase of a picker.

With a comparatively small acreage of corn to husk, the ownership of a machine by an individual farmer may not be warranted because of the cost, even though it enables him to do his husking quicker and with less expense and labor. The joint ownership of a picker is often practical and where satisfactory arrangements can be made, such ownership is recommended by men who own their machines jointly.

L. A. Reynoldson.

## MILK Flavors and Odors Ascribed to Four Main Causes

Cow's milk invariably has a characteristic flavor and odor more or less pronounced, but comparatively little is known concerning the factors contributing to these characteristics. The flavors vary from those which make the milk pleasing to others which make it objectionable and unpalatable.

Flavors and odors in milk result mainly from four causes: (1) The internal or physical condition of the individual cow, (2) highly flavored feeds, (3) odors absorbed by the milk after production, (4) biological changes in the milk.

Flavors and odors of the first and second classes are noticeable just after the milk is drawn and usually do not increase with time. Those of the third class may develop when the atmosphere to which the milk is exposed is permeated with pronounced odors, while those of the fourth class become more apparent after some time has elapsed.

Milk of pleasing quality can be produced only when the factors deleteriously affecting the flavor and odor of milk are controlled. In 1921 the department began investigations, considering principally the factors of the second and third classes. Throughout the investigations the department has endeavored to suggest methods of assistance to dairymen in the production of milk reasonably free from feed taints frequently found in market milk.

### Objects of the Investigation

The objects of the investigation are as follows: (1) To determine whether or not certain feeds affect the flavor and odor of milk, (2) if they are found to do so, to determine how these feeds may be used and the milk handled so as to minimize their effect on the quality of the product.

For this work cows are selected giving milk relatively free from abnormal flavors and odors when fed a basic hay and grain ration. These are known as check cows. In addition to the basic hay and grain rations, the other cows receive varying quantities of the experimental feed at different stated times before and immediately after milking. The cows in the various groups are interchanged at frequent intervals in order to equalize any abnormal results due to the milk of any individual animal. Samples are taken from the milk produced by these cows and judged for flavor and odor. The opinions of the judges determine the degree to which the feed affects the flavor and odor of the milk.

From the work thus far completed it has been shown that when corn silage, legume silage, green alfalfa, cabbage, and turnips are fed to dairy cows one hour before milking, the flavor and odor of the milk are seriously affected. Green rye, green cowpeas, potatoes, dried beet pulp, and carrots affect the milk only to a slight degree; whereas green corn, green oats and peas, pumpkins, and sugar beets have practically no effect on the flavor and odor of the milk produced.

Throughout the work certain facts have been proved, namely:

While feed-tainted barn air may have some effect on the flavor and odor of milk, it is of relatively small importance even under extreme conditions; for feed flavors and odors are imparted to milk mainly through the body of the cow and not by absorption from the surrounding atmosphere.

Highly flavored feeds may be fed immediately after milking without seriously affecting the flavor and odor of the milk produced at the next milking.

Most feed flavors and odors are more pronounced in cream than in the milk from which the cream is skimmed.

Proper aeration reduces strong feed flavors and odors in milk, and slight feed flavors and odors may be eliminated.

### Time Element Involved

In order to obtain further and more definite information concerning the time required for feed flavors and odors to enter the milk and the time required after consumption before the flavor and odor will have disappeared, as well as the methods by which the flavor and odor may enter the milk, experimental work was carried on with garlic, and the following conclusions were reached:

Garlic flavors and odors may be detected in the milk when the samples are taken one minute after feeding one-half pound.

The intensity of the garlic flavor and odor increased as the time interval between feeding the garlic and taking the milk samples increased, until at 10 minutes a high degree of intensity was reached. This intensity remained to an objectionable degree for 4 hours, after which there was a decrease, and at 7 hours it had practically disappeared.

Strong garlic flavor and odor were found in milk drawn 2 minutes after the cows inhaled garlic odor for 10 minutes. The inhalation took place in such a manner that it was impossible for the cows to eat any of the garlic. The cows were then milked in an atmosphere free from garlic odor. The garlic flavor and odor imparted to the milk in this manner practically disappeared in 90 minutes.

Garlic odor was readily perceived in samples of blood drawn 30 minutes after feeding the cows 2 pounds of garlic tops, and strong garlic odor was present in the blood drawn 45 minutes after such feeding.

These data indicate that the feed flavor and odor are absorbed by the blood from the stomach, or, in cases where the feed has a pronounced odor, to some extent from the lungs and thence transmitted to the milk.

### Time of Feeding Important

Milk is often rendered unsalable by feed flavors, while a product of pleasing taste extends the market by increasing the quantity consumed. Feed flavors may be avoided by controlling the time of feeding, for in most cases feed flavors are not imparted to milk except for a few hours after feeding. For this reason dairy cows should be fed highly flavored feeds immediately after and not just before milking.

Pastures should be cleared of weeds which cause objectionable flavors and odors in milk. Until this is done, cows should be removed from infested pastures as long as possible before milking. The longer the interval between removing the cows and milking, the less the intensity of the undesirable flavors. Some weeds, however, have a tendency to impart objectionable flavors several hours after consumption. When such weeds are present it may be necessary to forego pasturing until the weeds are exterminated.

C. J. Babcock.

**MILK Production Indexes** Milk production in the United States during the first nine months of 1926 exceeded production during the first nine months of 1925, as measured by production per cow on the first day of each month from January to October. The department has attempted to obtain some data which will answer the many requests it receives for information on relative milk production. Since September 1, 1924, the crop reporters have been asked on the regular crop-report blanks to answer the following questions: Number of cows milked on your farm yesterday. Number of all milk cows in your herd yesterday (both dry and in milk). Total production of milk by your herd yesterday (pounds or gallons).

The chart, Figure 154, represents the number of pounds of milk per day per cow in herd as reported by crop reporters. It would appear that production during September, October, and November in 1925 was less than in the same months in 1924 for both the North Central States and for the United States as a whole. Production in 1926 to date (October 1) was somewhat in excess of 1925 for the United States as a whole. In the North Central States, however, production was slightly less during July and August. The increased production in 1926 is attributed largely to larger supplies of home-grown feed (except hay) and the relatively lower prices of feed grains, and to a lesser degree to a greater proportion of mature cows in 1926 and in 1925. The department's estimates of heifers kept for milk on January 1, 1926, indicated fewer than a year earlier. The proportion of heifers included in the " cows in herd " numbers would therefore be smaller than in 1925.

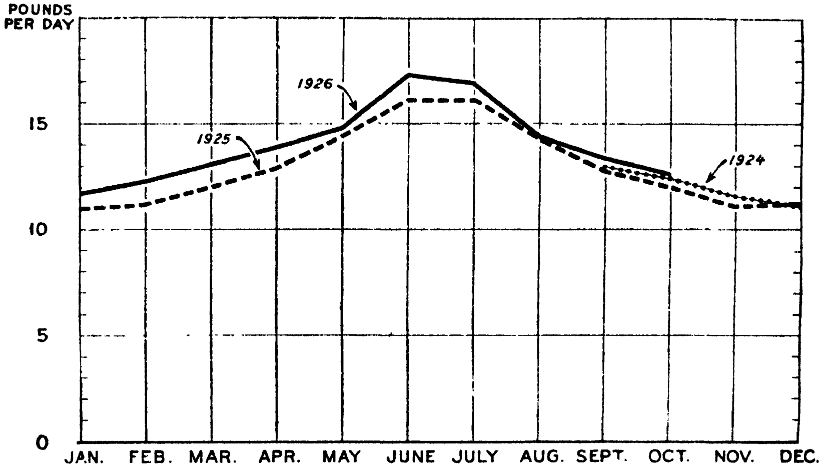

FIG. 154.—Milk production per cow in herd on 1st day of each month, September 1, 1924, to October 1, 1926

### Average Production in 1925

A preliminary calculation of average production per cow per year from the 12 " sample " days reported indicates an average production for 1925 of 4,730 pounds. This differs somewhat from production as computed from data on manufactured dairy products, estimates of farm consumption, etc. Further study is needed of the raw data to establish a basis of estimating total production from these figures.

It was anticipated that the returns from this inquiry would give an indicated production in excess of average production for all farms. It has been the experience of the department that crop reporters are somewhat more efficient than the average farmer. They operate larger farms, have a greater percentage of their farm area in crops, have larger holdings of livestock, etc., than the average farmer as measured by census figures. It is felt, therefore, that the results of this inquiry are more useful as indicating relative production as between months or years than as a measure of absolute production.

The seasonal change in milk production; as shown by these reports, is generally in agreement with accepted ideas. Here, again, however, crop reporters may not be strictly representative of all farmers. A comparison with a larger sample, of more strictly average farmers in Wisconsin, indicated that the crop reporters produced a larger percentage of the year's production in the winter months and a smaller percentage in the summer months. The curves shown may therefore show less seasonal change than milk production as a whole.

The data upon which the chart is based refer only to production per cow in herd. No allowance is made for changes in the number of cows in herd, either seasonal or annual. These changes, however, appear to be slight in comparison with changes in production per cow. Thus, for the United States the number of cows and heifers, 2 years old and over, on January 1, 1926, was only 1 per cent less than on January 1, 1925, while production per cow was 6 per cent greater. A study of the number of cows per farm reporting indicates only a slight seasonal change in number per farm. For the North Central States, in 1925 the number of cows in herd for May 1 and June was 3 per cent above the number for January and February, and the number for September and October was 1 per cent above.

### Effect of Pasture Conditions Shown

In the North Central States pastures in 1926 were later and less plentiful in the spring than in 1925. Milk production reflected this on May 1. Again, pasture conditions in July and August were lower than in 1925, but better in September. This apparently influenced milk production in these months. In the early summer of 1925 grain prices were high and grain scarce, whereas during the same period of 1926 prices were low and supplies plentiful. Doubtless more grain was fed during July and August, 1926, than in 1925, which helped to hold up milk flow; otherwise it would have shown more decrease than now indicated.

JOSEPH A. BECKER.

---

**MORGAN Horse Record** The story of the Morgan horse is one of the most unusual in the annals of the country's livestock industry. The breed is founded chiefly on one famous stallion; it flourished for many years; then almost became lost, and finally was reestablished. Morgan horses are of unusual interest because of their hardiness, soundness, and remarkable utility qualities.

The stallion Justin Morgan, foaled in Vermont in 1793, was the progenitor of the Morgan breed of horses. His prepotency was so great as to cause his descendants to be easily recognized. Justin Morgan was a small horse, under 15 hands, but powerful and of quick action. He is said to have excelled any horse with which he competed in walking, running, and pulling. Though this famous stallion was a remarkable individual, little is definitely known of his ancestry. After his death, in 1821, the influence of Justin Morgan on the light-horse industry of America continued with pronounced effect.

The breed flourished. In the New England States, Morgans were used almost to the exclusion of other horses until a craze for trotting speed struck the country. The new interest brought about a mixing of the best Morgan stock with trotting blood. Some writers have asserted that the Morgan added stamina to certain trotting-horse families. But the mixed breeding resulted in some cases in the loss of the Morgan's beautiful form and other of its qualities. For many years this diluting and scattering of Morgan blood continued, and little serious thought or foresight for preserving the breed developed until about 20 years ago.

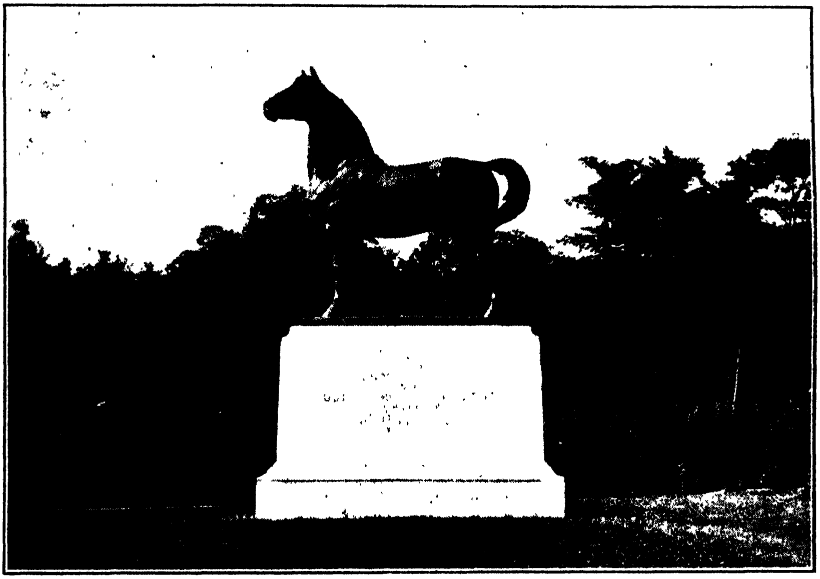

FIG. 155.—One of the few statues erected to the memory of a horse, Justin Morgan, progenitor of the breed bearing his name. This statue is at the United States Morgan Horse Farm, through presentation by the Morgan Horse Club of America

In an effort to preserve the best specimens of the Morgan horse, several public-spirited men who knew personally its many meritorious qualities, took collective action which soon bore fruit. One of the first steps was taken by Joseph Battell, of Middlebury, Vt., who established the American Morgan Register as an authentic record of Morgan blood lines. He also gave the United States Department of Agriculture a 400-acre farm near Middlebury. In cooperation with the Vermont Agricultural Experiment Station the department assembled a small band of Morgan mares as the beginning of a permanent project to conserve and perpetuate the breed.

### Superior Specimens Produced

The farm, known as the United States Morgan Horse Farm, now consists of 1,000 acres and maintains a stud of about 60 animals. One of the first steps after its establishment was that of tracing the descendants of the best Morgans sold to purchasers in other sections of the country. Stock was obtained in Kentucky, Kansas, Texas, New York, Washington, Idaho, Rhode Island, New Hampshire, and Illinois, as well as in the breed's native State of Vermont. The whole effort was to get into the Government stud the best Morgan blood to be obtained anywhere in the country. Privately owned Morgan stallions also have been used liberally as a means of restablishing desired blood lines.

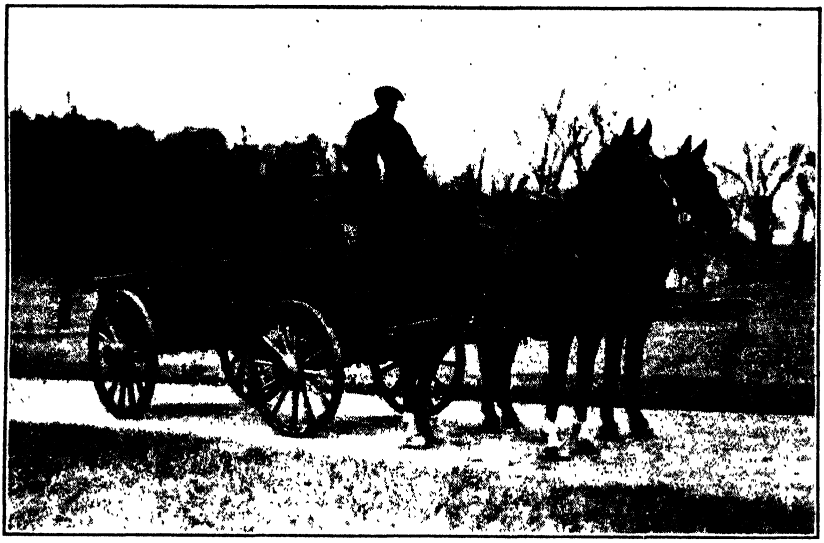

FIG. 156.—Morgan mares used for heavy, farm hauling, and other farm work at the United States Morgan Horse Farm

Prizes won at numerous fairs and expositions wherever horses from the United States Morgan Horse Farm have competed are evidence of superior specimens of the breed resulting from its reestablishment. The prizes have included two champion stallions, one reserve champion stallion, and numerous first premiums in breeding classes for both sexes. Animals shown in driving and riding classes also have won many premiums.

Morgan horses produced at the farm likewise have made creditable showings in several official endurance rides sponsored by breed associations and individuals active in horse improvement.

Morgans are now found in most of the important farming sections of the United States. They have earned a reputation for hardiness, soundness, and usefulness. As saddle horses, Morgans are noteworthy for their great intelligence and hardiness. The First Vermont Cavalry in the Civil War was mounted on Morgan horses and made a great reputation. The horses also called forth general admiration. In Sheridan's famous ride to Winchester, made immortal in verse, his mount was a Morgan horse. After its death the animal was stuffed and is now to be seen at the National Museum in Washington.

### Make Good Cow Horses

As a breed the Morgan has a smart, alert walk, an easy trot, and a smooth, collected canter. Among cattlemen of the West and South, Morgans have acquired a reputation as desirable cow horses. They learn quickly and have the strength and courage necessary for work among cattle on the Great Plains. Morgan stallions bred to the proper type of range mares are said to produce ideal cow horses.

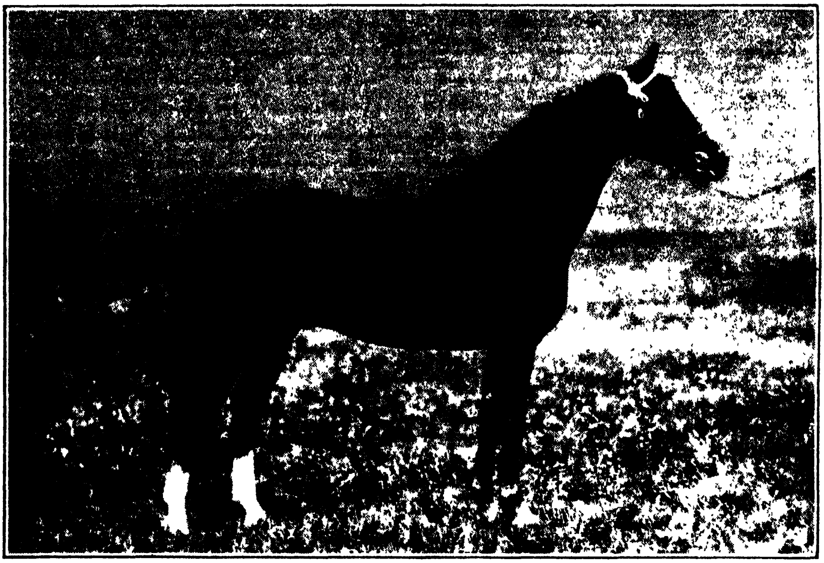

FIG. 157.—Mansfield, 7255, A. M. R. A very promising young Morgan stallion now in stud at the United States Morgan Horse Farm

Department records show that Morgan horses have been sent to Japan, the Island of Guam, Porto Rico, and Central America. Reports indicate that the Morgan breed is well adapted to conditions in those countries. In the short span of 20 years the Morgan breed, which almost became extinct through diffusion of its blood, has been reestablished.

The adaptability and value of this horse is now more fully appreciated and recognized than in the past. It is no longer a breed associated with New England horse-breeding activities but is known nationally and abroad. Morgan stallions are especially valuable for improving native stock in various parts of the country owing to their remarkable prepotency and ability that adapt themselves to new environment.

JOHN O. WILLIAMS.

**MOTHS—Preventing Their Depredations** Over 50 years ago the gipsy moth one of the insects most destructive to tree growth in many European countries, became established in the suburbs of Boston, Mass., and in 1897 serious defoliation by the brown-tail moth, another European pest, was discovered in Somerville, Mass. The gipsy moth increased slowly, and about 30 years later it caused havoc to forest, fruit, and shade trees in the region where it was introduced. In many cases practically all foliage was devoured by the caterpillars and the insects swarmed over walks and houses in the residential sections and became an unendurable nuisance. The State of Massachusetts then attempted to exterminate the insect and carried on this campaign for about 10 years, reducing the pest to such small numbers that public interest in the project waned and the work was discontinued.

Less than five years later the insect multiplied to such an extent and caused such enormous damage that the State resumed operations, but in the meantime the insect had spread into Maine, New Hampshire, and Rhode Island. Federal aid was obtained in 1906, with the idea of preventing the spread of the insect to other parts of the United States. The infestation was so severe that thousands of acres of woodland, in addition to fruit and ornamental trees in all of these States, were being defoliated annually. Every effort was made to reduce the infestation and prevent further spread, but owing to the extent of the territory and the density of infestation, the insect continued to spread toward the north and west. The brown-tail moth infestation also increased in severity and for a number of years spread more rapidly than the gipsy moth. During the war and the years immediately following, control work was seriously handicapped on account of rapid turnover in personnel.

In 1920 a large colony of gipsy moths was found in Somerville, N. J., which was believed to cover an area of about a hundred square miles. With the cooperation of the New Jersey Department of Agriculture, the Bureau of Entomology attempted to exterminate the insect in this area, and although careful field work demonstrated that it was present in a territory of over 400 square miles, the work was continued and the project vigorously pushed. In view of the fact that the insect had been completely exterminated in a number of vigorous isolated colonies, including one at Cleveland, Ohio, Geneva,, N. Y., Rutherford, N. J., and Mt. Kisco, N. Y., it seemed feasible to attempt its extermination in this larger New Jersey area. Since that time the infested area has been reduced nearly one-half and the insect controlled so completely that no damage has resulted. This project is being continued and a successful conclusion is anticipated.

### Pest Enemies Liberated

As early as 1906 investigations were begun in Europe by the Bureau of Entomology in cooperation with the State of Massachusetts, to introduce and establish the natural enemies of these two pests. This proved to be a slow and tedious undertaking owing to the difficulty of obtaining correct information concerning the parasites and natural enemies in their native home, and the extreme difficulty of shipping them to this country in the live state. Many difficulties were also encountered in successfully handling the parasites after they were received and liberating colonies in the infested areas. Since this work was begun the gipsy moth laboratory at Melrose Highlands, Mass., has liberated over 85,000,000 of these beneficial insects. Some were received from Europe, others from Japan, but by far the greater number developed by increasing some species under laboratory conditions and by recolonizing from field collections of some of the species that had become established. Of more than 50 species brought to this country in connection with this work, only about 15 have been able to maintain themselves under New England conditions. The object of the parasite work was to accomplish by natural means the reduction of the gipsy moth infestation to the lowest possible point.

Other experimental work has been conducted by the laboratory for the purpose of developing more efficient methods of field control, many of which have been put in operation.

A system of inspection has been worked out which operates in the area that is quarantined by the Federal Horticultural Board. This safeguards the shipment of all products sent from the gipsy-moth infested area to other parts of the country and has been successful in preventing long-distance spread of the insect.

Each of the infested States in New England has been carrying on field-control work within its borders and has been striving to reduce the infestation as rapidly as possible. The Federal field work has been confined to the outside infested area, but owing to the density of infestation it was necessary periodically to shift the operation westward. By 1923 small colonies were found in western Massachusetts and southwestern Vermont, and two colonies were located in New York, east of the Hudson River. At that time the plan of work was radically changed, and in cooperation with the State of New York, an area was laid out from the Canadian line to Long Island Sound, some 30 miles in width, approximately one-half the territory being in New York east of the Hudson River, with the idea of doing intensive work in this belt and keeping it free from infestation. (Fig. 158.)

### Number of Colonies Reduced

The work has been carried on in this zone, and although more colonies were found during the first year or two than was anticipated, it has been possible to reduce the number of colonies. This plan is working effectively and gives promise of preventing spread of the gipsy moth to the west. The Adirondack and Catskill Mountains lie directly west of this zone area, and every effort is being made to prevent the insect from becoming established in these regions. As a precautionary measure a large number of towns have been examined west of the zone. The only dangerous infestations have been found recently and these are being given proper attention. With the exception of a strip of towns extending south from the Canadian border, the conservation commission of the State of New York is handling the field work in that State and treating a few isolated colonies on Long Island. The entomological branch of the Dominion of Canada is carrying on scouting work along the Vermont and New York State lines and has cleaned up the only colony found in Canada.

The results of the work in the barrier zone have been very satisfactory and have made possible the elimination from quarantine of a large number of towns in all the States concerned on account of the satisfactory condition of the territory.

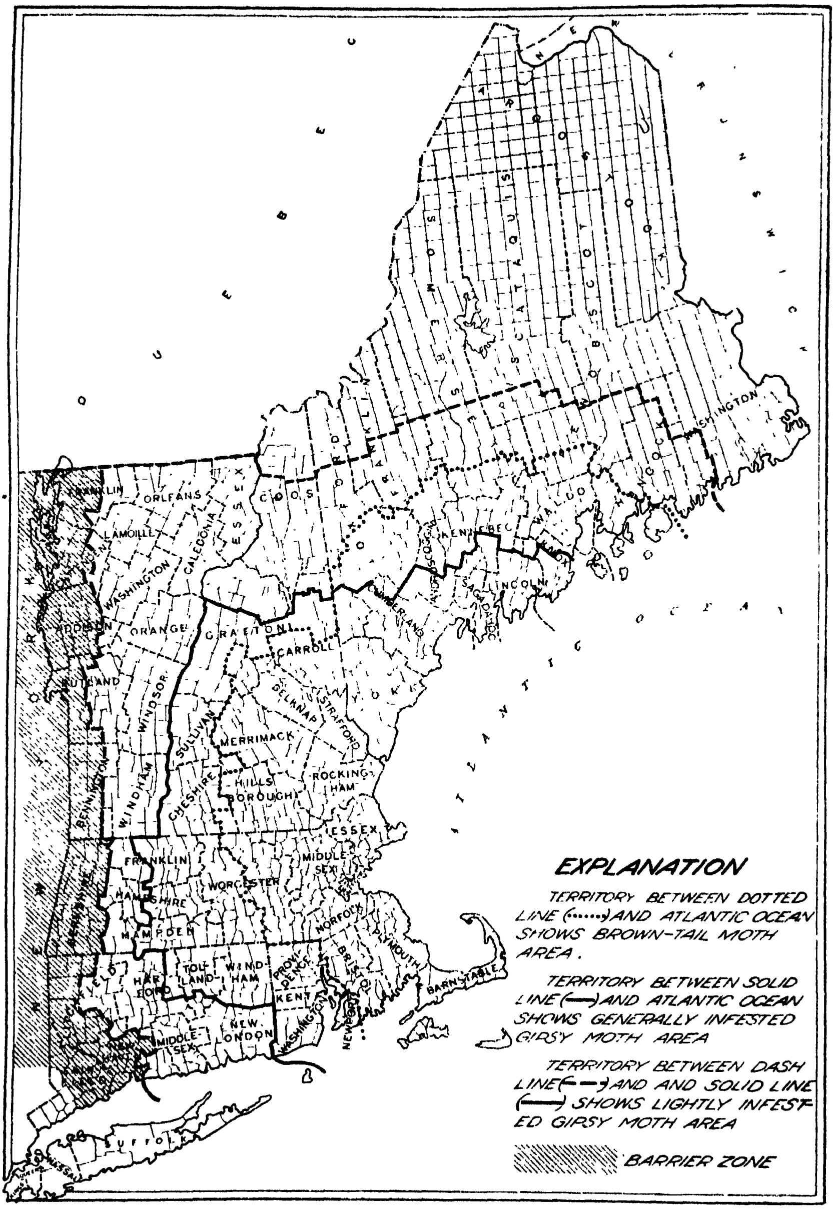

FIG. 158.—Map of New England showing gipsy moth barrier zone

During the last five years the density of the gipsy moth infestation in nearly all the towns east of the barrier zone has gradually decreased. This has resulted in part from the field work that has been carried on by the States, towns, and individuals, but the greatest improvement is due to the gradual increase and effectiveness of introduced parasites and natural enemies.

In 1924 the total acreage defoliated by the gipsy moth was less than at any time since the work on this insect was begun by the Bureau of Entomology, and natural enemies were most abundant. Since that time the gipsy moth has increased slightly in most of the area east of the barrier zone, and in the Cape Cod region in Massachusetts enormous areas have been completely defoliated. (Fig. 159.) This has been due to a sharp decline in the number of the parasites, and it is impossible to foresee just what will happen in this respect during the next few years.

### Area Infested by Brown-tail Moth Has Decreased

The area infested with the brown-tail moth has gradually decreased, and at present the moth is causing marked damage only in limited areas along the seacoast in northern Massachusetts, New Hampshire, and Maine, and in some towns along the Merrimac and other rivers in New Hampshire. Persistent destruction of the webs of this insect, high winter mortality of the caterpillars in certain parts of the infested territory, and heavy parasitism of the insect by their imported enemies, have brought about this result.

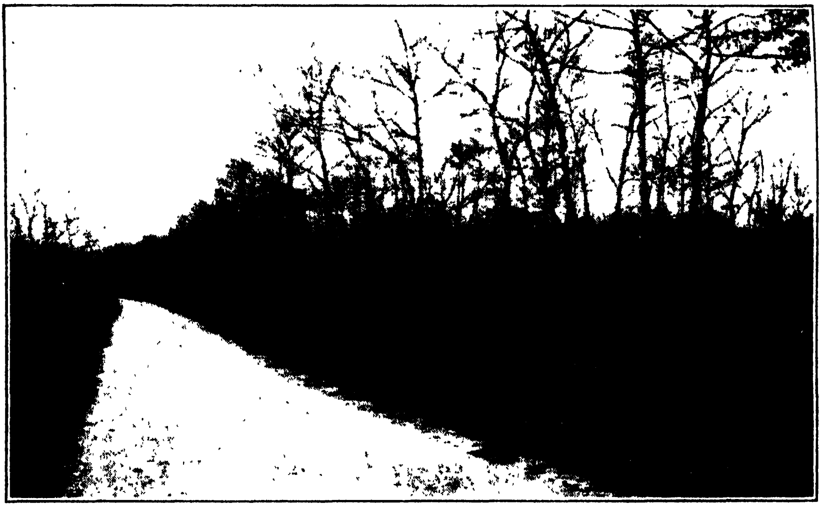

FIG. 159.—Defoliated forest at Barnstable, Mass. Photo taken July 15, 1926. Nearly 50,000 acres were in this condition in the summer of 1926

The work on the gipsy moth and brown-tail moth is the most intensive that has been applied to any insect introduced into the United States, and the operations have extended over a longer period of years. The parasite work alone is the largest project of its kind that has been attempted in this country. An enormous amount of time and effort has been spent in protecting the nation as a whole from the ravages of these pests and the progress made up to the present time indicates that the efforts put forth are producing substantial results.

A. F. BURGESS.

**MOVIES for the Farmer** In making motion pictures during the last 14 years the department's "movie" directors and photographers have experienced many thrills. Flights in airplanes and balloons, climbing mountain peaks, and risking life and limb in photographing the fighting of forest fires and the blasting of mountain sides for road building have been their portion.

Not all the thrills have been theirs, however. Dangers quite as great have sometimes been experienced by those who have sought to overcome hostile public opinion by the use of motion pictures in the department's campaigns for the eradication of plant and animal diseases and insect pests.

Vigorous opposition, for instance, has often been met in some sections of the South in the campaign for the eradication of the tick which acts as a carrier of southern cattle fever. Some of the department's agents, provided with trucks equipped with motion-picture projectors, have gone into these communities with films showing the benefits of tick eradication. Threats have often been made to "blow up the tick wagon" and "beat up" the operator. In one such community, long known to be hostile to the project, the department's film, "Molly of Pine Grove Vat," was shown, despite such threats.

This three-reel picture shows how plucky people in one community eradicated ticks in spite of serious obstacles and opposition by a lawless element. The show began before an audience that included a crowd of bullies and the local bad man. With the unweaving of the story, however, which showed clearly that only selfishness and prejudice oppose the useful work of tick eradication, opposition melted. The leader, instead of whipping the department's agent, as he had said he would do, shook hands with him before he left. In other districts where opposition has been so strong as to make the efforts of tick eradication hazardous, the power of the silent drama has made friends of former opponents and is preparing the way for better livestock and more prosperous citizens.

### Films on 300 Subjects

In the past 14 years, the department has produced films on more than 300 subjects, of which 230 are now in active circulation. From its laboratories in Washington it is distributing regularly more than 2,000 reels, while nearly as many reels of these subjects are being distributed by State agricultural colleges and other institutions that have purchased them. The department maintains its own production staff, and each year has been releasing 25 to 30 new films.

In its film production, the department has sought to make every film relate directly to its work and to give each one a definite educational purpose. Special effort has been made to present technical subjects so that they are easily understandable by the average layman. Human interest has been introduced wherever practicable. Applicability and value over the widest possible territory and to many classes of people have been considered essential. Competition with commercial producers of theatrical and educational films has been avoided.

A wide variety of important lines of the department's work already has been covered. Films now in circulation include the following subjects:

**Beef cattle, dairy cattle, dairy products, diseases of cattle, parasites of cattle, horses, sheep, swine, diseases and parasites of swine, poultry production, poultry pests, wild game and bird protection, destructive rodents, cereal crop production, cereal crop handling, cereal insects and diseases, cotton production, cotton insect control, fruit production, fruit insects and diseases, truck crop production, plant diseases, home gardening, miscellaneous crops, farm engineering, types of road construction, food inspection, other inspection services, forest fire prevention, forest insects and pests and tree diseases, lumbering, scenic and recreational resources of the national forests in the East and West, reforestation, miscellaneous forest uses, bees and other insects, marketing of farm products, cooperative marketing, rural organization, agricultural extension work, boys' and girls' club work, rural sociology, and weather forecasting.**

The field for distribution of the department's films includes, first of all, the widespread organization of the agricultural extension service, made up of county agricultural, home demonstration, and boys' and girls' club agents and subject matter specialists, employed cooperatively by the State and Federal Governments and working in practically every agricultural county in the Union. A large proportion of these 4,700 agents now use these films regularly, others use them occasionally, and the remainder are prospective users. Other active users include the field staffs of the various bureaus, such as the forest rangers of the Forest Service and the animal disease control forces of the Bureau of Animal Industry.

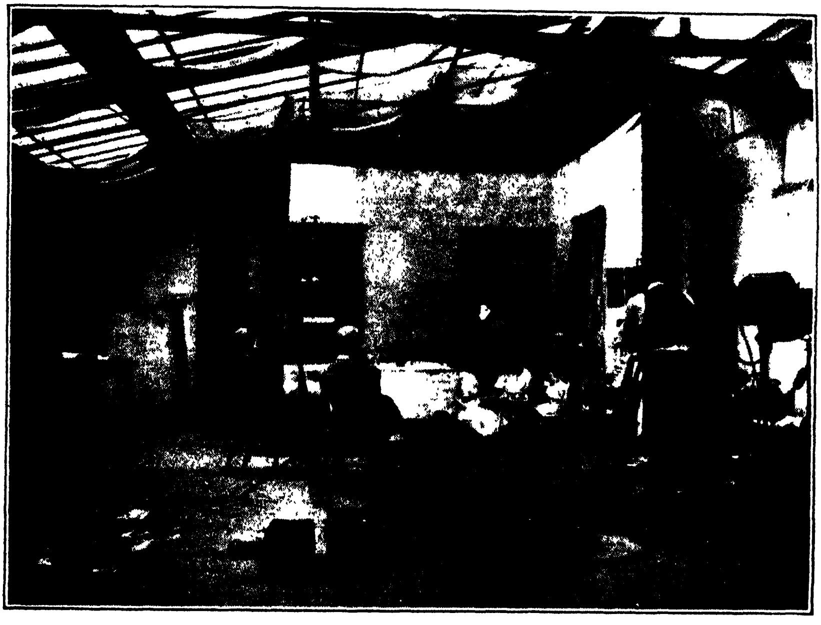

FIG. 160.—Studio work on a film dealing with nutrition

### Requests for Films Granted

Preference is given to film requests from these workers, but pictures have been sent whenever available to thousands of other applicants, including farm and community organizations, schools and colleges of every grade and kind, women's clubs, garden clubs, sportsmen's and breeders' associations, churches, Boy Scout troops, business men's organizations, museums, theaters, fairs and expositions, conventions, hospitals, penitentiaries, hotels, and summer resorts, and for use by traveling lecturers and railroad development trains.

Films are loaned for use during periods ranging from a few days to six months. The number of film shipments from the Washington laboratory indicates the growing demand for the department's motion pictures. In the fiscal year ended June 30, 1922, the number of such shipments was 2,066; in 1923, 2,715; in 1924, 3,199; in 1925, 4,260; and in 1926, 4,276. Thus, in four years the number of shipments has more than doubled. The films in one of these shipments may be exhibited before 10,000 or 100,000 people or more before they are returned to the laboratory. Sales of prints, especially to State agricultural colleges, have increased steadily. With the purchase of projection machines by agricultural extension and farmers' organizations and by other classes of nontheatrical film users, the field for department films will continue to widen. The audience which now views them annually is, perhaps, 10,000,000 persons.

### Extension Men Value Movies

County extension agents and other field men of the department who are in constant contact with the public are best able to estimate the value of educational films. From an inquiry sent to extension agents asking their opinion of the usefulness of motion pictures in their work, 982 replies were received. Of these, 820 favored using films, 149 were noncommittal, and 13 did not favor them at all. The opinions of many agents are well summed up in the following extract from the annual report of the county agricultural agent of Lyon County, Kans.:

> This was the first farm bureau in Kansas to purchase its own complete motion-picture outfit. Motion pictures have been exhibited at 52 meetings, to a total attendance of 6,608 people.
>
> The advantages of using motion pictures in conducting educational extension work might be summarized as follows: Holds attention of all audiences; increases attendance at meetings; brings out more forcefully and more intelligently the points desired; "seeing is believing," and more people put into practice things they can see and understand than those they hear about; a balanced and varied program can be put on to interest all in attendance; the agricultural agent can carry more specialized work to the farmers and be independent of outside specialized assistance; and the cost of maintaining extension work, figured on the basis of work accomplished and people reached, is materially reduced.
>
> The disadvantages from using motion pictures are that the county agent is forced to do more night work, work considerably longer hours, take on the added responsibility of pleasing more people and never disappointing them, take on the worry and grievance that is bound to come from the delicate mechanism of motion-picture machines and apparatus, travel all kinds of roads in all kinds of winter weather, and be content with using the kinds of films that can be secured.

The Department of Agriculture is impressed with the efficiency of motion pictures in advancing its work. Most of the important extension or educational projects have included the making of a film for campaign use, and motion pictures are now regarded as one of the essential field guns in educational campaigns. Films will not, however, displace other methods of presenting information. Lantern slides, for instance, have their own particular use. Just as it is impossible for the slide to perform the function of the motion pictures, so it is not possible for the motion picture to take over entirely and efficiently the function of the slides.

The one big use of the educational motion picture is to "break the ice" and create favorable sentiment for a particular movement. Used in advance, it makes the way easier for the main effort. Backed by efficient follow-up work, it has achieved results that are truly notable. Wisely used, it will continue to do so.

FRED W. PERKINS.

## MUNG Bean in United States Agriculture

The mung bean, green gram, or golden gram is native to southern Asia. It is undoubtedly of very ancient culture, as it is grown by the natives throughout the southern half of Asia and the principal Malayan Islands as well as in southeastern Africa. In these countries the mung bean is grown mainly for the seed, which is an important article of human food, but in India the straw is also prized as forage for livestock.

The mung bean was introduced into American agriculture as early as 1835, when it was known as the Chickasaw pea, and somewhat later as the Oregon pea. Notwithstanding its wide testing thus early in the Southern States and much testing in recent years, the mung bean has not been able to find a place in American agriculture in competition with the cowpea and soy bean.

Varieties of mung beans are very numerous, differing in habit, maturity, and the shape, size, and color of seeds. The seeds are spherical in most varieties, and green, yellow, brown, or marbled in color. During the past 20 years the Department of Agriculture has introduced about 150 different lots of mung beans from various sources. Extensive tests have been conducted at several experiment stations and by various individual cooperators. Although the varieties exhibited a wide range of comparative excellence, it has seemed rather doubtful if the best would prove a permanent addition to any type of the American farming system.

### Extensively Used as Food

As a food, the beans are extensively used, especially in China, supplying the people with bean sprouts, bean vermicelli, and bean gelatin. As a food crop in America the mung bean will not compete with common field beans and peas, but it may find considerable use for sprouting. Considerable quantities of mung beans are imported into the United States, and have been utilized almost entirely by Chinese restaurants for sprouting. Within the past two years several factories in the United States have undertaken the canning of mung-bean sprouts, using imported beans. The canned sprouts, which are an excellent article of food, have found a good market. The popularity of bean sprouts may be said to be almost nation-wide, and the use of the sprouts as a green vegetable has been experimented with more especially by many schools of domestic science; their use is being encouraged by many hospitals and dietetic schools. Undoubtedly, with an increase in the use of the canned sprouts, the production of mung-bean seed in certain sections can be made a profitable industry.

Although under present economic conditions the mung is not to be recommended as a general farm crop, it has apparently a place in certain systems of agriculture. To a limited extent the production of beans suitable for sprouting meets the needs of the canning industry. The mung bean is an excellent poultry food, both as a pasture when mature or sprouted as a green winter feed in the same way that sprouted oats are used. In a few sections the mung bean has been used as a forage crop. A most important factor in the culture of the crop is its freedom from attack by the Mexican bean beetle, which has caused so much damage to bean crops, especially in the Southern States.

W. J. Morse.

---

## NATURAL Plant Cover and Soil Potentialities

The use of vegetation as an aid in forecasting the agricultural possibilities of unimproved lands originated with primitive man and was used to some extent by the early settlers in our own country. Primitive man, with plenty of land on which to locate his fields, chose only the best. He was guided in his choice largely by the natural plant growth and the wealth of accumulated experience as to the type of crop to be grown on land characterized by different types of native vegetation. This method was also used in the older farming sections of our own country, but without scientific study it could only be used successfully where there was accumulated experience to serve as a guide. With our rapid migration into new and unknown territory in many cases having no agricultural history, the choice of land fell either on chance or was directed by exploiting agencies. It thus happens that in the newer settlements farms will frequently be found located on types of land least suited to crop production, or, again, equal settlements in regions of very unequal potentiality.

By a careful study of the types of natural vegetation and the type of soil and climate associated with each, and by the use of all available agricultural history, it has been possible to assign to each type of vegetation a value in terms of agricultural potentiality. Intensive studies of this kind have been made on the high plains, in the Great Basin, the Colorado Desert, and more extended but less intensive investigations in other portions of the United States. Practical application of these studies has been made by the Geological Survey in the classification of the 640-acre homesteads. Many of these homesteads, located in regions with little or no agricultural history and no climatic data, were readily classified on the basis of the natural plant cover.

### Estimating Soils by Their Plant Growth

One can easily estimate the relative worth of an acre of land covered with cat-tails as against an acre of oak and hickory; an acre of willows as against the same of hard maple; sagebrush as against seep weed. It is more difficult to distinguish between the value of an acre of land covered with hard maple and one of white oak, or an acre of sagebrush and one of shad scale. In the case of sagebrush and shad scale, studies have made it possible to give the two types separate values. A good, healthy, uniform stand of sagebrush indicates land well adapted to dry farming. However, dry farming on shad-scale land is not advisable, as it involves too great a risk. Again, sagebrush land is well adapted to irrigation farming. Shad-scale land, even under irrigation, requires careful handling and especially where it borders greasewood or is mixed with greasewood there is much chance of future alkali trouble.

In the southwestern deserts the lands covered with a good stand of desert sage will be farmed wherever there is water available for irrigation. The bulk of the best land farmed at the present time is of this type. Although creosote bush indicates land with a lower salt content, it is more often sandy or stony, not so level and less fertile, so that a smaller percentage is fit for farming.

On the other hand, lands covered with good growths of seep weed, saltbush, pickleweed or salt grass are mostly unfit for farming or hazardous at best. The high water table and the high salt content call for reclamation and for intelligent and special handling.

That the native vegetation can be used as a criterion in making estimates of the crop possibilities of land still unimproved is substantiated in comparisons of the large agricultural or nonagricultural areas of the United States with the areas of native vegetation.

The greatest block of agricultural land in the United States was that originally covered by the tall-grass prairies. As we pass westward, the tall grass gives way to short grass and there is a corresponding change in agriculture. Farms give way to ranches; with the increase in size of farms goes a decrease in land in crops and an increase in grazing land as crop production becomes less certain and the land becomes better adapted to grazing. Within the tall-grass area the type of farming is indicated to some extent by the type of vegetation.

### Corn Belt in Tall-Grass Area

The great Corn Belt lies in the central portion of the tall-grass area, the area characterized by bluestem sod grasses. The spring-wheat area is largely in the wheat-grass area. The best of the short-grass lands is the grama-stipa portion lying in the Northeast, whereas the poorest, from this point of view, is the Muhlenbergia lying in the Southwest. Crops can be produced with fair certainty on grama-stipa land or grama-buffalo-grass land, but are very doubtful on Muhlenbergia land. In the Northwest the wheat-grass sod lands of Washington and Oregon are now given over largely to the production of spring wheat. The only forest area of the west which is giving way to agriculture is the cedar-hemlock forest of western Washington and Oregon.

One of the areas showing practically no agricultural development is the spruce-fir area, covering the higher altitudes of the Rocky Mountains, of the West Coast Range, and of the northeastern highlands of New York and the New England States. The spruce-tamarack area of the Great Lakes region, which has no agricultural value in its original state but is capable of reclamation, shows slight agricultural development.

Contrasted with the spruce-fir, which has no agricultural value, the cypress, tupelo, and red gum of the southern lowlands has been largely turned to agricultural land. In its original state, like the spruce-tamarack, it has no agricultural value though its capabilities after reclaiming are high.

### Vegetation a Guide to Scientists

The natural vegetation can also serve a very useful purpose in indicating the limits of the region over which any experimental data, climatic data, or agricultural history can be applied with a reasonable degree of safety. Often the results of an experiment station nearest the local farm should not be applied, but preferably those of a station located in a region showing the same type of vegetation even though it might be more distant. It may, therefore, serve as a useful guide to agriculturists in the application of agricultural history or the results of scientific experimentation.

If rightly understood, the natural plant cover indicates the suitability of land for crop production, either with or without irrigation, and offers an important indicator not only of the kind of crop but also of the most desirable type of culture. A large economic waste might be prevented by correctly determining the future use of land. The natural vegetation affords a sound basis for such a determination.

## NEMAS and Recent Progress in Nematology Research

Nemas[15] are eel-shaped organisms varying more in relative size than animals of other groups, the smallest being one two hundred and fiftieth of an inch long when full grown, while the largest is several feet long with a diameter of a slender lead pencil. The largest vertebrate organism on the same relative scale would be a good fraction of a mile long instead of about 100 feet long, as is actually the case (the largest fossil).

Nemas are among the most abundant and widespread of all organisms—so abundant that if all the other matter in the universe could be magically swept away and we could then as disembodied spirits revisit these scenes, we should find them still recognizable. There would still exist in space a hollow sphere, the size of the earth, represented by a surface film composed of the nemas formerly inhabiting the mundane soil and waters, plants and animals. We could recognize lakes, rivers, and oceans by the nemas peculiar to them. So, too, we could recognize the soil and tell where there had been one kind of soil and where another. We could recognize the cities by accumulations of nemas peculiar to human beings and domesticated animals and domesticated plants. The trees would still stand in ghostly rows along the streets, represented by the nemas that once inhabited the bark of their trunks and branches.

Nemas are highly organized. Take man as a standard. The human body consists of a number of systems of organs; nervous system, digestive system, respiratory, glandular, circulatory, sexual, etc. Now in spite of its minuteness a nema contains all these systems except the circulatory and perhaps respiratory—it has no heart or blood vessels and no definite lungs. It is one of the miracles of organization that all these systems are packed into a narrow microscopic speck only about one two hundred and fiftieth of an inch long.

---

[15] Nematodes—roundworms.

Nemas vary among themselves very much and do a multitude of different things. They can digest all sorts of food—not that any one species can digest all sorts of food, but that among them, one or another, they have learned to digest starch, fats, proteids, and practically all other kinds of nutritious matter. It is not surprising, therefore, that they are so widespread. Wherever there is a speck of nutriment we are no longer surprised to find nemas, whether it be in utter darkness miles below the surface of the sea, or in some niche, brought for a little while above the freezing point once a year by the midsummer sun in the Antarctic Continent far beyond the range of any quadruped or bird, and, so far as we know, of any insect—not of course beyond the range of microscopic plants, for nemas are animals and must have organic food.

### Nemas of Economic Importance

Nemas are of great economic importance, but the world is late in recognizing this, largely because most nemas are so small and because the technic of their examination is difficult. They are responsible for some of the worst and most destructive diseases of plants and animals, and are responsible for annual losses aggregating billions of dollars, and for death, suffering, and inefficiency on a large scale among human beings and their domesticated animals and plants.

Though nemas were known in very ancient times, and have been studied scientifically for 150 years, it is only quite recently that their full significance has begun to be recognized and emphasized. The eighteenth and nineteenth century scientists, knowing nemas mainly as parasites, gave little heed to the host of free-living aquatic and terrestrial nemas.

One of the most outstanding recent advances in nematology is a radical change in conception—a recognition of the biological significance of the free-living nemas. This recognition now steadily influences us, changing our conception of what nemas are, what their structures signify, how to interpret their behavior, what their relatives may be, and how, by specialization, the parasites arose from various free-living types. The completion of this revolution will reveal nematology as a definite and important branch of natural science, its designation no longer confused with or obscured by such terms as helminthology and parasitology, and dealing with one of the most definitely marked of all phyla, consisting of an enormous number of exceedingly varied species astonishingly widespread.

The occurrence, on a great variety of nemas, of segmented organs—setae, mandibles, deirids, spicula—and the orderliness of the annules and external appendages; together with the numerical relationships involved, are among the most strikingly suggestive of all the recently disclosed features of nemas.

Our recently acquired better knowledge of the sense organs of nemas, and especially of the amphids, has far-reaching theoretical and practical results. It has been recently determined that the amphids, not previously properly recognized in the parasites, but classed there as papillae, are fundamental features, always present.

**Taking the amphids of the free forms as a basis, the amphidic nature of the so-called lateral papillae of the parasites has been demonstrated. The amphids, together with the other head sense organs, have important taxonomic interest, becoming also a means of identifying larval nemas only somewhat less accurately than adults.**

### Amphids a Factor in Nema Life

The importance of such an aid in studying nemic diseases, where the larva passes from freedom to host and from host to host, can hardly be overemphasized. The amphids now appear a primary factor in the behavior of nemas, each species having amphids of a specific form and function. They are believed to act in such important matters as orientation, finding food, locating proper life environment, and seeking the other sex. How far-reaching, even for practical purposes, this knowledge may be, is seen in recent attempts of German scientists to apply chemical stimuli (believed to reach the nema through the amphids) to bring the sugar beet nema, a most serious pest, to development at a time when other conditions are unfavorable for it, so that it perishes.

Another novel development in nematology, based on recent careful experiments, is the proposed use of nemas for the control of insect pests. For instance, certain nemas, mermithids, are a very important factor in decreasing the birth rate of grasshoppers, and may prove available as a grasshopper control. Certain soil-inhabiting nemas, for example certain mononchs, prey upon the gall nema, one of the worst of all agricultural pests, and have been the subject of promising initial investigations in this new direction.

Nemas continue their historic rôle of originally furnishing profoundly suggestive facts connected with the subject of heredity, recently furnishing a parallel to the alternating haploid generation in plants.

Recent discovery of a wide diversity in the cells of the nemic intestine explains the diversified digestion of nemas, and hence their wide distribution in nature. Information of this sort is a very important aid in determining the probable character of the numerous new nemas constantly being discovered, since it aids in forecasting whether or not they may prove to be serious pests.

In the control of nemic diseases of man, animals, and plants, advances of outstanding importance have been made in the use of drugs and the development of sanitary and cultural measures based upon more detailed knowledge of the life histories of specific nemas. Notably the introduction of carbon tetrachloride ($CCl_4$) and later tetrachlorethylene ($C_2Cl_4$), used alone or combined with other drugs, for the removal of hookworms in man and animals has been of special merit. The stabling, pasturing, and transportation of animals, the methods of culture of crops, and the methods of handling them in manufacture and in commerce, have been, in numerous cases, profoundly altered by the application of recently acquired knowledge of nemas and their relationships.

### Internal Structures Connected

What other animals are most closely related to nemas is still a mystery. Pores connecting with longitudinal series of internal organs have long been known to exist in nemas. Latterly these pores have been discovered in a much greater variety of genera, and, in a few cases, it has been discovered that the corresponding internal structures are connected with each other, and that a liquid is at liberty to flow along the internal tubular connections. That these structures may be homologous with corresponding lateral systems in other phyla, is a recent suggestion aiming at a solution of the mystery.

Current science involves a vast amount of detail work; only through the accumulation of details are the great generalizations made possible. In the science of nematology recent years have seen accomplished a vast amount of detail work; much knowledge concerning nemas has been accumulated, which, although it can not be touched on here, is a prime incentive for further progress.

A number of improvements in microscopic technic devised by nematologists have helped very materially to make possible the recent advances in nematology.

N. A. Cobb.

---

**NEWS Service on Grain Markets** Development and extension of the grain market news service during the past few years has brought to an increasing number of farmers the timely, accurate, and comprehensive interpretation of factors influencing the market which is necessary to an intelligent understanding of the market situation. Such information has long been available to traders on the large exchanges and through them has been made available to other large dealers. Farmers in general, however, have had only the price quotations and futures market comments to guide them in their marketing operations with little information relative to the basic factors which determine price trends. The grain market news service is giving to the farmers not only domestic but world-wide information which directly affects the prices farmers receive for some of their grains and which has not previously been readily available to farmers from other sources.

The grain market news service has three major activities: (1) The assembling of crop and market information both domestic and foreign; (2) the interpretation and analysis of the material assembled; and (3) the distribution of this information through special and regular reports and reviews.

### Broad Field Covered

The material assembled covers a very broad field and comes from a great number of sources. It includes both foreign and domestic reports of crop conditions, acreage, and production estimates; stocks of grain in various positions; grain movement in commercial channels and into consumption; the probable supply, demand, and price trends, as well as special reports from various sources which are of value to the American farmer in marketing his crop.

Analysis and interpretation of these reports must be done quickly so that the information may reach the farmer while it has the greatest possible value. To facilitate this work various statistical devices such as charts, graphs, and tabular statements of receipts, prices, supply and distribution, grain stocks, exports, imports, etc., are kept up to date and ready for use at any time with the latest available information.

The speedy distribution or dissemination of the material received is one of the most important phases of this service. The weekly grain market review which is the principal medium of distribution is prepared in the Washington office each Saturday morning. Reports summarizing developments in domestic markets during the week and including comments on the foreign situation which are influencing the domestic markets are received by telegraph from representatives of this project in all of the important markets of the United States.

### Reports Are Telegraphed

The information contained in these reports is combined with that from the other sources noted and incorporated in the review. Copies of this report are forwarded immediately by telegraph to Minneapolis, Chicago, Kansas City, Fort Worth, and San Francisco, where they are mimeographed upon receipt and delivered directly or mailed to newspapers and other agencies and individuals receiving the reports from those offices. They are also mimeographed at the Washington office and distributed to the Southern and Eastern States. In general, the reviews are available for publication or broadcasting on Monday in the principal producing and consuming areas.

According to a recent survey, more than 300 newspapers with a circulation of over 5,000,000 were printing these reviews regularly, about a dozen of the larger radio stations were broadcasting them, and several hundred copies were being mailed to State marketing officials, county agents, and other interested individuals who had requested them.

In addition to these regular reports, special market reviews and numerous press releases relative to market conditions of particular interest are given out from time to time through the press service of the department. Reviews covering commodities of special interest to certain sections are also issued. These include a barley review for the California barley growers who must depend upon an export market for the disposal of much of their crop, a corn review prepared for the farmers in the Corn Belt, and a price service for spring wheat farmers giving premiums paid at the principal markets for high protein types of wheat.

### Weekly Grain Stocks Reports

Another recent, important development of this project has been the weekly compilation and release of domestic grain stocks in commercial channels. These stocks include the grain in store and afloat at the principal markets. The quantity of Canadian grain in store in bond in United States markets is given and the United States grain in store in Canadian markets. These data are more nearly complete than previous statistics and provide a better figure for use in computing the domestic grain supply.

With the information which this service provides readily available to all important farming areas of the country, farmers are in a better position to plan and adjust their marketing programs to prevailing conditions and to secure more profitable returns for their products.

G. A. COLLIER.

**NEWS Service on Farm Feedstuffs** The feed market news service provides timely and accurate information concerning feedstuffs which farmers buy. Most farmers buy some feed, particularly high protein concentrates, and some buy large quantities. The cost of these feeds makes up one of the largest items in farm expenses in the United States. The farmers feed bill in 1909 totaled nearly $300,000,000, and in 1919 over $1,000,000,000. With such large quantities of feed to buy, dependable market information is of great value to farmers and dairymen in making their feed purchases. In addition, the spread of authentic information tends to stabilize market conditions and to reduce marketing costs.

The feed market news service provides reliable information upon wholesale market conditions, together with representative quotations on feeds at important markets. It shows the production of important by-product feeds, the prices current at the principal markets, and the immediate demand for these feeds as indicated by the way they are being taken at the prevailing levels. Various local conditions which affect the market and are of great interest to buyers are included from time to time.

Material from widely scattered sources is utilized in the preparation of the reports issued by the service. The production of important feedstuffs is obtained at regular intervals and in some cases this is supplemented by inquiries direct to manufacturers. Imports and exports of feedstuffs are obtained monthly. Weather conditions are considered in their effect upon the demand for feedstuffs as are also the supplies of feed grains and of hay available in various areas. The exchange of reports with foreign correspondents supplies valuable information concerning the effect of foreign demand upon the domestic feed market. Representatives or correspondents at all the important markets of the United States telegraph market conditions and prices at those points each week or more often, depending upon the importance of the market.

### Reports Quickly Distributed

Based on this material weekly reports are prepared covering the market developments and the factors underlying price changes for bran, shorts and middlings, linseed meal, cottonseed meal, gluten feed, hominy feed, alfalfa meal, tankage, and dried beet pulp. In order to make this information available promptly this weekly feed market review is telegraphed to Chicago, Kansas City, and Minneapolis for distribution by mail or radio from these cities. It is also mailed from Washington the same day and should be available within 24 hours at practically all points in the United States east of the Rocky Mountains. The reports are furnished upon request to individuals, farm organizations, and farm and trade papers.

Through cooperation with state departments of agriculture a special service is furnished farmers in a number of States which are important buyers of feeds. Brief statements of market changes are supplied, together with representative delivered prices at convenient points based on current wholesale market prices. These quotations enable farmers to compare feed costs and encourage economical buying.

Additional distribution is given feed market information through reports prepared for radio stations, farm papers, and cooperative purchasing organizations. From time to time special reports are prepared for cooperating State departments of agriculture with especial reference to local conditions in their territories. Other material of more general interest is given wider publicity through press releases, farm papers, and trade journals.

### Prices Are Affected

Wide distribution of this information helps to make market prices reflect more closely the balance between the supplies of the various feedstuffs and the probable feeding requirements as well as to keep local conditions in line with the changes at terminal markets. It also assists farmers to plan their feeding practices to take advantage of feeds which may be plentiful and relatively low priced at any time.

H. S. Irwin.

## NITROGEN Availability Varies in Green Manures

The gradual change in this country from the extensive system of farming of the pioneer farmer to the more intensive type necessitates the more widespread use of fertilizing materials. Animal manures have always held first place in maintaining the nitrogen balance of soils, but the increased demand for nitrogenous fertilizers without a corresponding increase in production of animal manures has stimulated the use of artificial fertilizers and leguminous green manures. In certain sections, especially those with a short growing season, artificial nitrogenous fertilizers undoubtedly are wisely used. There are other sections, however, and this comprises the greater part of the country, where conditions favor the use of green manures. The availability of the nitrogen in these manures is therefore an important point.

Experiments reported by various workers have shown that the availability of the nitrogen in leguminous green manures varies widely, due for the most part to the quality and quantity of the green substances, the character of the soil, temperature and moisture, and the time of application. Immature material has a higher nitrification than old, but this is often more than compensated by the lower weight of the young plants. If applied to rich soil, a stimulation of the biological activities of the soil may occur, resulting in the production of nitrates from the soil humus and in the recovery of more nitrogen in the first crop than had become available from the green manure. Periods of high temperature of air and soil with sufficient moisture hasten the nitrification of green substances resulting in an accumulation of nitrates. Losses through leaching are liable to occur if replanting is delayed too long.

### Much Variation in Availability

In view of these facts, it is not surprising that the nitrogen availability of leguminous green manures may vary from 10 to 80 per cent.

As a rule, 40 to 50 per cent return may be expected under ordinary conditions. This compares favorably with the availability of nitrogen in animal manures but, as might be expected, it is not ordinarily as high as the return from artificial fertilizers. However, the lower efficiency of the organic manures is probably more than offset by the production of carbon dioxide from the decaying material, by the improvement in the physical condition of the soil, and by other influences affecting the biochemical activities of the soil.

The beneficial effect of legumes whether grown for green manure or for hay upon succeeding crops is influenced by a number of factors. Most attention has been directed to the increase in soil nitrogen through the activity of the bacteria in the root nodules. Since these organisms furnish the growing legume with most if not all of its nitrogen, thorough inoculation is therefore essential. Much also depends upon the selection of legumes to be grown. Those adapted to the particular soil and climate and which make a vigorous growth should be chosen. Good tilth and a neutral reaction of the soil are very important if the most is to be realized from the legumes. The production of seed in some cases reduces the after effect, notably in the case of soy beans.

### Effects of Uninoculated Legumes

Legumes grown without inoculation and free of nodules show a beneficial effect when used as green manure but there is no indication that this influence is any greater than that produced by nonlegumes under the same circumstances. Obviously such an effect can not be explained by symbiotic nitrogen fixation. In some cases, the transportation of minerals such as phosphates and potash from the subsoil to the surface has been partly responsible. In other cases, the suppression of weeds by the thickly growing plants and the improvement in the physical condition of the soil have had their influence. In nearly all cases, however, increased bacterial activity of the soil, especially an intensified nitrification has been observed. Since uninoculated legumes and nonlegumes do not add to the store of nitrogen already present in the soil, no lasting benefit can be expected from the increased production of nitrates unless the nitrifiable material of the soil is replenished by organic manures or by the growth of inoculated legumes.

The growing of inoculated legumes effects the microflora of the soil as well as succeeding crops. The total numbers of bacteria are increased. Certain groups such as the *Bacillus radiobacter* and related groups are greatly stimulated. Since these organisms are known to be able to fix small amounts of nitrogen, it is conceivable that they may be partly responsible for the increase in soil nitrogen under legumes.

NATHAN R. SMITH.

**NITROGEN Fertilizers Listed and Described** The rapid development of nitrogen-fixation processes during the World War has resulted in a large increase in the quantity of nitrogen available for fertilizers. The capacity of the fixation plants in Germany has been increased and new plants built, and other countries have constructed nitrogen-fixation plants. The result of such developments has been the production of a number of new materials, several having come from Germany under special trade names. The following is a list of these principal products with a brief description of each:

Ammo-phos, a mixture of ammonium phosphate and ammonium sulphate produced in the United States. One grade contains 13 per cent of ammonia and 47 per cent of phosphoric acid, and another grade contains 20 per cent ammonia and 20 per cent phosphoric acid. The production costs up to the present have been too high to allow a general consumption of this material.

Ammonium phosphate, a salt obtained by treating liquid phosphoric acid with gaseous ammonia. It contains 14.8 per cent ammonia and 61.7 per cent phosphoric acid.

Leuna-saltpeter, a double salt of ammonium nitrate and ammonium sulphate, containing 31.5 per cent ammonia. About one-fourth of the nitrogen is nitrate and the remainder is ammonia nitrogen. It is equivalent to a mixture of 165 pounds of ammonium sulphate and 100 pounds of ammonium nitrate.

Urea (or floranide), a compound manufactured by combining ammonia and carbon dioxide gas. It contains 46 per cent of nitrogen, which is equivalent to 55.6 per cent ammonia.

Nitrate of lime or calcium nitrate, a compound of lime and nitric acid so treated as to give a physical condition suitable for broadcasting. It contains 15.5 per cent of nitrogen, equivalent to 18.8 per cent of ammonia, and 28 per cent of lime.

Potassium-ammonium nitrate, a mixture of potassium and ammonium nitrates containing 15.5 per cent nitrogen, equivalent to 18.8 per cent ammonia (half as ammonia and half as nitrate nitrogen), and about 27 per cent of potash.

Diammonphos, a compound containing ammonia combined with phosphoric acid, which contains 23 per cent of ammonia and 47 per cent of phosphoric acid.

Leunaphos, a mixture of diammonphos and ammonium sulphate, containing 24 per cent ammonia and 15 per cent phosphoric acid, or a ratio of one unit of nitrogen to three-quarters unit of phosphoric acid.

Leunaphoska, a mixture of leunaphos and potash salt, which contains 13 per cent of nitrogen, or 15.7 per cent of ammonia, 10 per cent of phosphoric acid, and 13 per cent of potash.

Soda-potash-nitrate, a mixture consisting of 75 per cent of sodium nitrate and 25 per cent of potassium nitrate, and containing about 14 per cent of nitrogen, or 17 per cent of ammonia, and from 10 to 13 per cent of potash.

Calcium cyanamide, a nitrogen salt, the first of the nitrogen-fixation products to be used in fertilizers. It contains from 20.5 to 25 per cent of nitrogen (equivalent to 24.5 to 30 per cent of ammonia), and from 10 to 15 per cent of lime.

Phosphazote, a product obtained from calcium cyanamide by treating it with carbon dioxide, and then rock phosphate is mixed with it. The product contains about 12 per cent of ammonia and 12 per cent of phosphoric acid.

R. O. E. DAVIS.

**NITROGEN Fixation Progress** The growth of the art of nitrogen fixation during the past 20 years from a rather uncertain experimental stage to the present industry which now supplies about one-half of the world's supply of inorganic nitrogen represents a most remarkable achievement. It is true that much of the rapid development of this art occurred under the urge of military necessity and that considerable impetus for the present expansion is being supplied by the desire of each country to acquire for purposes of national defense an independent source of combined nitrogen. There is, however, behind the industry the great and growing demand for nitrogen in agriculture, which assures it a permanent and stable position in our economic scheme.

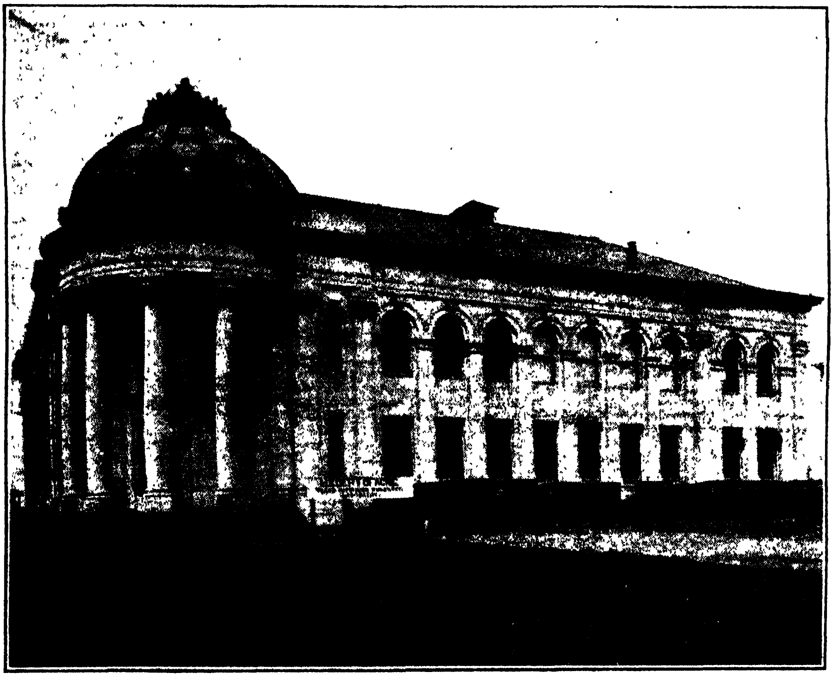

FIG. 161.—The Fixed Nitrogen Research Laboratory of the United States Department of Agriculture

There are three principal sources of combined nitrogen suitable for our present demands: (1) Ammonia obtained as a by-product in coke and gas production; (2) Chilean nitrate, and (3) the various products of atmospheric nitrogen fixation. The increased consumption of inorganic nitrogen during recent years has been very largely supplied by the latter source and the indications are that it will continue to furnish the greater part of the increased demand in the future.

The quantities of combined nitrogen supplied by each in 1925 were as follows: Atmospheric fixation, 607,000 metric tons; Chilean nitrate, 340,000 metric tons; by-product ammonia, 330,000 metric tons. The greater part of this total of 1,277,000 metric tons, probably nearly 90 per cent, was used in agriculture.

The problem of nitrogen fixation is that of making available in combined and useful form the free nitrogen which comprises four-fifths of our atmospheric air. Three methods of accomplishing this have attained commercial importance. The arc process, in which the combination is effected by passing air through a high temperature electric arc, was established in 1905 in Norway. Its power consumption is very large and for that reason its commercial application has been largely confined to Norway, where cheap water power is abundant. The chief final product of this process is a fertilizer salt, nitrate of lime, which is obtained by neutralizing the oxides of nitrogen from the arc with lime.

In the cyanamide process, calcium carbide at high temperatures is made to react with gaseous nitrogen to form a compound of calcium, carbon, and nitrogen, called calcium cyanamide. This product has found considerable use as a fertilizer, but certain undesirable properties have definitely limited its consumption.

The synthetic-ammonia process is the newest method and it has, because of its rapid development since 1913, contributed most to the growth of the nitrogen-fixation industry as a whole. In this process, purified hydrogen and nitrogen gas are made to combine at high pressures and temperatures in the presence of a catalyzer to form ammonia. This ammonia may be transformed readily into a variety of salts suitable for fertilizer use.

Table 19 shows the growth of these processes during the past decade.

TABLE 19.—*Production of nitrogen in metric tons per year for 1915, 1920, and 1925*

| Process | 1915 | 1920 | 1925 |
|---|---|---|---|
| Arc | 15,000 | 25,000 | 37,000 |
| Cyanamide | 100,000 | 140,000 | 170,000 |
| Synthetic ammonia | 25,000 | 110,000 | 400,000 |

Germany is still the center of this great industry and her present output probably accounts for 70 per cent of the world production. The expansion in other countries has been very rapid in the last few years. The United States, which five years ago had no plants for the fixation of atmospheric nitrogen, now has seven synthetic-ammonia installations with a combined capacity of about 80 tons per day. None of this present output is finding its way directly into fertilizers, but it is having the indirect effect of forcing more of the by-product ammonia into agricultural uses. The projected plans for expansion indicate that it is only a matter of a few years before the products of atmospheric fixation will be competing directly with other sources of fertilizer nitrogen in this country also.

### Fixed Nitrogen in Agriculture

Nitrogen, potash, and phosphorus are the three important elements of plant food and hence the desirable constituents of fertilizers. It was realized long ago that fixed nitrogen, because of its limited occurrence in nature, would present the greatest problem in the maintenance of soil fertility and that the nitrogen of the air would have to be the ultimate source. The nitrogen fixation processes have gone far in making available more and hence cheaper combined nitrogen. In addition to increasing greatly the world's supply of nitrogen, the development of atmospheric-nitrogen fixation into a highly competitive industry is having the effect of directing attention to the whole problem of producing better and more concentrated fertilizer materials. Many such fertilizer salts are now being produced and marketed as a direct result of the influence of the synthetic-nitrogen interests. Among them may be mentioned ammonium nitrate, particularly in admixture as mixed salts with ammonium sulphate and potash compounds, calcium nitrate, urea, which contains 46 per cent nitrogen, and phosphates of ammonia in which the plant food phosphoric acid serves as a carrier for the nitrogen. Practically all of this development has occurred in Europe, where the problem of soil-fertility maintenance is more acute than in our own country, where the availability of new land has postponed the necessity of practicing more intensive agriculture.

It is only a question of time, however, before we too must turn toward more intensive methods of agriculture, and the growth of the nitrogen-fixation industry now impending in this country is certain to be an important factor in the soil-fertility problem of the near future.

J. A. Almquist.

---

## NITROGEN From the Air Makes Good Fertilizer

Nitrate of soda from the Chilean fields and small deposits of potassium nitrate are the only natural supplies of nitrogen in a form available for fertilizers.

Other available forms are by-products; ammonium sulphate from coke ovens, gas works, etc., cottonseed meal from cotton, animal tankage and dried blood from slaughterhouses, fish scrap from nonedible fish and small quantities of material from other sources. The by-products containing organic nitrogen are being used more and more for feeding purposes and the supply available for fertilizers is becoming smaller and smaller. As a result of this condition the attention of investigators in recent years has turned to the production of nitrogen salts by obtaining nitrogen from the atmosphere through chemical methods. The effect of air-derived nitrogen salts in commercial fertilizers on crop production is now a much discussed subject by farmers, fertilizer manufacturers, and investigators.

The development of nitrogen-fixation processes and the operation of nitrogen-fixation plants is making available to agriculture a large supply of high-analysis nitrogen salts. Information concerning their effect on crops and suitability for use as fertilizers is of considerable interest.

The materials which have received most attention by manufacturers and investigators are ammonium chloride, which contains 31.8 per cent ammonia; ammonium nitrate containing 42.5 per cent ammonia; urea containing 55.6 per cent ammonia; urea phosphate containing 21.5 per cent ammonia and 45 per cent phosphoric acid; ammonium phosphate containing 14.7 per cent ammonia and 61.7

per cent phosphoric acid. All of these materials possess a high plant food content, as is evidenced by a comparison with nitrate of soda, which contains 18 to 19 per cent ammonia. That the greater use of chemical salts in the maufacture of fertilizers possesses a marked trend is shown by the much greater production of air-derived nitrogen salts, especially in Europe.

### Great Increase in Nitrogen Fixation

It is estimated at present that at least one-half of the world's inorganic nitrogen comes from the atmosphere through nitrogen-fixation methods, as against only 7 to 8 per cent in 1913.

Experiments to determine the effect of these concentrated air-derived nitrogen salts under American farm conditions have been made covering a period of several years with cotton, potatoes, corn, garden, and truck crops. These have been located on official test farms and on commercial farms on some of the principal soil types in the Eastern States. (Fig 162) The effect of the air-derived nitrogen salts, when used in mixed fertilizers with acid phosphate and potash, has generally been good. and compares favorably with nitrate of soda and sulphate of ammonia.

FIG 162—One of the experimental fields used by the department to test the effect of new nitrogen fertilizers on cotton

In the fertilization of cotton. ammonium nitrate and urea have proven to be very good forms of plant food and have produced larger yields than did ammonium chloride, which has given a relatively smaller production than other nitrogen materials. The use of these air-derived nitrogen salts containing relatively high concentrations of ammonia when used in mixed fertilizers under cotton has not produced any injurious effect on germination or on the plants in the early stages of growth. Neither has there been any indication of unusual leaching from the soil.

With potatoes, a crop requiring large quantities of fertilizers, the air-derived nitrogen salts have shown up well. Fertilizers having their nitrogen derived from these concentrated materials have produced as large yields as those having their nitrogen derived from nitrate of soda or sulphate of ammonia. This has proven true in all the large potato-growing sections of the Atlantic seaboard.

### Successful With Truck Crops

These new fertilizer salts have also been successfully used with garden and small truck crops, which make a rapid growth, fruit, and mature in a relatively short period. Their effect on garden peas, Lima beans, snap beans, and sweet corn has been good, producing somewhat larger yields than has nitrate of soda or sulphate of ammonia.

Although the effect of air-derived nitrogen salts, most of which are highly concentrated, on crop growth and production, are generally good when used in mixed fertilizers, there are difficulties to overcome. The keeping qualities of fertilizers as to caking, moisture, etc., and the ease with which they can be distributed in the field are important factors. Some of them, like ammonium nitrate, may have undesirable physical features in bulk mixtures or in storage and require that methods of preparation, mixing, storage, and application may have to be worked out, as had to be done with some of our ordinary fertilizer salts and their mixtures.

Small quantities of nitrogen-fixation products are now being used in commercial fertilizer mixtures, but their introduction into general use will no doubt be gradual, as it should be, in order to allow sufficient time to overcome the difficulties which may arise in commercial mixing and farm application.

## OAT Varieties for the Winter Wheat Belt Yield Well

Three new oat varieties belonging to the common oat group (*Avena sativa* L.) have achieved economic importance in the winter wheat belt. They are Albion (Iowa No. 103), Richland (Iowa No. 105), and Iowar. All are early varieties and all were developed as pure-line selections from the well-known and widely grown Kherson or Sixty-Day oat, introduced into this country from Russia by the United States Department of Agriculture and the Nebraska Agricultural Experiment Station about 30 years ago. They were produced in extensive cooperative oat-breeding experiments conducted by the Iowa Agricultural Experiment Station and the United States Department of Agriculture. Albion and Richland were selected in 1906 by L. C. Burnett and were first distributed to Iowa farmers as Iowa Nos. 103 and 105 in 1913 and 1914, respectively. The Iowar was isolated by Mr. Burnett in 1910 and first distributed to farmers in 1919.

Because of their white kernels the Albion and Iowar have met with the most favor. It was estimated that the Albion was grown on nearly 1,400,000 acres in Iowa alone in 1924, with perhaps an equal or greater acreage distributed throughout central Illinois, northern Missouri, northeastern Kansas, and eastern Nebraska. Iowar was grown on about 800,000 acres in Iowa in 1924. Iowar has a little taller straw and is from two to three days later than Albion in maturity. It also is superior to Albion in yielding power, and therefore is the more promising of the two strains. It already is widely distributed in the more northern portion of the winter wheat belt, where it is replacing the Albion to some extent.

The Richland has been less popular because of its short straw and yellow kernels. Its distribution, therefore, has been limited. In yielding power Richland has been superior to Albion and about the equal of Iowar. It is primarily a special-purpose oat for growing on low, rich soils, where taller and later varieties frequently suffer loss by lodging. Richland also is resistant to stem rust of oats, which gives it exceptional value in years of severe rust epidemics, such as occurred in the northern portion of the winter-wheat belt in 1926.

### Probably a Natural Hybrid

The Fulghum oat probably originated as a natural hybrid. It was developed in southeastern Georgia about 20 years ago as a plant selection from the Red Rustproof (Red Texas) variety, which until recently was the standard oat of the South. The Department of Agriculture had no part in its selection but was largely concerned in its testing and distribution. It is a so-called red oat, belonging to the same group (*Avena byzantina* C. Koch) as Red Rustproof and Burt. It is grown both as a winter and as a spring variety. However, in recent years it has become much more important as a spring-sown variety, especially in the transition zone between the southern winter-oat and northern spring-oat belts. It is now grown most extensively in Kansas, but is becoming more popular each succeeding year in southern Ohio, Missouri, Oklahoma, and northern Texas, where it is largely replacing Burt. Its early maturity and ability to produce satisfactory yields under conditions which usually are unfavorable to early varieties of common oats have made Fulghum the most important new variety of American oats.

A recent mass selection from Fulghum, known as Kanota, originating in Texas and developed in Kansas, has become popular, especially in Kansas. Of the 1,712,000 acres of oats grown in Kansas in 1925 over 700,000 acres were devoted to Kanota. It is believed that this area for 1926 may have exceeded 1,000,000 acres.

If these new oats on the average outyield the previously grown varieties by only 3 bushels to the acre, which is an extremely conservative estimate, the aggregate increase in production amounts to several million bushels. It is probable that the Iowa varieties were grown on at least 6,000,000 acres, and the Fulghum (Kanota) on 2,000,000 acres in 1926. This would mean an increase of 24,000,000 bushels of oats with very little additional cost to the farmer.

## OIL Test for Oil-Bearing Seeds Found

Industrial enterprises are constantly in search of methods of analysis which will shorten their laboratory work and give more efficient plant control. Typical of such rapid methods are those now in use by the steel chemist for determining carbon, phosphorus, etc., by the sugar chemist for determining the sugar content of sirups and similar materials, and of the cereal chemist for denoting the percentage of moisture in cereal grains.

That a test of a similar character would be of great assistance to the vegetable-oil industry goes without question, as the buyer or seller of oil-bearing seeds would be in a position to know within a very short time the composition of the raw material. In addition, more efficient operation of the oil presses in the plant would take place, as by means of frequent check tests it would be known how much oil was being expressed from the raw material and adjustments could be made in the pressroom to insure uniform conditions.

In the past the greatest difficulties attending the development of a rapid test for determining the oil content of oil-bearing materials have been the lack of a suitable solvent to dissolve the oil, and remain fixed during the period of the test, as well as to the lack of simple laboratory apparatus to measure the oil after it has been removed from the raw material.

It has recently been found that a substance known as halowax (which, chemically speaking, is a monochloronaphthalene) is an ideal solvent. This compound has a very high boiling point so that it remains fixed during the test. Among other advantages it is non-hydroscopic, has a very small coefficient of expansion, and its cost is very small.

To make the test on most materials the following technic will give good results:

> Grind 25 grams of material to be tested to a very fine state of subdivision. Place 2 grams of the material in a warm mortar and to it add 4 cubic centimeters of halowax. Stir vigorously for two minutes. Filter through a small filter paper. Let the oil cool to room temperatuie. Place a drop of oil on the prism of a 5-place water-jacketed refractometer and note the refractive index; also note the temperature. Make a temperature correction (for flaxseed 0.00045 points should be added to or subtracted from the refractive index reading if it is over or under 25° C.). Compare the corrected reading with the figures in a standard chart prepared as described below and determine the percentage of oil in the test sample. Wipe off the prism.

### How Oil Content is Found

Making use of these general principles, and giving special attention to details, it has been found that the oil content of such substances as flaxseed, linseed meal, cottonseed, cottonseed meal, soy beans, cocoa beans, cocoa and cocoa products, peanuts, sesame seed, and mustard seed can be easily determined by noting the refractive index of a mixture of a definite quantity of halowax and the indefinite quantity of the vegetable oil under test, with the readings on a chart computed from definite quantities of halowax and known quantities of the same vegetable oil for which the test is being made.

The minimum equipment necessary for carrying out the test by the refractometer method is as follows:

> Suitable grinding equipment, a refractometer capable of being read to the fifth decimal place, one pipette, one analytical balance, several mortars and pestles, small funnels, test tubes, folded filter paper, and absorbent cotton.

On the average it takes about 15 minutes to make a simple determination by the optical method. This time, of course, can be reduced if the tests are made in volume. This is in contrast to the 24 hours necessary to extract the linseed oil from flaxseed to the 16 hours necessary to extract cocoa butter from the cocoa bean, and to the 3 to 4 hours necessary for the extraction of cottonseed oil from cottonseed meal.

The cost of making the test is slight. After the initial expense of purchasing the equipment necessary for completing the test, the expense of reagents and other necessaries should not be over 2 cents per test.

H. C. Fellows.

## OLIVES of the Barouni Variety Do Well

In the Mediterranean countries where the olive has been cultivated for centuries it is in many areas one of the staple foods of the laboring classes. When playing this important rôle it is not the pickled green olive nor the stuffed green pickle commonly known on the American table that is used, but the ripened fruit cured in salt, which makes a most nutritious and apparently healthful product. The ripe olive is less well known in America and is very rarely used here as a dried, salted product. However, methods of processing and canning the ripe fruit have been developed which have resulted in a product greatly relished by many who have become familiar with it. At the present time an area of about 100 acres is planted to the Barouni variety in California.

In the fall of 1904 one of the department's explorers traveling in northern Africa obtained from the premises of M. Robert, of Kalaa-Srira, near Susa, Tunis, a variety of olive known as Barouni, which has proved adapted to the olive-growing areas of the southwestern United States and is of special value as a ripe pickle olive. T. H. Kearney, who obtained

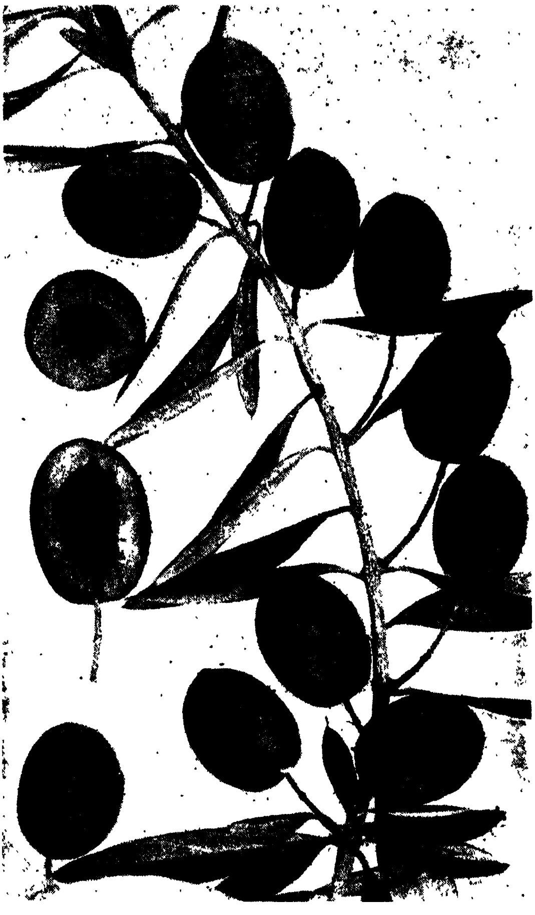

FIG. 163.—Fruits of the Barouni olive (S. P. I. No. 12569) grown at the plant introduction garden, Chico, Calif. Fruiting branch from nonirrigated tree

the variety, wrote at the time: "This is the largest olive in the country, and M. Robert's is about the only place where it can be secured." Nine small cuttings of this variety were forwarded to the department's plant introduction garden at Chico, Calif., and received there January 12, 1905.

### Three Trees Grown

Three trees were grown from these cuttings and planted in the trial grounds. After a few years when they came into bearing the fruits were of such large size that they at once attracted special attention and indicated the probable value of the variety for commercial use. (Fig. 163.) However, it seems possible that the large-sized fruits might be due in part to the trees being young and producing but a light crop, and the production of subsequent years was necessary to establish its real merits. The tree of the Barouni is extremely vigorous and free growing. (Fig. 164.) It is rather precocious, bearing while quite young and maturing fruits of large size and excellent quality about 10 days ahead of the Mission variety. In size it is much larger than the Mission, comparing favorably in this respect with the Sevillano and Ascolano, which are used for the queen olives of our commercial trade. It has a good oil content, being similar to the Mission in this respect. The pit is comparatively free, but inclined to be a little large. It takes lye readily and is easily pickled. When utilized for commercial canning the Barouni should be picked from when it turns a straw yellow to when it has a purple tinge on the tip. When gathered at this stage the oil content varies from 12.75 to 16 per cent, and when allowed to mature fully on the tree it contains about 18 per cent of oil. One large

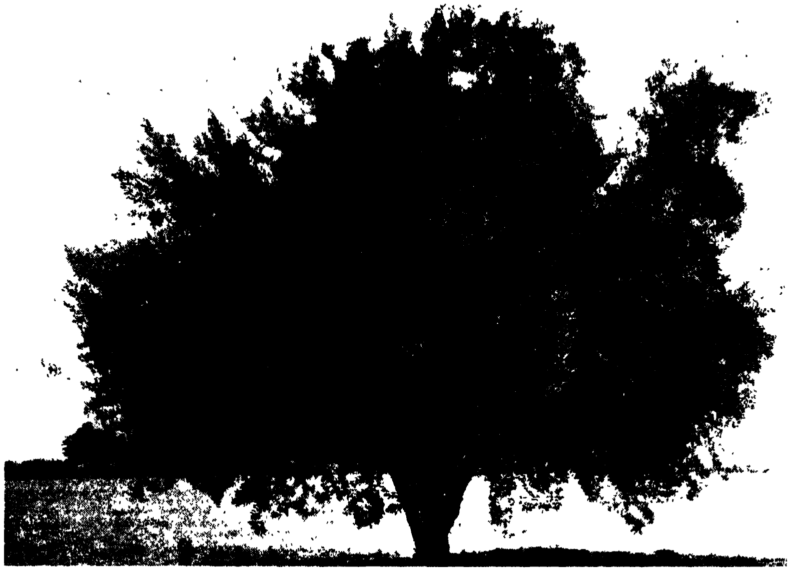

FIG. 164.—Tree of the Barouni olive (S. P. I. No. 12569) at the plant introduction garden, Chico, Calif. It is about 20 feet high, with a spread of 27 feet

tree at the plant introduction garden when 11 years old produced 328 pounds of fruit, or at the rate of 10 tons of olives to the acre.

The Barouni can be propagated from cuttings or by grafting the same as other varieties of olive. When top working trees, bark grafting is quite commonly practiced.

Roland McKee.

## ONION Curing to Prevent Decay While in Storage

Mycelial neck rot (*Botrytis byssoidea* W.) is the most important storage decay of onions in the Middle West, where the crop is grown not only for table stock but also to a large degree for sets. The causal fungus overwinters in the soil or on refuse and subsists during the growing period of the crop primarily as a saprophyte upon old onion leaves or other dead organic material. When the plant is mature the organism enters chiefly through the neck of the bulb, whence it proceeds down the succulent scales causing a semiwatery decay. Thus the disease is in general initiated in the field during the process of harvesting or curing. In extreme cases as much as half of the bulb may have rotted before it is placed in storage, but in the main the infection is in the incipient stage at this time and may not be recognized macroscopically.

A study of this disease which has extended over a period of some 10 seasons in southern Wisconsin and northern Illinois has brought out some important facts which have a direct bearing upon control. These point to the conclusion that conditions which prevail during harvest and subsequent curing in a large measure determine the amount of decay which follows. Briefly, dry clear weather which tends to check the development of the fungus and at the same time hasten the drying of the neck tissues of the bulb tends to prevent infection while the reverse condition enhances infection. Thus, in certain years when favorable weather prevails at this critical time, the disease is negligible in storage, whereas in other seasons it may cause losses varying from 10 to 90 per cent.

### Control Through Artificial Curing

Effective control has therefore been worked out through providing artificial means for sufficiently rapid curing of the bulbs, in spite of inclement weather. It has been found by experimentation that a surprisingly short treatment is sufficient to check the disease effectively. The procedure consists simply of forcing a current of warm dry air (first heated to 100° to 115° F. by drawing over a cast-iron stove or steam coils) through the onions in the slatted containers in which they are later stored. The period necessary will vary with the material at hand, but should be continued until the outer neck tissue is well dried. With onion sets this usually requires three to six hours. The bulbs may then be handled in the usual manner.

This control measure has been tested first in connection with white onion sets, where extreme susceptibility of the plant, the high value of the product, and the protracted storage period necessary all combine to warrant the extra cost involved. The results of 1923, 1924, and 1925 leave no doubt that the process is commercially practicable for this crop. The question of commercial adaptation to large onions is still unsettled. The greater succulency of the neck tissue makes a much longer treatment necessary, and the additional cost is enhanced by the fact that initial value per bushel of the large onion crop is ordinarily appreciably less than that of onion sets.

J. C. WALKER.

---

**ORANGE Freezing a Hazard in All U. S. Groves** Freezing is one of the hazards in the production of oranges in the United States and none of the citrus regions of this country are so located geographically as to be entirely free from possibilities of low temperatures sufficiently prolonged as to seriously injure the trees and destroy the fruit. The fruit is much more easily injured than the matured wood or foliage of the trees and temperatures of 26° F., especially if they are of long duration, are almost certain to cause some injury to fruit and to any new growth or young leaves. Temperatures of 22° to 24°, long continued, are liable to cause injury to the trunks and limbs of most of the varieties of round oranges (*Citrus sinensis*) grown in California and Florida. This injury is manifested by splitting of the bark and wood of the trees, defoliation, killing back of the smaller limbs and, in extreme cases, the whole tree will be killed.

Frequently the trunks of young trees up to 3 or 4 years of age are wrapped with newspapers, cornstalks, or other materials, to protect them from freezing injury and these wrappings afford a considerable protection though the top and portion of the tree unprotected may be killed. A bearing tree can be produced more quickly and with less expense from the uninjured trunk of such a tree than by replanting. The best protection the orange growers have found is the supplying of artificial heat by burning of crude oil, coke, or such products in orchard heaters. In the California citrus region, which uses this method of frost protection extensively, about 1,500,000 orchard heaters are in use. In practice the heaters are usually lighted in orange groves at a temperature of 28° F. in order that all the heaters be lighted when the temperature reaches the danger point.

### Evidences of Freezing Injury

The fruit may be injured at somewhat higher temperatures than the trees. The pulp of Valencia and navel oranges freezes at temperatures varying from 26.5° to 29° F., and the peel at somewhat lower temperatures. It is thus possible to freeze the pulp of an orange solid without noticeable injury to the peel, and oranges frozen under natural conditions usually exhibit no external evidences of freezing, even though the interior of the fruit may be a mass of partially dried, disorganized pulp. Freezing the pulp kills the juice vesicles so that the juice can escape and the interior of the fruit loses water. It becomes lighter in weight in proportion to its size, and it is thus possible to separate the sound fruit from the frosted by the difference in their specific gravity. Inasmuch as this test is not applicable commercially until several weeks after freezing and fruit which is severely injured by freezing is liable to lose moisture and deteriorate in transit, other methods of separating sound and frosted fruit have been developed. Perhaps the best index of frost injury soon after freezing is the presence of crystals of the glucoside hesperidin in the septa between the segments. These crystals are very commonly found in frosted oranges. They form within two or three days after the fruit is frozen and can easily be distinguished. The presence of these crystals, or the discoloration and wrinkling of the tissues which sometimes accompanies freezing, afford a reliable test as to whether oranges have been injured so that they will deteriorate while being marketed.

It is sometimes said that oranges which have been frozen are unwholesome. Although they are not as attractive and may not be as palatable as sound oranges, the conclusion that they are actually injurious has little, if any, foundation.

LON A. HAWKINS.

---

## OUTLOOK Reports—Their Preparation

The growing feeling among farmers of need for complete and up-to-date economic information led the Department of Agriculture in 1923 to begin preparing and issuing statements on the outlook for the production and marketing of the principal agricultural commodities. These reports met with such a favorable reception that the work has been expanded and made a regular part of the program of the Bureau of Agricultural Economics. In the preparation of the reports this bureau has the assistance of other bureaus which have information that needs to be considered, and it collaborates with the extension service in the distribution of the reports.

In January of each year a comprehensive report is prepared covering the outlook for all the commodities on which sufficient information is available. During the summer of each year special reports on the outlook for hogs, sheep, and cattle are prepared and a report on the outlook for wheat production is issued each year just prior to the time of planting winter wheat. The general report on the agricultural outlook for 1926, issued in February, contains statements on 31 different commodities in addition to statements on the domestic and foreign demand situation, agricultural credit, and farm labor and equipment. This report covers a greater number of commodities than any of the reports that had been issued up to that time

The reports are designed to give to farmers prior to planting and breeding time information as to what the probable conditions will be when their products are ready for market. The statement on every commodity is based on all available information which will be of assistance to producers in planning their production programs and balancing their different lines of production so as to obtain the greatest returns and avoid as far as possible the overproduction or underproduction of any commodity.

### Committee for Each Crop

For each of the agricultural products, a committee composed of those in the bureau who are most familiar with the production and marketing of the commodity assembles all available information on the present supply of the product and the demand for it, and on the trends of production and consumption. The committee, assisted by representatives of other bureaus of the department interested in the production and marketing of the commodity in question, studies the information carefully and makes a tentative judgment as to the outlook for its production during the coming year. The commodity committee then presents its analysis of the situation and its judgment as to the outlook to a larger committee consisting of one member at least of each of the commodity committees, with the chief of the bureau as presiding officer.

This larger committee makes a critical review and appraisal of the findings of each commodity committee so that the statements when made public represent the consensus of opinion of the entire staff of the Bureau of Agricultural Economics and of the assisting members of other bureaus.

The preparation of the reports on cotton illustrates the many points that are considered and the varied sources of information on which the statements are based. Something like half our cotton is exported and careful attention must be given to the foreign demand. The foreign representatives of the department furnish special reports on the trend of conditions in the cotton industry in the countries where they are stationed.

Production from other countries supplies a considerable part of the world's cotton, and trends and conditions in foreign-producing countries must be studied by the committee.

When the prospective domestic demand is under consideration the many ways in which cotton is utilized are reviewed and the trends of general business activity and industrial conditions are appraised with regard to their probable effect on the demand for finished goods.

The supply of old cotton remaining unused when the new crop begins to move has a marked influence on the returns to growers, and the committee must estimate the probable carry-over of old cotton into the new crop year. The likelihood of damage by the boll weevil during the coming season is stated in so far as it can be foretold from the conditions during the previous season and the winter temperatures in the cotton belt. The committee also considers the probable costs of fertilizer, labor, machinery, feed for work stock, and poison for weevils.

### Corn Conditions Complex

The outlook for the production of a commodity such as corn depends upon conditions almost entirely different from those which determine the outlook for cotton. Almost all our corn is consumed by livestock and the demand for corn is determined to a large extent by the number and kind of livestock to consume it. Here a judgment must be made as to the probable numbers of hogs, beef cattle, dairy cows, and other livestock that will be on hand when the corn crop not yet planted is matured and ready for consumption. Consideration must also be given to the fact that oats, barley, and other feed crops can be used as a partial substitute for corn. If corn should be scarce and high in price while the supplies of other feed crops are plentiful, livestock producers who must buy feed will be inclined to use less corn. Likewise in arriving at a sound judgment as to the outlook for livestock production, the prospective supply of feeds must be given considerable weight.

The statements necessarily present the national point of view and should be carefully considered by producers in every region to determine whether the general suggestions apply to a greater or lesser extent to their conditions.

In making his plans each farmer must bear in mind not only the probable conditions of the market for the different commodities he can produce, but also the conditions under which he is farming and the characteristics of his own farm. Both the requirements for production and the probable returns from the product should be considered in making decisions as to what to produce and how much to produce.

Since conditions vary so widely in different parts of the country, no blanket recommendation applicable to all the producers of a given commodity can be made in statements which present the national point of view. If the outlook for the production of some commodity is good it does not necessarily follow that all the producers of that commodity would profit by increasing their production. Neither does it follow that it would pay all the producers of a commodity to curtail their production when the outlook is for a lower demand or increased supplies from foreign countries. On account of this, many of the State colleges, through their experiment stations and extension services, have adopted the plan of preparing and issuing statements for farmers within the State, these statements being based in part upon the department's report and in part upon the local conditions that affect the possible lines of producion in which the farmers there may safely engage.

### Useful to the Cooperatives

These reports have been of particularly great value to cooperative marketing associations and many of these associations have been very active in disseminating the reports among their farmer members. Frequent requests are received from these associations calling for more complete information or information on additional commodities.

The general outlook report issued in January is followed by a report on farmers' intentions to plant spring crops. This information gives producers an opportunity to make adjustments in their plants should there be a tendency to overplant or underplant particular crops. A report on intentions to plant fall crops is issued in August. Frequent surveys of breeding intentions with regard to specific classes of livestock are giving producers more information upon which to base their plans.

It is the intention of the Bureau of Agricultural Economics to expand this work so as to cover a larger number of commodities, to concentrate on the collection of economic information and the analysis of statistical data needed to furnish a better basis for subsequent reports, to obtain wide dissemination of the reports, and to assist the State colleges, cooperative organizations, and others in every way possible in preparing and disseminating localized statements that apply specifically to the farmers in different areas and regions.

When farmers in general come to base their production programs on a well-considered judgment as to the probable demand for their products when they are ready for sale and on the trends of production in competing countries and in competing areas in this country, just as successful men in other businesses have been doing for years, farmers will have made marked progress in placing the agricultural industry on a parity with the other industries of the country.

H. R. TOLLEY.

## PACKERS and Stockyards Act; How it is Administered

The livestock and meat-packing industry taken as a whole is probably larger than any other single class of business in the United States.

The remarkable growth and extent of livestock production developed certain agencies which came to be recognized as essential to the marketing and processing operations. The livestock markets, or public stockyards, have become the central points through which a large part of the livestock produced in the United States passes on its journey from the farms and ranches to the consumers of the meat and other animal products.

In sending his livestock to these central markets to be sold the shipper usually consigns it to a commission man, or cooperative agency, who make it their business to represent the shipper in caring for and selling the livestock. The buying side of the stockyard markets consists of packer buyers, order buyers, and dealers.

For some years before the passage of the packers and stockyards act there was a more or less general feeling among livestock producers that conditions in the livestock markets were such that general supervisional authority over the many phases of this important business should be exercised by the Federal Government. Specific defects were known to exist and there was much controversy concerning the facts as to the operation of the market machinery by which the value of livestock was established. Leaders in the industry came to realize the need for intelligent and impartial supervision.

### The Packers and Stockyards Act

In August, 1921, after extensive hearings, Congress passed a law known as the packers and stockyards act, which vests in the Secretary of Agriculture certain regulatory authority over the packers, stockyard owners, market agencies, and dealers. This authority extends to the business of packers done in interstate commerce, whether carried on at a public stockyard, or elsewhere. Such packers are prohibited from engaging in unfair, unjustly discriminatory, or deceptive practices; or from doing anything to restrain competition; or from establishing a monopoly.

On June 30, 1926, 77 stockyards were within the provisions of the act. A stockyard is defined as a place commonly known as a stockyard, and conducted for compensation or profit as a public market, consisting of pens and inclosures for holding, selling, or shipment of livestock in interstate commerce, containing an area of 20,000 square feet or more. When the Secretary finds that a stockyard meets all these requirements, it is posted as a public market, and due notice is given to the public, and to the stockyard owner. Ordinarily facilities furnished by a stockyard owner are holding, feeding, weighing, or otherwise handling livestock in commerce.

There were located at posted public stockyards on June 30, 1926, approximately 1,265 market agencies, whose services consist in the buying and selling of livestock on a commission basis, or furnishing other stockyard services. In addition there were approximately 4,455 dealers engaged in the business of buying or selling livestock, either on their own account or as the employees or agents of others. The market agencies and dealers are required to register with the Secretary, showing the place and character of the business conducted.

### Fair Charges Required

The law provides that the regulations and practices of stockyard owners, market agencies, and dealers must be just, reasonable, and nondiscriminatory. It prohibits any practice which is unfair, unjustly discriminatory, or deceptive. Stockyard owners and market agencies are required to furnish reasonable service upon request. Schedules of rates and charges for these services must be filed with the Secretary, and kept open to the public. Changes in these schedules can be made only after proper notice to the Secretary and to the public. The rates and charges for services must be just, reasonable, and nondiscriminatory.

Prior to November, 1924, a regulation of the Secretary provided for a bond to be furnished by market agencies covering the proceeds of sale of livestock. Under an amendment to the packers and stockyards act, effective July 1, 1924, a new regulation was issued, effective November 1, 1924, which provided that all market agencies and dealers should furnish bond covering their obligations. Under this regulation it was necessary to have new bonds filed, or to require revision of old bonds.

The Secretary may hear complaints, as well as make inquiries of his own, with reference to rates or practices of any of the agencies subject to the terms of the act. He can determine and prescribe reasonable rates and practices, as well as prohibit the use of practices found by him to be in violation of the act, or rates which have been found by him to be unreasonable or discriminatory.

The Secretary can require special and annual reports from packers, stockyards, commission men, and dealers. Authority is given to investigate their books, records, and accounts, and to prescribe the manner in which such records should be kept, if it is found that they do not properly disclose all transactions involved in their business.

Certain rules and regulations have been promulgated by the Secretary. These rules generally cover the proper weighing, feeding, and handling of livestock, and the rendering of true and correct accounts to the shippers.

### How Law is Administered

For the purpose of administering this law the Secretary has created an organization known as the Packers and Stockyards Administration. This is in charge of a chief administrative officer, who acts for the Secretary. A staff of administrative and technical assistants is located in Washington and in the field. Twenty offices are located at the more important public stockyards. Supervisors experienced in marketing supervise operations at these points, as well as at other small stockyards assigned to them. These men make numerous special reports of their activities. Through them it is possible to maintain a close contact with the persons and agencies whose business operations are affected by the act, and to adjust minor troubles quickly and informally.

The supervisors attend to complaints by shippers and others concerning service, such as cleanliness of pens, adequate water supply, prompt unloading and delivery, price and delivery of feed, physical condition of pens and alleys, and prompt delivery to and removal of livestock from scales. Practices of the trade, involving such things as the sale, price, or weight of livestock, complaints by and between market agencies, dealers, and stockyard companies, sale and disposition of crippled livestock and dead animals, operations of packer buyers and traders, likewise receive close attention.

Specifically supervisors have brought about improvement in facilities for receiving livestock, especially by motor truck, and removed unfair price discriminations between truck and rail livestock. The quality and weight of feed at a number of markets have been improved, and delays in weighing livestock overcome.

Other special investigations have been made into the practice of direct buying by packers, and the competitive relation of markets to learn whether any manipulation of supply exists for the purpose of controlling prices.

### Accurate Weights and Scales

The administration is attempting to see that accurate weights are obtained for livestock. The purpose is to have suitable scales properly tested and maintained, and operated intelligently, to insure accuracy. This work is in charge of two weight supervisors skilled in scale mechanics. They work in cooperation with stockyard companies and with city, State, and commercial scale-testing agencies.

Audits of books and accounts of stockyard companies, market agencies, and dealers are made, with a full report to the Washington office. The auditor procures and furnishes information necessary to a complete understanding of the finances and practices of the business. When the audit of a market agency is made, if its financial condition is unsatisfactory, action is taken to safeguard the interests of the shippers and patrons of the market. This may involve the addition of capital, or separation of the shippers' money from the funds of the market agency, or both. Many commission firms with strong finances have adopted this plan of carrying the shippers' proceeds in a separate account.

The administration aims to carry out the spirit as well as the letter of the act fairly and impartially and to safeguard livestock marketing fully. It is felt that these efforts are building up a greater confidence in the central markets as a safe and satisfactory place in which to buy and sell livestock.

JOHN T. CAINE III.

---

## PEACH Prices are Mainly Governed by Size of Crop

The size of the peach crop determines in large measure what the average price to growers will be for the season. A less important factor, though an important one at times, is the general level of prices, which reflects business conditions and measures changes in the value of money.

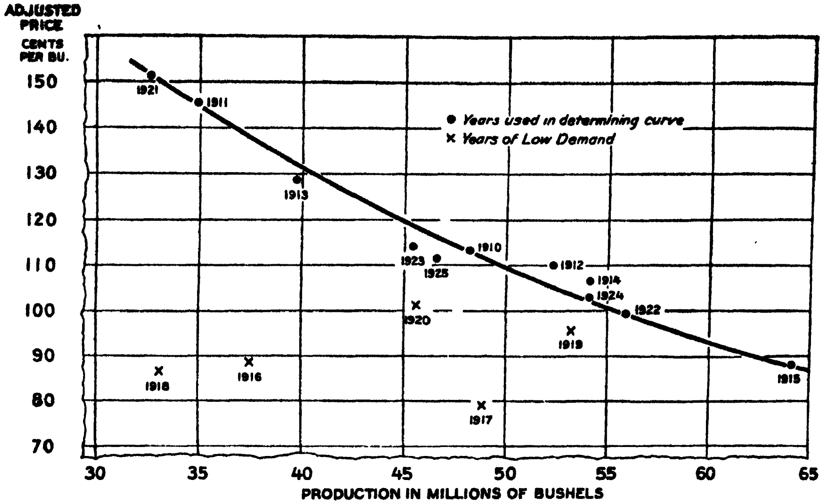

FIG. 165.—Relation of total peach production to United States farm price adjusted, 1910–1925

Figure 165 shows the nature of the relationship between the size of the peach crop and the average farm price of peaches, corrected for changes in the price level, as disclosed by a comparison of those two factors over a period of years. The larger the crop the lower the price has been, following up and down a rather definite curve, except during the years from 1916 to 1920, when the demand for peaches was low on account of the sugar shortage, car shortage, decline in real incomes of wage earners, and other factors.

This curve may be used to estimate what the average farm price for the season will be, when the size of the crop is known. What, for example, would be the probable average price if a 50,000,000 bushel peach crop were harvested? Follow the 50,000,000 line up on the chart to where it strikes the curve, then follow across to the

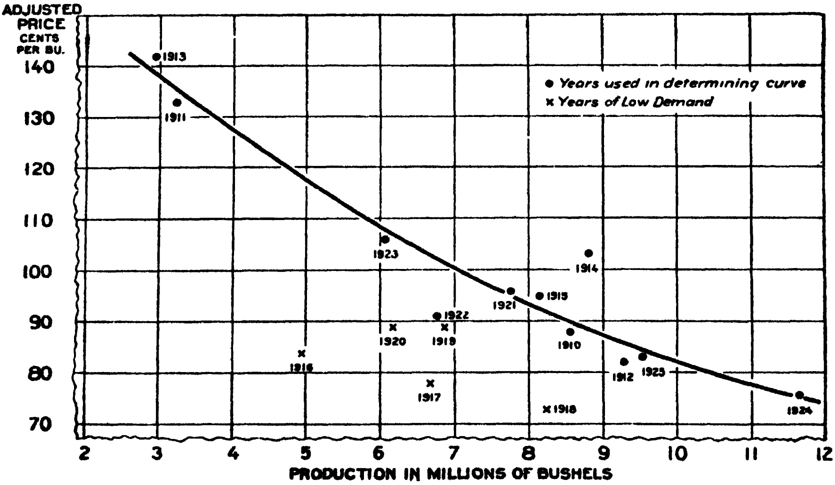

FIG. 166.—Relation of peach production in North Carolina, South Carolina, and Georgia to Georgia farm price adjusted, 1910–1925

price scale. The indicated price is $1.09, corrected for price level variations. Multiply this by a value for the all-commodities price level index of the Bureau of Labor statistics for September, which will give the desired estimate.

Such a comparison is more useful when localized to a single State. Georgia is the most important peach-producing State. In Figure 166 a comparison is given of the average July and August price in Georgia with the production of peaches in the Georgia region, including Georgia, North Carolina, and South Carolina. The same type of curve is observed as in the preceding chart, though 1914 and 1922 are somewhat off the line.

E. M. DAGGIT.

## PEACH Survey of National Scope Shows Pitfalls

Costly mistakes are frequently made in the development of peach orchards. From three to four years are required to bring a peach orchard into bearing and often conditions prevailing at the time of setting out the orchard are much different from those prevailing during the producing period. Improved methods of transportation and marketing have placed the peach industry on a national basis and although trees may be grown over the greater part of the United States, certain districts have outstanding advantages. Thus, it is important that new plantings be carefully planned.

During the fall of 1925 the Bureau of Agricultural Economics, in cooperation with various State and other agencies, undertook to collect and assemble information on the fresh-peach industry for the guidance of growers. Special attention was given to tendencies in production, to recent plantings of trees of various varieties, to problems of competition and distribution, to the extent to which peaches are marketed by rail, and to the cost of developing an orchard to bearing age.

Car-lot shipments of fresh peaches increased at the rate of about 2,000 cars annually. It is likely that shipments by auto trucks also increased materially but no figures are available to show the extent of increase. This increase in commercial shipments of peaches has come about, not because of an expansion in the number of trees all over the country, but because of extensive plantings and improved management of orchards in a number of the more favored peach-producing districts.

### Prices Low in Some Districts

In some districts production has increased so rapidly and extensively that prices have declined greatly. In Georgia, North Carolina, and in others where the increase in production has been great, 1926 prices to growers were so low that many orchards were decidedly unprofitable. Recent plantings in many States have been so extensive that production may be expected to increase for some years to come, providing the orchards now planted are not badly neglected.

The figures on the ages of trees in 1925 indicate that much of any increase in production will come from Georgia, North Carolina, Michigan, Illinois, New Jersey, Tennessee, New York, and Arkansas.

Relative numbers of young and of old trees reported in the survey for 26 States show that in Georgia, the leading fresh peach producing State, 59 per cent of the trees were less than 6 years old in 1925, and 28 per cent had not then come into bearing. Other States of less commercial importance at present show much larger percentages of young trees.

Keener competition in the marketing of peaches from some States may be reasonably expected during the next few years. The cost of transportation and refrigeration set rather definite limits on the distance which peaches from a given district can be sent to market. As transportation costs increase with increased distance, it becomes more and more necessary to ship only fruit of high quality and attractive pack if the best returns are to be realized. This is particularly true in years when there is a large crop throughout the peach-producing districts. Thus, during years of low production in the East and South it becomes more possible for distant producing districts to ship to the larger markets and it is at such times that California increases the shipments of fresh peaches to the Central and Eastern States.

### Distribution of Shipments

Normally Georgia supplies most of the territory east of the Mississippi River until the States farther north begin to send their crops to market. Texas shipments are confined mainly to the States west of the Mississippi River and to Illinois. North Carolina shipments go to the Atlantic seaboard region mainly. States lying directly north of Tennessee take most of her peaches. Arkansas peaches are marketed largely in the near-by States of Illinois, Iowa, and Missouri. Illinois peaches go to Chicago, St. Louis, and the smaller cities in the Middle West. The Middle Atlantic section, such as New Jersey and Eastern Shore of Maryland, depend upon New England, the Middle Atlantic States and Ohio for markets. Most of the Michigan crop is usually consumed in the Middle West. New York peaches go to the eastern cities, while Colorado and Utah peaches are marketed for the most part in the region lying east of them and extending to Illinois. Car-lot shipment implies relatively large movements and long distances to markets. The motor truck has, however, been effective in getting peaches to consumers who could not be reached otherwise.

According to the survey of 1925, nearly 50 per cent or more of the merchantable crop marketed in each of the States, West Virginia, Idaho, Alabama, New Jersey, Kentucky, Michigan, Pennsylvania, Indiana, and Ohio, was sold locally or hauled to market by truck or wagon. A very large percentage of the crop in some of these States goes to near-by towns and cities, usually by truck or wagon, although some shipments are made by express. In Ohio less than 15 per cent of the 1924 crop was marketed by rail. In 1924, on the other hand, Georgia sold locally or hauled to market by wagon or truck only 4 per cent of the peaches sold. The same conditions as in Georgia, although to a lesser extent, obtained in the other important peach States of the South, West, Midwest, and East.

Of the many varieties of peaches grown, only a few are of commercial importance. Good commercial peach trees must be hardy and produce regularly. The fruit must be of good shipping quality, so that it can be sent to distant markets and remain in good condition. The Elberta is by far the most important variety east of the Rockies, as it meets these requirements. Other varieties of importance in certain districts are the Belle, Hiley, J. H. Hale, and Carman.

In some States a fairly large number of trees are found of little known varieties and of seedlings. In general, fruit from such trees may prejudice consumers against buying more peaches of the well-known standard varieties.

### Care in Orchard Site Selection

Too much emphasis can not be placed upon the necessity of exercising care in the selection of the orchard site and in planting the orchard. With cost rates as in 1925, land could be bought and a peach orchard set out and cared for until 4 years of age for a sum amounting to $90 to $650 per acre, depending on the district selected. The cost of the land is the largest single item. In the commercial peach districts land is not a limiting factor in setting out an orchard, but a really good site may not be easily found. An enterprise like a peach orchard, that requires much time and money to develop, should be undertaken only after one is convinced that in due time the orchard will be profitable. Competition from near-by orchards and from competing districts during the bearing life of the orchard should be considered. An orchard that costs little, but bears fruit only occasionally, or bears fruit of poor quality, or even good fruit that must be sold on a glutted market, may be less profitable than one of higher cost, which produces good fruit regularly, for which there is ready sale.

M. R. Cooper.

## PEANUTS: How They Reach the Consumer

Few people who buy a small bag of roasted or salted peanuts from a street vender know of their origin or of the many processes the peanuts have passed through since leaving the ground. Peanuts are supposed to have originated in Brazil, but were taken in slave ships to Africa, Spain, and other countries at a very early date, and the types of peanuts that we know in America were probably developed in Spain and various parts of Africa.

The growth of the peanut industry in the United States was slow until the introduction about 45 years ago of labor-saving machinery for the various cleaning and shelling processes. The increase of the boll weevil in the cotton-growing States was responsible for a wave of peanut planting throughout the Southern States 10 or 12 years ago. During the last three or four years peanut production in this country has been less than during some of the war years, largely because of lessened returns and the preference of the southern farmer for planting cotton when reasonably profitable.

Peanuts require a long summer in which to mature properly, and so are not planted commercially north of a line running west from southern Virginia. Virginia-type peanuts are large-podded and seem to do best in the soils of southeastern Virginia, northeastern North Carolina, and central Tennessee. Elsewhere in the peanut belt the small-podded Spanish is the preferred type, although many Runners, with pods of medium size, are planted in Alabama and Florida.

### Left in Stack to Cure

After the peanut plants are dug or pulled from the ground, they are left in a stack or windrow to cure for a month. This lessens the tendency of the kernels to shrivel. Then the pods are picked from the vines by means of a mechanical picker or threshing machine and taken to the cleaning or shelling factory. Large storage houses at a number of the factory points provide a means for holding over peanuts from the time of harvest until they are needed later in the season. Millions of pounds of peanuts are also stored in the cleaning and shelling plants.

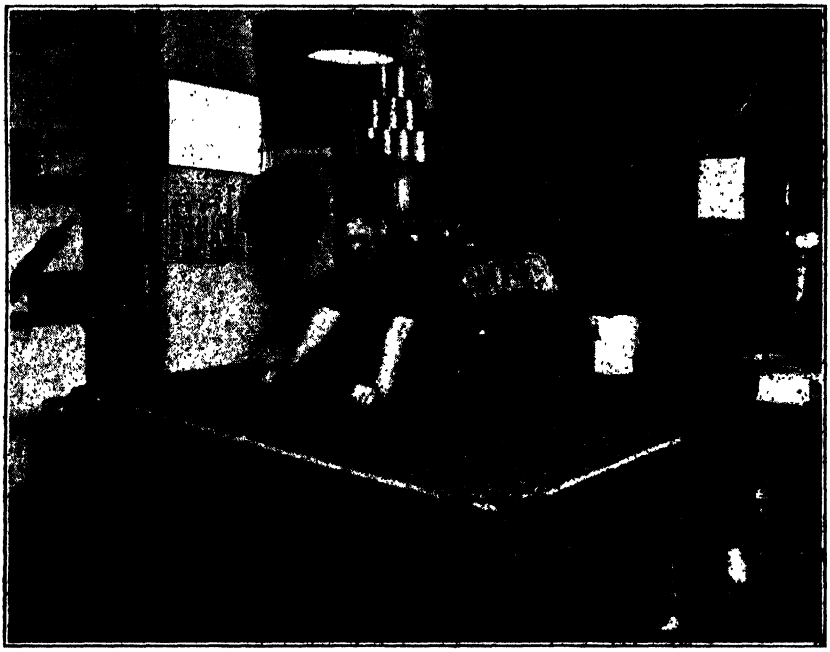

Fig. 167.—Cutting peanut candy into 5-cent bars. The past two or three years has seen a great increase in the volume of peanuts used in making peanut candy, and new kinds are frequently placed on the market

As the peanuts come from the farm the pods are often partially covered with dirt and accompanied by sticks, stones, and other foreign material. In consequence, cleaning operations are necessary as a preliminary step in making the peanuts ready for sale. This is especially true in the Virginia-North Carolina section, where the best of the large-podded nuts are sold in the shell for roasting. Before peanuts in the shell are considered ready for bagging they pass through a revolving reel, where excess sand and dirt drops out, through a machine for cutting off the little stems attached to the pods, past various fans to blow out chaff, light stems, and lightweight pods, through grading machines, and even a polishing drum, which contains a white, dustlike powder in which the pods tumble around sufficiently to give them all a fairly uniform color. Finally, the pods pass along revolving, endless belts, along which workers are seated to remove discolored misshapen pods and any remaining foreign material.

### Peanuts for Salting

Peanuts that are to be shelled and sold for salting, peanut butter, or peanut candy do not need such elaborate preparation, but usually pass through some recleaning machinery before being shelled. It is important that stones be removed, however, and a device using air currents and gravity is employed for this purpose with Spanish peanuts. The shelling is accomplished by forcing the pods between two cylinders, the inner one revolving, while the outer is stationary. To the revolving cylinder are attached two steel "beaters," which strike and crack the hulls of the nuts. Shelled Virginia-type peanuts are graded into two sizes, the larger of which is salted and the smaller worked into peanut butter and peanut candy. Peanuts which have been split in going through the machinery are used for cheaper grades of butter and candy.

Spanish and runner peanuts are always sold shelled. Shelled Spanish are so uniform in shape that they are well adapted to the penny vending machines, so numerous in some cities for the sale of salted peanuts, and enormous quantities are sold for this purpose. Spanish peanuts are also used to blend with Virginia-type nuts in making peanut butter, and a considerable and increasing volume is used in peanut candy. Runners are used primarily as a substitute for Virginias in peanut butter and peanut candy.

Shelled peanuts of the Virginia type which are to be salted have the thin outer skin removed before being placed in the vegetable oil in which they are cooked. With salted Spanish, however, the thin red skin is left on.

Peanuts in the shell are roasted from 15 minutes to an hour, depending upon the size of the roaster and the amount of heat used. Scorching is likely to result if the heating is too rapid. The machinery for roasting peanuts on a large scale is similar to that used for roasting coffee. In fact, coffee roasters are using their equipment increasingly for roasting peanuts as a side line.

## PECAN Trees Require Abundant Sunshine and Space

Abundant sunshine and free space are no less essential to the parts of a pecan tree that are to produce their share of its crops than is liberal plant food in available form and space to the roots. This fact did not receive the attention it demanded from most of the pioneers in the industry who were the first either to top-work the wild groves of the Southwest or to plant the first orchards farther east.

The pecan tree is the largest growing nut tree under orchard cultivation. The average spread of ordinarily big trees, 50 or more years of age, standing in the open and in locations favorable to their growth is probably from 100 to 125 feet, although maximum trees of materially greater range are not unusual. This is fully three or four times the usual size of normally big apple trees and from four to six times that of the peach, yet many of the first pecan developments were spaced at from 15 to 30 feet, which represented the usual planting distance of these species at that time.

The planting distance between pecan trees has increased an average of approximately 1 foot a year since 1900. It was then about 35 feet. At present, few orchard trees are being set less than 60 feet each way. The end is apparently not yet in sight as 100 feet is being speculated upon and occasional orchards are being so spaced.

Evidence of greatly reduced bearing surface in the lower parts of the trees because of the shading and subsequent death of, first the fruit spurs and then the entire branches, is to be seen in nearly every orchard of the South that has made normally rapid growth and has been of adult bearing age for more than five years. The branches of many of these earlier plantings form a canopy from 20 to 50 feet high from one row to another, below which there are few or no bearing branches except on the outside of the end rows.

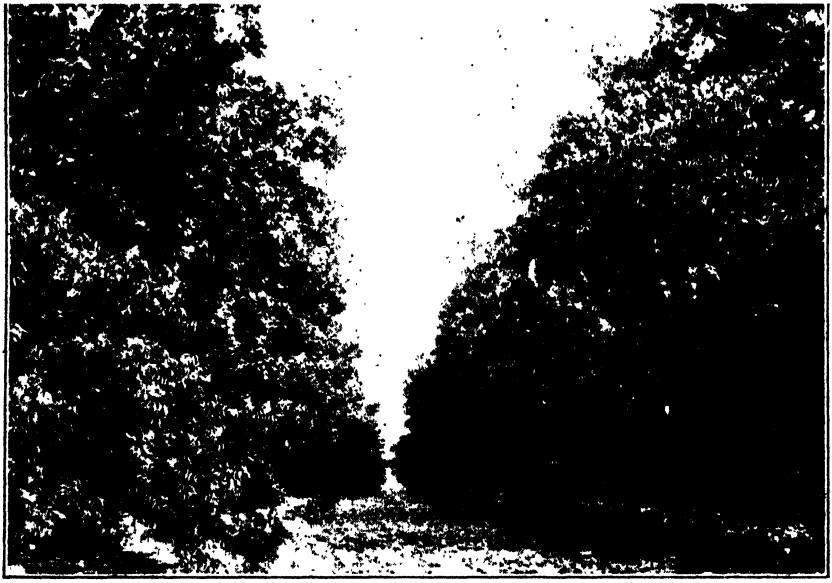

FIG. 168.—Pecan branches about to come together in the middle of the rows. With varieties known to be intolerant of shade, the alternate trees should be removed promptly when this condition develops. These are Frotscher trees, standing 50 feet apart each way. The photograph was taken 14 years after planting

## Only One Cure for Crowding

There is but one remedy to apply, once crowding has begun; namely, to eliminate some of the trees. This costs money and takes courage, especially as not infrequently crowding has begun before the trees have begun to bear profitably.

Regardless of whether or not the trees are destined to become profitable in later years with thinning, they are most unlikely to do so without it, once serious crowding has begun. As to the exact time at which they should be thinned, much will depend upon the variety, original spacing distance, rate at which they have grown, and various other factors. Some varieties are less promptly affected by shade than others, either because of greater ability to endure shade or because of an erect habit of growth and the causing of less shade, or both. The Stuart affords a good illustration of the upright-growing type, very resistant to shade, and requiring a minimum of actual space during a long part of its early bearing period, and the Frotscher, an equally good illustration of a variety that is both broadly spreading and intolerant of shade.

The extent to which the branches of the trees in an orchard may come together at the middles and serious shading begin is shown in Figure 168 photographed near the end of the fourteenth growing season after the trees had originally been set out 50 feet each way.

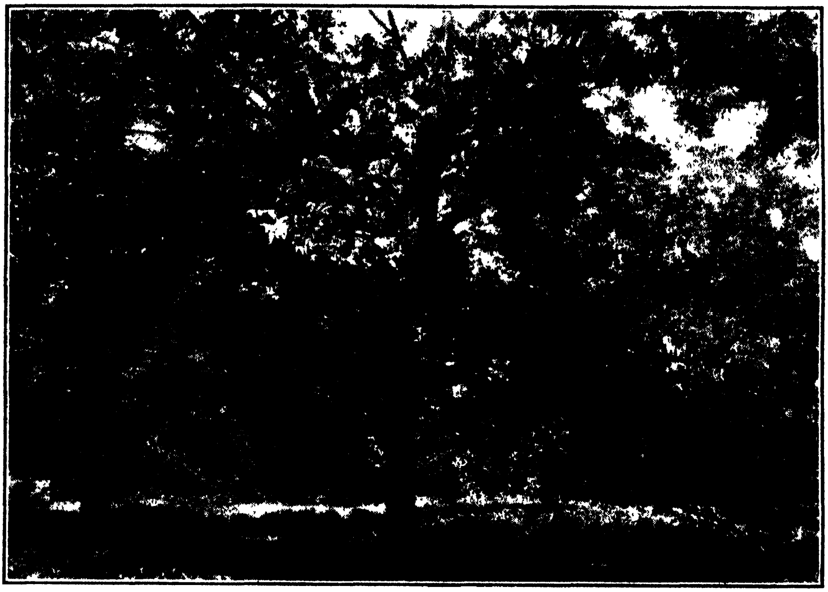

FIG. 169.—A Frotscher pecan tree at the end of a crowded row, showing the extent to which the lower branches have dropped on the inner side as a result of shading, and been retained in full bearing on the sunny side

The damaging results of shading were much in evidence at harvest time of the year in which this picture was taken. The leaves on the lower branches matured and dropped prematurely and the nuts from the same branches were so poorly filled that they seriously lowered the average condition of the entire crop.

### Alternate Trees Removed

One year later the branches crossed the middles of the tree rows to such extent that the vision was entirely obstructed and great spaces became vacant about the lower parts of the trees where recently there had been heavy-bearing branches. It was then so obvious that the process of self-pruning was likely to continue indefinitely unless prompt action was taken that the alternate trees in the part of the orchard where they were the largest and incidentally the best bearers, were removed.

None of the trees in the outside rows were disturbed, as these had one side on which they were free to develop. The lower branches on the inner sides of these trees continued to drop off as shown in Figure 169, by which it may also be seen that those on the outer side were still being retained seven years later when the picture was taken.

Following the removal of the alternate trees, not only did the lower limbs cease to die but those not too far gone put out new leaves and spurs and began again to bear crops. The filling quality of the nuts was restored to normal and the yields per acre continued to show a satisfactory increase. The ends of the lower limbs began to sag with weight of nuts and to again occupy the space which had been vacant.

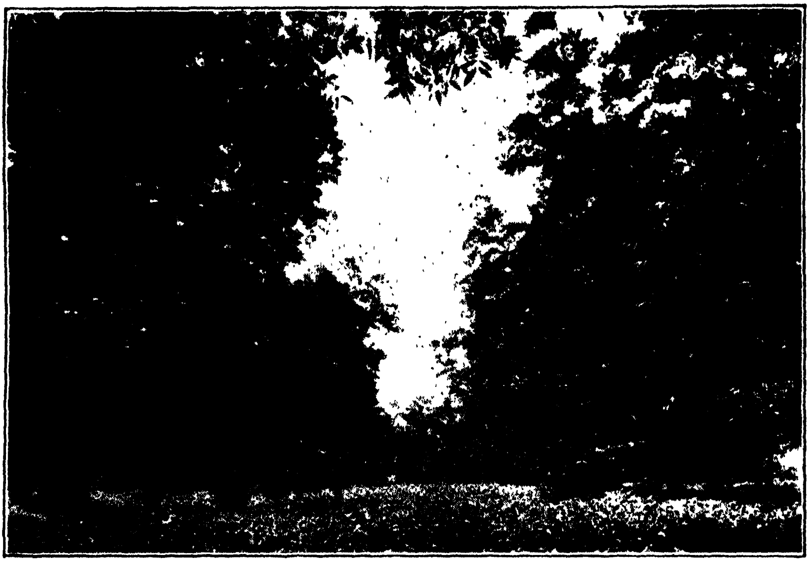

FIG. 170.—Diagonal view showing the amount of space between the rows in a 22-year old Frotscher pecan orchard, originally set 50 feet each way, seven years after the alternate trees had been removed

A typical view between the trees, taken seven years after the thinning process took place, on the diagonal, which had become the order of alignment with the thinning process, is shown in Figure 170. This shows that it will probably be only a few years before the branches will so overlap that thinning will again be advisable.

C. A. REED.

### PERQUISITES Hold Good Farm Help

The majority of farm operators give their men hired for the season various privileges on the farm, or allowances of farm products in addition to their wages. Some of these perquisites have been customary for many years and are given and taken as a matter of course. Others are so new that frequently the farm operator feels they have been forced upon him—that he had to give in or lose a good farm hand.

Perquisites are a more important factor in the wages of farm labor than has generally been realized, but many farmers have given these matters little thought. They are an important means of attracting to and holding good hands on the farms.

For many years rates of farm wages have been commonly quoted with or without board, but with no reference to the additional value of perquisites given. Farm wages seem low compared to wages paid nonagricultural laborers. What are the perquisites given noncasual or steady farm hands? What are they really worth to these men? How much do they make up to them for the low cash farm wages? How much does it cost farmers to give these perquisites? How are they helpful in getting and keeping good farm hands? A recent investigation by the Department of Agriculture has partly answered some of these questions.

### Perquisites Are General

The perquisites considered here are those of month hands, hired in most cases for the crop season or a year. Comparatively few farmers who reported give these men cash wages without perquisites of some kind. Those most commonly given are board, lodging, house rent, fuel, milk, meat, vegetables, fruit; a chance to keep livestock such as poultry, pigs, a cow, or a horse or mule; feed or pasture for the livestock kept; garden, and use of employer's horses or mules.

Practically all single men reported on receive board. The other perquisites most commonly given them are use of horses or mules and vehicles, and garage space for their own motor vehicles.

Few married men are given board, but the majority receive the use of a house or cabin and some fuel. In addition, the variety of perquisites given them is much greater than for single men. Those most commonly given besides house or cabin, fuel (usually wood), are milk, meat (usually pork or its products), vegetables and fruits (especially potatoes and apples); the privilege of keeping poultry, pigs, cow, horse, or mule; allowance of feed or pasture for the livestock kept; garden space; use of horse or mule and farm tools and vehicles; garage space for the man's own motor vehicle.

The average money wage of unmarried farm hands reported upon in this study was $42, and of married men, $50 per month. The total farm value of the perquisites given each class of men was nearly the same; for the former, $30, for the latter, $31 per month.

### Board For the Unmarried Men

Board and lodging are given nearly all unmarried men. They are the perquisites most costly to the farm operators who give them. Board alone averaged over twice the value of any other perquisite reported. The separate values of the more numerous perquisites given married men averaged lower; for instance, house rent, when given, $9; wood or coal, $4; dairy and poultry products, $10; meats, $5; feed for livestock the man was allowed to keep, $6. Few men got more than a few of these perquisites. The usual kinds vary considerably from one part of the country to another.

In this study the farmers were asked to value perquisites at their actual value on the farm, but it is believed that frequently the cost to farm operators of giving perquisites is very little compared to their value to the hired hands. Wood furnished may be simply dead stuff the man cuts himself; chickens or pig or cow may pick up much of their feed from what would otherwise go to waste or be idle fields. Vegetables and fruit given may be unmarketable because of blemishes or small size, but fit for home use. The farmer is seldom put to inconvenience by allowing the hired hand garden or garage space, or put to much expense for his man's use of farm tools, horses, and vehicles.

If the hired man had to pay average city prices for the perquisites given him on the farm, the cost to him would often be more than twice their farm values. For example, the average monthly rental for a city home of five rooms is about $22 per month; fuel and light add $7 more. In the city the average family buys barely a quart of milk a day at a cost of over $4 per month; the hired farm hands reported on got over 3 quarts a day, valued at over $8 per month. The city family pays $2 a bushel for potatoes, and buys less than a bushel a month; the farm hand was given almost 2 bushels, worth nearly $3. In cities there is little chance to have a garden, to keep poultry or other livestock, or to get meat free and other things many farm hands receive. The average married farm hand's perquisites, worth about $30 per month on the farm, would probably cost him nearly twice as much if paid for in the city. Besides, he gets other perquisites for which it is hard to estimate costs and values, yet which would be missed by a family accustomed to them.

Many farmers needing a good class of steady hired help should consider giving additional perquisites possible on their farms, especially those which cost little but mean much to the laborers. Working men not on farms usually hear little of farm work except that wages are low; they would more often consider it as an occupation if they knew what perquisites and consequent savings in expenses were offered in addition to wages. Giving perquisites is an important means of attracting and holding good farm hands.

J. C. FOLSOM.

## PHOSPHATE Fertilizer Deposits of U. S. Ample

Phosphate comprises more than two-thirds of the 7,000,000 tons of fertilizer used in the United States annually. From this we may assume that phosphate is our most important fertilizer material. Its importance in relation to agriculture and the domestic fertilizer industry is emphasized by the fact that the United States possesses the largest known deposits of phosphate rock, making us entirely independent of foreign sources.

Phosphate fertilizers may be divided into two classes—(1) those in which the phosphorus is readily soluble in water, and (2) those in which the phosphorus is practically insoluble in water, but is in such a form that it can be slowly utilized by plants. Basic slag, bone meal, bone ash, bird guano, precipitated phosphate, and finely ground raw rock phosphate belong to the second class. Basic slag is an important phosphate fertilizer in Europe, but its use in this country is limited because of our very small domestic production.

Bone meal, bone ash, bird guano, and precipitated phosphate are valuable fertilizers, but they are produced only in comparatively small quantities. Under certain conditions of soil and climate good results have been obtained with finely ground, raw rock phosphate; for example, when it is used on an acid soil or when it is applied with farmyard manure or green manure.

Our most important phosphate fertilizer is acid phosphate, or superphosphate. It is manufactured by treating phosphate rock with sulphuric acid, and it contains from 16 to 20 per cent of phosphoric acid ($P_2O_5$), practically all the phosphorus of which is soluble in water and can be readily utilized by plants. Acid phosphate also contains a large percentage of gypsum, which is formed during the manufacturing process. Although gypsum has some value for certain types of plants and soils, no direct charge is made for that which is present in acid phosphate. However, its presence increases the cost of the fertilizer to the farmer, since on it the farmer must pay as much freight as on an equal quantity of the real fertilizer.

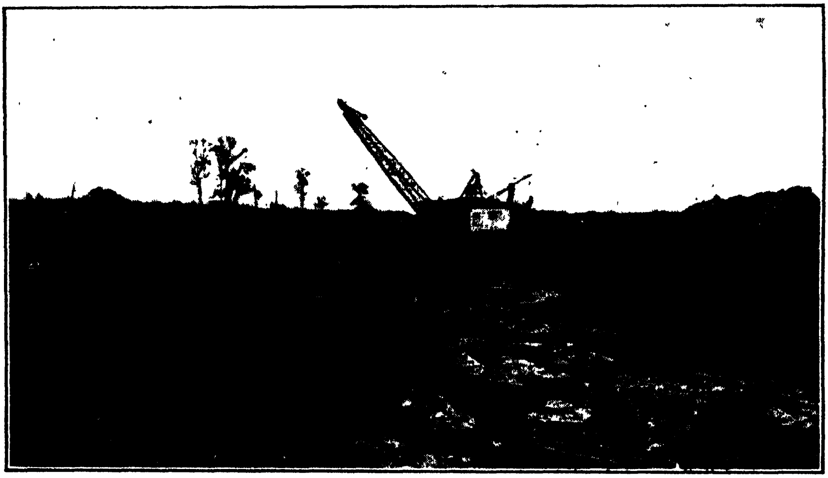

FIG. 171.—Mining Tennessee brown phosphate rock, Mountpleasant, Tenn.

Double superphosphate, a material similar to acid phosphate, is produced in limited quantities in this country. It contains from 40 to 45 per cent of water-soluble phosphoric acid ($P_2O_5$) and practically no gypsum. A relatively high-grade phosphate rock is now used in the manufacture of both acid phosphate and double superphosphate.

### Much Phosphate Lost

Approximately 4,000,000 tons of phosphate are lost or wasted annually during the process of treating the phosphate rock as mined, to obtain the high-grade material required for the manufacture of acid phosphate. There are also enormous deposits which can not be utilized for the manufacture of acid phosphate because they contain undesirable impurities or comparatively little phosphate. Recognizing the importance of prolonging the life of our phosphate resources, the Government has done considerable work in the last few years on methods for utilizing these low-grade and waste materials. The production of liquid phosphoric acid seems to be the most desirable method, and several processes have been worked out for its manufacture from both high-grade and low-grade phosphate rock. Liquid phosphoric acid can be combined with ammonia or potash to form soluble, highly concentrated, solid fertilizers which can be handled and transported at a minimum cost. Although these concentrated materials are not produced in any appreciable quantity at the present time, it seems very likely that they will constitute a large portion of the phosphate fertilizer used in the future.

K. D. Jacob.

## PHOTOGRAPHS Tell Story of Agriculture

The coming of the motion picture and the much more general use of photographs in educational publications, magazines, and newspapers in the last 20 years have made the present generation in the United States both in the city and country picture minded. Pictures telling a definite story or lesson relating to the farm and farm home have found important uses in extension education. They are used to help tell effectively the story of successful demonstrations in efficient farming and home-making practice. Such photographs make clearer and more readable bulletins, circulars, leaflets, and posters sent out by the extension divisions of the State agricultural colleges and the United States Department of Agriculture. They illustrate stories about successful extension demonstrations appearing in newspapers, magazines, and farm journals. As lantern slides and in charts and posters extension workers use them to show more clearly the things talked about. In extension

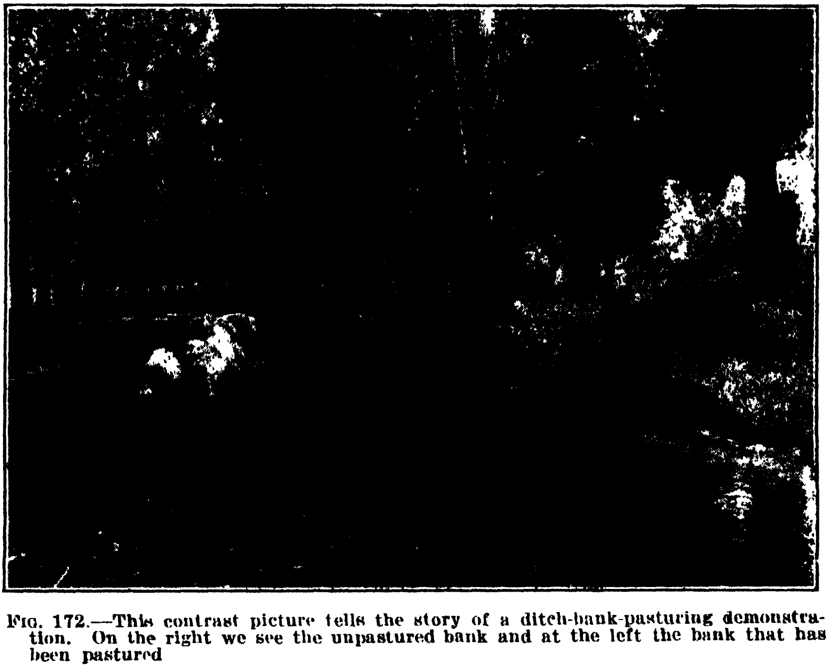

FIG. 172.—This contrast picture tells the story of a ditch-bank-pasturing demonstration. On the right we see the unpastured bank and at the left the bank that has been pastured

exhibits they show steps in demonstration and better ways of doing certain things.

A series of well-taken photographs showing the progress of an extension demonstration gives to the many who can not watch from week to week the demonstration itself a clear idea of how the demonstration is carried out and what are its results. Photographs make it possible for people to see at any season of the year what a demonstration is like, whether it is in growing a crop, feeding animals, making a dress, or rearranging a kitchen. The photograph has proven particularly valuable in showing before and after views illustrating changes, due to improvements or treatment. For example, the beautifying of the grounds around a house or improved feeding of a farm animal. Photographs of contrasting kinds of materials, methods of handling equipment, or types of animals are often helpful in driving home an extension lesson. It is found that extension activities such as tours, team demonstrations, contests, camps, and short courses are much better understood by the reader or listener when good photographs of them are used.

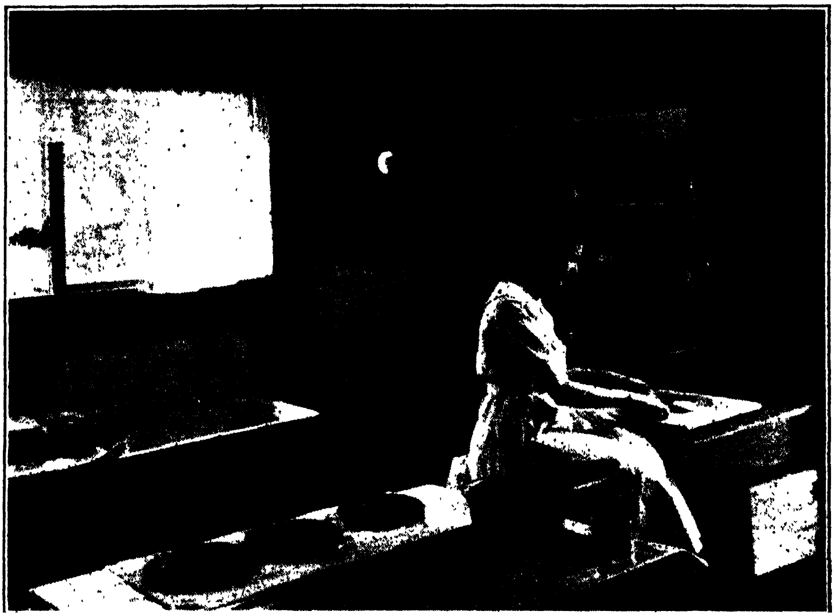

FIG. 173.—Farm woman in her improved kitchen. This picture answers the requirements for natural surroundings, costume, and action

### Interest Should Be Concentrated

Photographs used in extension education to be effective must be good photographically. They must show clearly the definite step in a process described. The eye should go directly to one center of interest in the picture and only one if the picture is properly taken. A photograph that has several centers of interest in it does not meet the requirement of a good teaching picture which is to tell clearly one definite thing. In photographs in which people are shown, the surroundings, costumes, and action of the people should be appropriate and natural. (Fig. 173.) If the people in a picture have the appearance of doing something they are not used to or if they are dressed in clothes or are in surroundings not suited to what they are doing, it has been found better not to use the picture since it is not likely to be convincing.

The supply of photographs suited for use in extension education is growing steadily. The extension service of the United States Department of Agriculture has a reference file of photographs on farm and home subjects for the use of extension workers and cooperators of over 25,000 photographs. Its loan collection of 60,000 lantern slides comprises about 150 series of interest to farm audiences. Each bureau of the department, also, has its own specialized collection of photographs illustrating the results of its investigations in the teaching use of which the extension service cooperates. Supplementing these sources of photographs many of the State agricultural colleges maintain large collections of photographs and lantern slides, touching every phase of extension education relating to the farm and in the farm home.

Reuben Brigham.

## PIG Surveys and Market Stabilization

The pig-survey reports issued by the department twice a year, as of June 1 and December 1, show the size of the spring and fall pig crops of each year as a percentage of the similar crop of the preceding year, and the number of sows bred to farrow the following season (fall or spring) as a percentage of the number actually farrowed the similar season of the preceding year. The survey of June 1, 1926, showed the size of the 1926 spring pig crop as a percentage of the spring crop of 1925, and the number of sows bred to farrow in the fall of 1926 as a percentage of the number actually farrowed in the fall of 1925.

Thus these reports have the dual character of "current production" and "intention to produce" reports. As such they furnish information from which can be estimated the probable seasonal market supplies of hogs. This is of great value to producers in making feeding and marketing plans. Indications of future production as shown by breeding intentions are useful to individual producers in deciding their own breeding programs.

The name "survey" instead of "estimate" is given to these reports because they are not estimates in the sense that crop reports are estimates or forecasts. The latter as issued by the department represent the judgment of the crop-reporting board after a study of all available data bearing on the respective items. The pig-survey reports give the results as computed from a tabulation of the returns made by producers covering their own operations. No attempt is made to modify these results on the basis of information received from other sources.

### Post Office Department Assists

The procuring of the basic material for these surveys is a joint activity of the Post Office Department and of the Department of Agriculture. The survey cards are prepared by the Department of Agriculture and distributed by the rural and star route mail carriers of the post office. To the postmasters of each post office, from which a rural or star route operates, a supply of cards is sent sufficient to furnish 15 to each carrier. These cards are given the carriers by the postmasters, with instructions as to the manner in which they shall be distributed. These instructions ask that the farms from which reports are obtained be as nearly as possible representative of all farms along each carrier's route, including large and small, owned and rented, good and poor. If possible, the carrier interviews the different farmers and fills out the cards himself; otherwise he leaves the cards in the mail box with requests that they be filled out and returned to him the next day. The carriers turn over the filled-out cards to the postmaster, who mails them direct to the Department of Agriculture.

### Advantages of the Plan

Among the advantages of this method of obtaining information are the following:

The returns furnish a more truly random sample than returns sent in from a selected list or returns from a list selected at random. There is danger, however, of the returns becoming selective if the rural carriers tend to distribute the cards only to the farmers who fill them out most readily.

The returns are much larger and better distributed than returns from mailed questionnaires. Between one-third and one-half of the cards sent out are returned.

The cost of procuring the returns and distributing the results is much less than with mailed questionnaires.

### Farmers Gain Contact with Department

Many farmers in this way are brought into contact with the crop and livestock reporting activities of the department who otherwise would be largely ignorant of them; many are interested in the pig-survey results who might not otherwise learn of them. This tends to increase the possibilities of these reports actually influencing the decisions of enough farmers to make them a real factor in production changes.

The number of cards returned is much larger than actually needed to give a stable sample. To expedite the report only the estimated minimum number are used. For the leading hog States these are distributed by counties on the basis of 1 card to each 30 farms reported by the census as raising hogs. This gives about a 3 per cent sample.

These reports are of greatest value to producers since they furnish information as to seasonal hog production some months in advance of the time when the marketing of this seasonal production takes place. This makes it possible for producers to adjust their feeding plans to this probable production. The reports also give marketing agencies, extension organizations, and farm papers dependable information upon which to advise hog producers as to market supplies, price trends, and marketing policies.

Such information tends to reduce the speculative factors in the packing business. In the past very little information was available as to hog supplies in advance of the winter packing season during which surplus storage stocks are accumulated. The pig-survey reports make possible advance estimates of total crop-year slaughter and the seasonal distribution of such slaughter. Financial arrangements, plant organization, surplus storage policies, and marketing programs can now be more definitely worked out in advance than was formerly possible.

In short, these reports furnish a basis for better adjusted production, more intelligent feeding, and more orderly market distribution of hogs and less speculative packing and better organized merchandising of the products.

**PINK Bollworm and Measures to Exclude It** The pink bollworm is now recognized as one of the most injurious cotton pests of the world, probably outrivaling the cotton boll weevil which has been estimated to cause, in this country, an annual loss in excess of $200,000,000. At present, the pink bollworm is established in all of the commercially important cotton-producing countries and in a number of them is responsible for losses ranging from 30 to 50 per cent of the crop. The cultivation of cotton in Hawaii has been practically abandoned, owing to the ravages of this pest, where it has been found to infest from 50 to 99 per cent of the bolls in the field. It affects the production of cotton in several ways; namely, reduces the yield, lowers the quality of products, and affects the oil content of the seed.

Briefly, the general color of the larval or worm stage is pink, from which the common name is derived. Eggs are deposited by the adult, which resembles somewhat in color the common clothes moth of this country and has a wing expanse of from three-fifths to four fifths of an inch from tip to tip, on various parts of the plant, about half being on the green bolls. These eggs hatch in about 10 days, and the small worms shortly thereafter penetrate into the interior of the cotton bolls or squares and later enter the seed. The fact that the larvae or worms may live in the seed for two years makes it possible for the insect to be transported to the most remote quarters of the earth.

### Preventive Action Taken Early

The department early realized the necessity for taking drastic steps to protect the cotton industry of this country from invasion by this pest, and in 1913 prohibited, under the plant quarantine act, the entry of cottonseed from all foreign countries and localities, with the exception of the Imperial Valley of the State of Lower California, Mexico, where the pink bollworm is not known to occur. Subsequently, a similar prohibition was placed on the entry of cottonseed from Porto Rico and Hawaii. Early in 1920, it was discovered that shelled corn shipped from Mexico was arriving at American ports of entry, fouled with cottonseed which may contain living pink bollworms; and to meet this situation, the entry of corn from that Republic was conditioned upon its being ground or subjected to a temperature of at least 200° F. for a period of not less than five minutes.

Investigations to determine the various ways in which the pink bollworm may be introduced, disclosed that bales of cotton may contain varying quantities of seed, and also that the wrappings used on cotton, cotton waste, etc., often have adhering to them cottonseed, thus leaving open an avenue for the entrance of the pink bollworm. Inasmuch as this insect can live for a long period within seed, the entry of bales of cotton and wrappings used to cover foreign cotton presented a serious risk; and following experiments conducted by the department to determine a method of safeguarding the entry of such products, an order was issued March 10, 1916, requiring that all foreign cotton be given vacuum fumigation with hydrocyanic-acid gas at the port of entry. (Fig. 174.) Since that date, upwards of 3,500,000 bales of cotton have been so treated, as well as numerous shipments of cotton waste and wrappings used to cover foreign cotton. Owing to the risk which accompanies the entry of cottonseed cake, meal, and oil, on June 23, 1917, an order was issued restricting the entry of the first two products from all foreign countries, and on the same date a similar order regulating the entry of cottonseed oil from Mexico was promulgated.

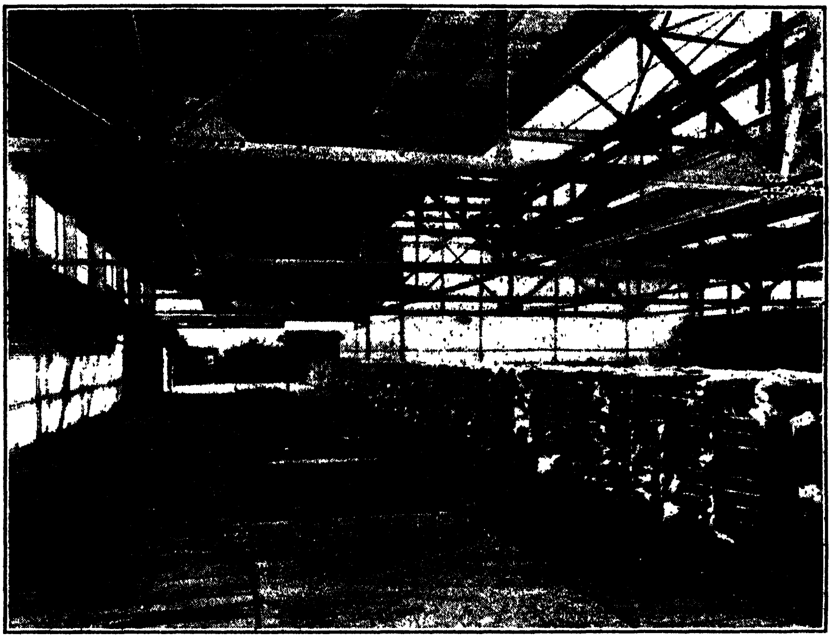

FIG. 174.—Vacuum cotton fumigation plant in Boston, Mass. Each cylinder will accommodate from 145 to 300 bales of cotton, dependent upon the size of the bales

### Pink Bollworm in Mexico

The discovery of the pink bollworm in cotton fields in Mexico and the finding of this insect in cottonseed in freight cars returning to the border presented a new problem. Inspectors were stationed at the more important ports of entry, and subsequently car-fumigation houses were erected for the purpose of fumigating all cars which might be the means of introducing the pink bollworm. These houses, six in number, vary in size from 6 to 20 car capacity. (Fig. 175.) Since 1918 inspectors of the Federal Horticultural Board have examined, in Mexico, over 242,000 freight cars; and of this number in excess of 122,000 were fumigated in the car houses referred to above. The risk, however, was not confined to freight cars, since cottonseed was frequently taken in passengers' baggage, particularly in that of Mexican laborers entering this country for a brief period to assist in the picking of American cotton. Living pink bollworms were, on a number of occasions, found in cottonseed mixed with cotton lint used in pillows and blankets. In an effort to prevent the entry of the pink bollworm through this source, inspectors of the Federal Horticultural Board cooperate with the inspectors of the customs service in the examination of passengers' baggage arriving either by train, motor car, or in the possession of pedestrians, and all material containing cottonseed is confiscated and destroyed. Similarly, baggage of passengers arriving at maritime ports of entry is examined for cottonseed and other prohibited plant products. In cooperation with the customs service and post-office officials, all foreign parcel-post packages are inspected for contraband plant material.

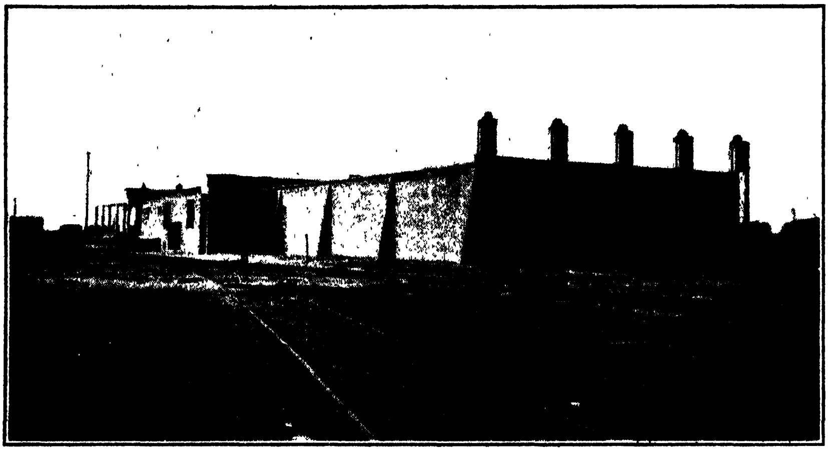

FIG. 175—Federal car-fumigation house at Laredo, Tex. This house will accommodate 20 freight cars and is believed to be the largest house in the world used exclusively for fumigation purposes

E. R. SASSCER.

**PLUMBING on Farms Inadequate** American farmers have more and better plumbing than the farmers of any other nation; yet 9 out of 10 American farms still have the old, backbreaking methods of supplying water. An unusual example, but valuable as an illustration, was noted recently on a farm in an eastern State. A woman was found to be walking 440 miles a year—as far as from Chicago to Omaha—carrying water from a spring uphill to her home, and in so doing was expending sufficient energy to plow 19 acres of land. The rough, steep, deeply-worn pathway bore evidence of needless toil and sacrifice. At least $50 worth of time was being thrown away yearly, which if saved would have paid for a modern, pressure water system in three years. Figure 176 affords some idea of what it means to have running water about the farm buildings.

A sink is the most useful plumbing fixture in a farm home, and yet it is estimated that half of the farms of the country have none. There is little real excuse for not having a sink when a fairly good one can be purchased for as low as $3. Where the commercial article must wait, a little time and ingenuity often provides a simple homemade sink, which though crude is much better than none and has proved a boon in many a home. Sinks should be located to insure light, air, and fewest steps. The waste pipe should be accessible for easy cleaning. Every housewife should determine by experiment what height of sink will give her an easy, erect, working position, bending at the hips rather than stooping from the shoulders. For a woman of average stature, a favorable height to the top of the sink rim is yard-stick length or 36 inches. Figure 177 is a one-piece, enameled-iron apron sink with two drain boards and combination swinging spout faucet. The setting gives plenty of light and air and utilizes the space beneath and above the sink.

FIG. 176.- The convenience of running water about the farm buildings

## Indoor Laundry Desirable

In good weather many people do the laundry work out of doors because it is more comfortable, and others do it in the kitchen. It is much better to have a separate room, equipped for laundry work, that can be used summer and winter. A rear room close to the

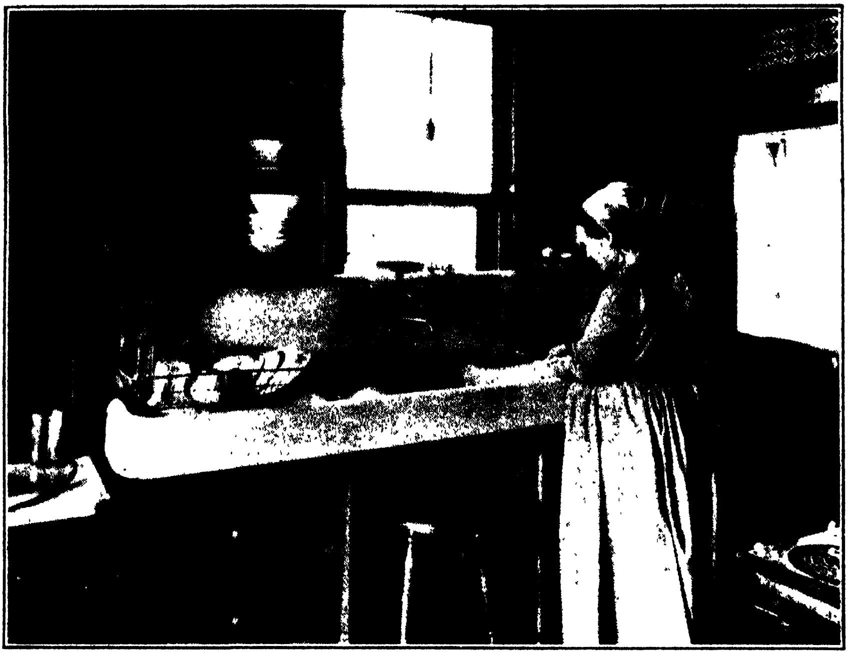

FIG. 177.—A sink set at the right height. This setting saves space and lightens work

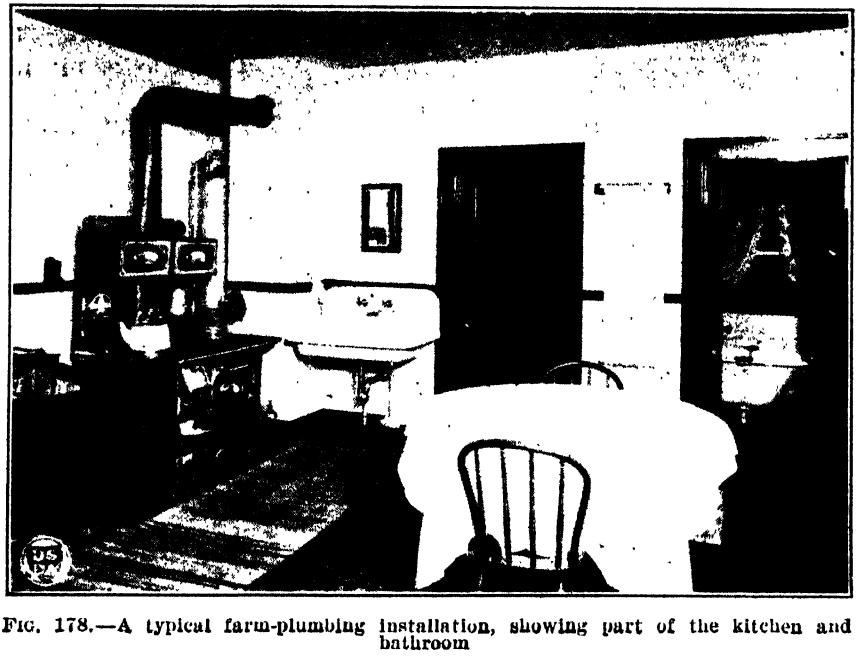

FIG. 178.—A typical farm-plumbing installation, showing part of the kitchen and bathroom

kitchen is desirable; a basement room is often utilized but is generally less convenient.

Considering the great benefits of a bathroom with the usual three plumbing fixtures—washstand, bathtub, and water closet—it is surprising how few farms are so provided. A farm-home survey in 1914–1916 by the United States Public Health Service in 14 average counties in 13 States shows there were only 808 water closets in 51,853 homes, and 16,733 of the homes were without a privy. Expressed in simpler form, only 1 home out of 64 had a water closet, and 1 home out of 3 had no privy.

A bathroom need not be large. It is not necessary that the fixtures be either large or costly or that they all be installed at one time. A small spare chamber or closet, a part of the old, little-used parlor or sitting room can often be made into a very useful, inviting bathroom and the fixtures may be added one by one. A typical farm-plumbing installation, with a glimpse of the bathroom, is shown in Figure 178.

### Bulletins on Plumbing

The farmer is unlikely to regret the day he took up the study of his plumbing problem. Few investments will yield surer, larger returns. To those interested the department will gladly send free a copy of Farmers' Bulletin No. 1426, "Farm Plumbing," and Farmers' Bulletin No. 1460, "Simple Plumbing Repairs." With the aid of such bulletins simple fixtures can be installed in keeping with the surroundings and the pocketbook. And it is well to remember that plumbing may be simple and yet be sanitary, that it may be sanitary and yet not unduly expensive, that it may be inexpensive yet durable—lifetime plumbing—provided it has proper usage and care. Those comtemplating such installations, however, should familiarize themselves with local and State plumbing regulations or laws. The services of a good, reliable plumber are recommended as being most likely to obtain a lawful, dependable job.

## POISONING of Livestock by Plants

Poisonous plants have long been recognized as the cause of serious losses of livestock to American farmers and stockmen. That many plants are poisonous has been known, of course, ever since the earliest historical times. These plants have been studied in detail, and there has resulted a great body of literature, published largely in European countries, especially in Germany and England. The plants in ancient times were studied with reference to their possible use in medicine, and were used also in the punishment of criminals, and sometimes in malicious poisoning. The recorded cases of the poisoning of domestic animals by plants in the eastern continents were, however, very few compared with the losses which have been suffered by American farmers and stockmen. That all kinds of livestock may suffer from these plants was known early in the history of America. For instance, it was recorded before the middle of the eighteenth century that our ordinary mountain laurel is poisonous to livestock.

Early in the history of the Department of Agriculture this topic came to the front. Probably the first recorded study was that of loco, which was discussed in 1873, before the establishment of the department. Since 1894 scientists of the department have studied this subject with the hope of reducing the losses and with material success.

### Regional Conditions Play Important Part

Though much work had been done on poisonous plants in other countries and though many American plants are either identical with those of foreign countries or closely related to them, the conditions under which domestic animals are cared for in America are so different that entire reliance can not be placed on preceding work. For example, the larkspurs, which cause so many deaths in our American cattle, are not recorded as making any trouble in other countries.

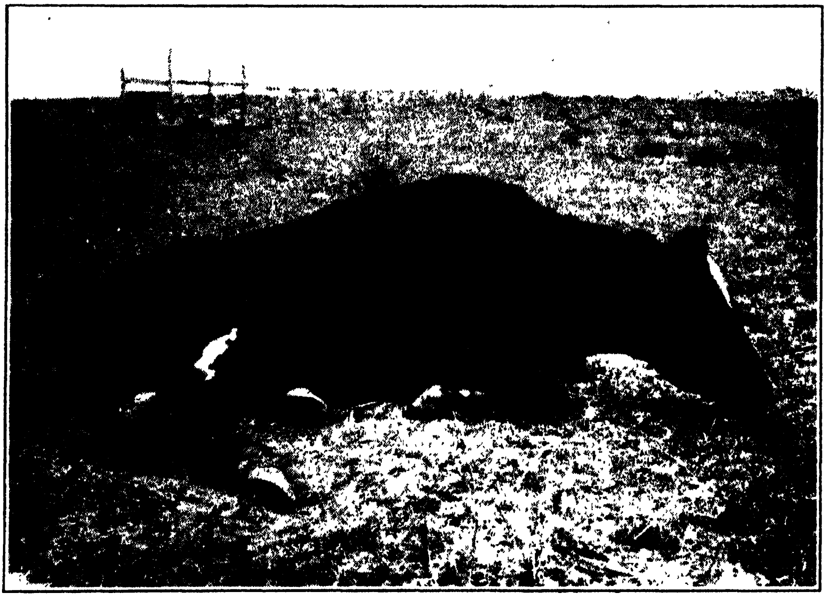

FIG. 179.—A locoed steer in the last stages of poisoning—too weak to stand

The losses in the eastern part of the United States are in many respects comparable with those in Europe, that is, comparatively few animals are lost. In the West, however, owing to the abundant growth of some poisonous plants, to climatic exigencies, and also to the manner in which range animals are handled, losses have been extremely heavy. The death of hundreds of sheep, or of 50 or more cattle at one time is not unusual, and sometimes, as in the case of loco poisoning, the horses in some localities have been almost wiped out.

In beginning the investigation it was essential to have as complete knowledge as possible of preceding studies of this subject. Fortunately, a card catalogue was commenced at the very beginning of the work in 1894, and has been kept up to the present time, so that now there are very nearly complete lists of the literature on the subject. Inasmuch as there was much doubt as to the plants which caused the losses in American pastures and ranges, extensive field investigations of poisoning cases were necessary. In this work a large part of the United States has been covered, the range region of the West with special thoroughness.

Early in the investigations, chemical and pharmacological work was begun for it was recognized that this was of fundamental importance for a complete understanding of the subject. Such studies have been continued up to the present time with important results.

Theoretically, many of the practical problems could be settled in the chemical laboratory. While this work is essential, it was evident that it would not take the place of field feeding experiments. Field conditions can not be reproduced in the laboratory, and from the beginning of the experimental work attempts were made to carry on feeding experiments in the localities where the plants were supposed to do harm, reproducing, so far as possible, the conditions under which animals under investigation had been kept.

### Experiments with Suspected Plants

With this in view feeding experiments in the field have been a continual feature of the investigations. One of the first subjects taken up was the study of loco through a series of feeding experiments in Montana. Later, a station for this purpose was established in Hugo, Colo., and used for four summers. Other feeding stations for the study of loco were established in Nebraska and in the Pike's Peak region of Colorado. Later a station was established in the mountains of Colorado with the main purpose of studying larkspur and lupine poisoning. Another station was conducted in the Yellowstone Valley of Montana, where the special subjects of study were loco, lupine, and death camas.

At the present time a well-equipped station is being used near Salina, in southern Utah. This was established with especial reference to studies of death-camas poisoning, oak poisoning, and sneezeweed poisoning. A large number of other subjects are also being taken up and carried to completion.

Besides these regular stations feeding experiments have been carried on in New Mexico on the rayless goldenrod and in Texas on shinnery oak. Another branch of the work has been plant surveys in many localities to determine the distribution of poisonous plants.

Some of the laboratory work has been handled at the field stations, but all that does not have to be done immediately is taken care of in the department laboratories at Washington, D. C. There the results of the first studies are carefully worked up, including microscopic examinations of tissues.

The object of all this work is to prove definitely whether a plant is or is not poisonous, and if it is poisonous to determine the symptoms which are produced, to find the conditions under which the poisoning takes place, whether a plant is more poisonous in one season than another, whether any particular part of the plant is especially poisonous, and then finally to find out what can be done to reduce the losses.

### Preventing Losses

It may be that a remedy can be found for the sick animals, as has been done in the case of loco and cocklebur. It may be that, by grazing only a part of the season, the trouble can be avoided. This is true of the low larkspur, for instance, which does no harm after about the first of July.

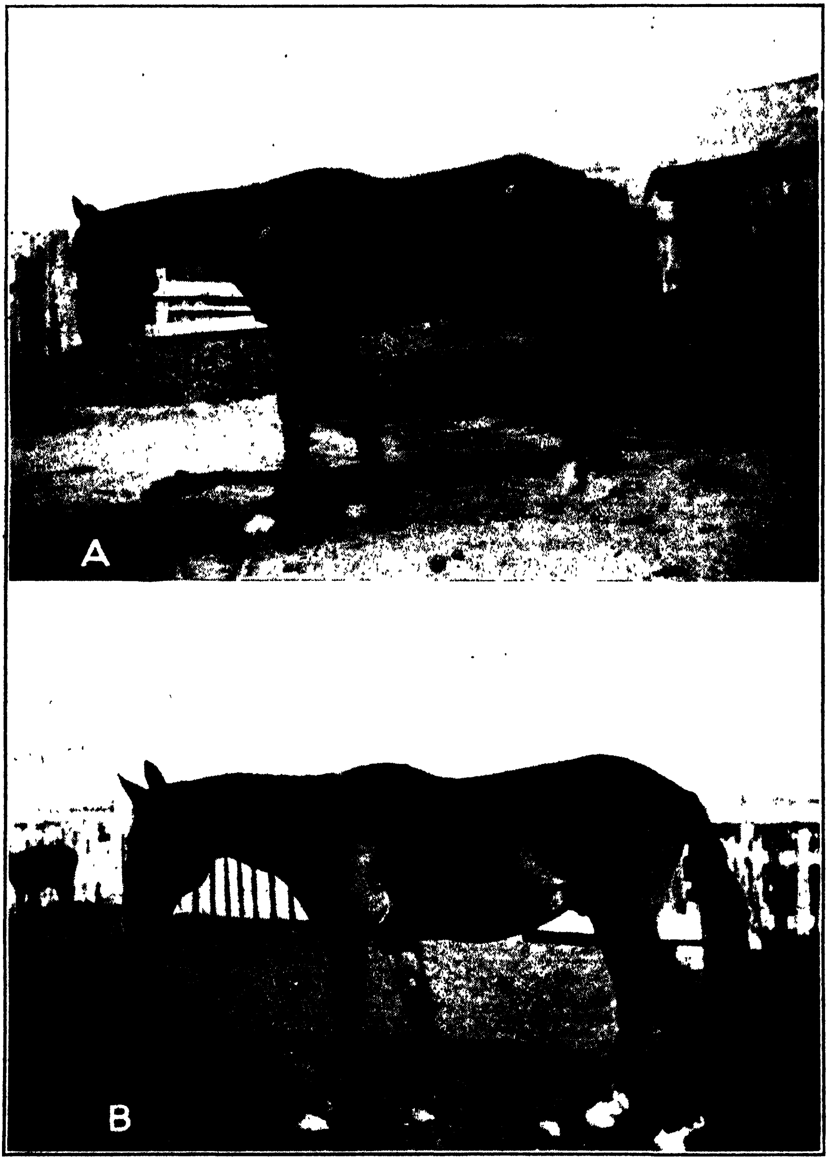

FIG. 180.—A, Horse in a badly locoed condition and weighing only 510 pounds. B, The same horse about three months later and following successful treatment of loco poisoning, formerly believed to be incurable. The horse gained 315 pounds in weight and was sold for a good price

This experimental work was begun in 1894 by the division of botany, which afterwards was included in the Bureau of Plant Industry. The work was carried on by the Bureau of Plant Industry until 1915. From 1915 to the present time the experimental work with animals and the general direction of the subject has been under the Bureau of Animal Industry.

Other agencies of the department, however, have contributed largely to this work. The botanical side of the subject is still cared for by the Bureau of Plant Industry. Such work includes a study of the distribution of the plants and the accurate determination of the species of the supposed poisonous plants, for it is essential to know definitely the species on which experiments are made. For example, there are many nonpoisonous, leguminous plants which so closely resemble the true loco plants that frequently they all are grouped together as loco plants. They must be definitely separated and such descriptions made as will be clear, not only to the experimenters but also, if possible, to stockmen.

The Forest Service has cooperated very largely in the work and has built for the purpose three of the field stations. Early in the work also there was cooperation with the Office of Experiment Stations, and there has been more or less cooperation with the State agricultural experiment stations.

The results of the work described are available to stockmen and to the public in more than a score of bulletins and circulars, most of which are free, others being obtainable for a few cents. Public addresses, articles in livestock journals, and, more lately, educational exhibits have also brought this important side of stock raising before stockmen of the country. Yet new problems are constantly arising and the end of the work is not in sight. But it is going forward gradually and systematically, each year adding more to current knowledge on stock-poisoning plants and bringing about a reduction of the losses.

C. DWIGHT MARSH.

## POPULATION Flow From Farms to Cities Declines

A steady stream of young men and women between the ages of 18 and 24 is moving from farm homes to cities. These young people are a surplus, and can not become farmers. A certain backflow of land-loving young people from city to farm also takes place.

Little is known of the normal size of this backflow. The retired-farmer movement is a regular current townward and cityward. A small retired city-man movement farmward may also be counted on. The special prosperity of farming will stimulate a movement of the less stable elements in cities to farms; and likewise any lack of prosperity of farming or unusual prosperity in cities will produce a movement cityward of the less stable elements of population on farms.

The movement of people from farms to cities and the reverse movement from cities to farms together constitute at any one time a fair index of the agricultural situation. The Department of Agriculture has made a survey of the gross movements of population to and from farms for the years 1920–1925, with the following results:

Information obtained from many sources indicates that during 1920 there was a net gain in total farm population of approximately 500,000 people over the preceding year, when (December 31, 1919), according to the census reports, there were 31,614,269 persons living on farms. The unusual prosperity attending the farm occupation during 1920 apparently restrained considerably the customary flow to cities of young people between the ages of 18 and 24, while the annual movement of prosperous retiring farmers to town was offset by the arrival of persons from cities drawn to farming by its prosperous condition. The excess of births over deaths on farms resulted in a natural increase.

The year 1921, marked by striking drops in prices for farm products, saw the beginnings of an unusual movement from farms to cities. While many persons who were tempted to leave farming stayed on farms, in the hope that soon the tide of prosperous times would turn and flow farmward, others who were close to the margin of livelihood were compelled to go where there was profitable employment. The result was that though there was a net increase of farm population, it was only 200,000, instead of 500,000 as during 1920.

In 1922 the department survey indicated that a net movement of a million persons from farms to cities had taken place, which entailed a net loss in the farm population of 460,000 persons.

In 1923 the loss to cities continued in full force, causing a net decline in the farm population equal to or possibly somewhat exceeding that of the previous year.

Another careful survey of the population situation in 1924 showed that while the forces at work on farms tending to drive people to cities were still operating in the lives of many—for over 2,000,000 persons moved to cities—other sets of forces were at work sending back from cities to farms a larger number than formerly, viz, 1,396,000 persons. The result of these movements was a net loss to the farm population of 182,000.

For 1925 a continued decrease in farm population was reported to the effect that 479,000 fewer people were on farms January 1, 1926, than January 1, 1925.

The Department of Agriculture estimates the farm population as of January 1, 1926, at 30,000,000 persons. These figures include all men, women, and children living on farms.

Each geographic division of the United States showed a net decrease in farm population during 1925, the lowest percentage of decrease being in the West South Central States, the highest being in the Mountain States.

The large gross movement from farms to cities, which has been at or slightly above the 2,000,000 mark a year since January 1, 1922, apparently still overbalances the gross movement from cities to farms, even when the increase on farms by births over deaths is added in.

C. J. GALPIN.

### POTASH Hunger in War Years Taught Lesson

Numerous field tests as well as the experience and observations of farmers have shown clearly the necessity for potash in crop production; not only in the effect it has on crop production but in many cases the influence it may have on crop quality. No more striking illustration of the importance of potash to agriculture, or one on a broader scale, will probably ever be in evidence than the situation created during the World War, owing to the acute shortage of potash brought on by war conditions.

Before the World War the United States was dependent on Germany for the potash it needed in agriculture and the industries. In 1913, for example, slightly more than 1,000,000 tons of potash salts were imported. This was equivalent to about 255,000 tons of actual potash. Of this huge order agriculture used from 90 to 95 per cent. During the war period the incoming supply of German potash was gradually cut down until in 1918 less than 300 tons were imported. In order to avert a potash famine, American resourcefulness and capital came to the rescue. As a result this country developed its potash resources to such an extent that the quantity of domestic potash produced gradually increased until in 1918 a production of about 55,000 tons of actual potash was reported. This was enough to take care of between 20 and 25 per cent of the pre-war potash requirements. With the end of the war and the importation of potash from both Germany and France, domestic production dropped off considerably, but in recent years has come up somewhat.

#### Shortage Acute in 1916 and 1917

In 1916 and 1917, the shortage of potash became so acute that crops suffered severely from a lack of it in fertilizer mixtures. This was more noticeable on lighter soils, and with crops which usually respond to potash, chiefly potatoes, sweet potatoes, tobacco, and cotton. Potash hunger was a term used to signify the condition resulting from lack of potash. On certain soils potash hunger showed itself much more severely than on others, even though in the same vicinity. In fact, some soils hardly gave evidence of the trouble. The potato crop was disturbed to a considerable extent and in sections where large fertilizer applications were customarily made the trouble was more serious. With very little, if any, potash in mixed fertilizers many growers still used a ton to the acre. So much nitrogen and phosphoric acid without potash in many cases cut the yield considerably. Experimental work showed that when enough potash was added to a nitrogen-phosphoric-acid mixture, the potato plants grew normally (fig. 181, A) and gave high yields. Without potash the potato plants presented a very dark-green foliage. The leaves were contracted, wrinkled, and drooped. Later on a bronzing effect appeared on the leaves. This was very prominent when looking over a large field of potatoes. Frequently the plants became so weakened that they actually drooped and finally collapsed owing to bacterial infection or other secondary causes (fig. 181, B). The final yields would be greatly reduced.

### Cotton-Rust Problems

In the case of cotton, the lack of potash was particularly marked on sandy soils and resulted in a condition known to cotton growers as cotton rust. This trouble became fairly general on coastal plain soils but was hardly observable on the Piedmont plateau soils, these soils being better supplied with potash than the sandy soils of the

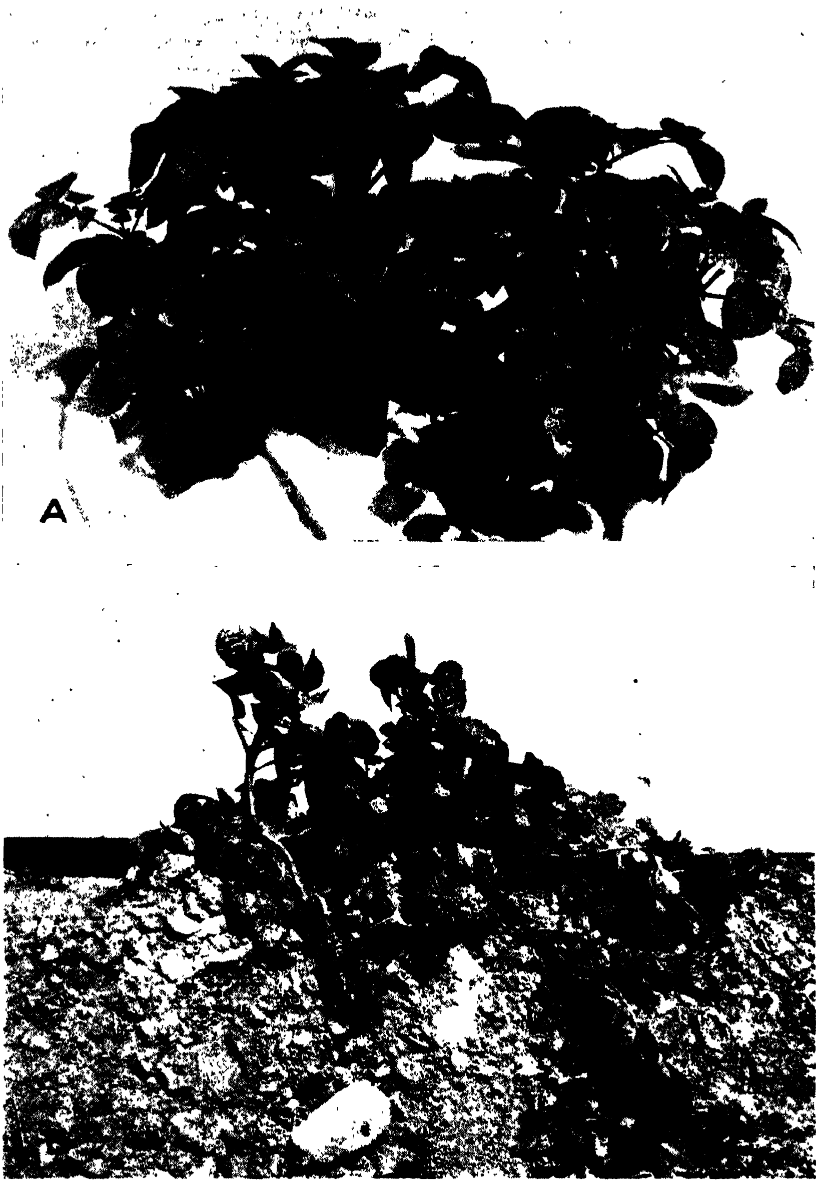

FIG. 181.—Potash and potatoes. A, Potato plant which received potash fertilizer. B, Potato plant suffering from lack of potash

coastal plain. In the case of the cotton plant the symptoms of potash hunger were just as marked as with the potato plant. When potash fertilizer mixtures were available the trouble was not in evidence. Other crops were affected in much the same way as potatoes and cotton.

Field tests carried on during the period when potash was lacking brought out some interesting facts. For one thing potash, regardless of the source, afforded direct relief and showed our agricultural dependence on potash salts. Even small quantities were helpful. Manure, which contains some potash, also was helpful in preventing potash hunger. It was found through such work that the high percentages of potash used in fertilizer mixtures before the war were not required for maximum crop production. Some soils could do with comparatively little potash. Owing to the lack of potash it was often found better to use less nitrogen and phosphoric acid. This was more marked on some soils than on others.

While the potash-hunger lesson was a severe one it was, nevertheless, instrumental in making the country more fully realize our dependence on foreign potash. The splendid efforts to utilize our domestic potash supplies and to develop our resources along this line were very gratifying and showed that we were able to become independent to an important extent. Coupled with the fact that less potash can be recommended on some crops than was being done before the war, this makes our knowledge of where we stand with respect to potash much clearer than before the World War.

B. E. Brown.
J. J. Skinner.

## POTASH Resources in United States Considerable

Following the discovery in Germany of great subterranean deposits of potash and the commercial exploitation of these deposits, the use of potash as a fertilizer became a matter of common practice in America. Prior to the World War practically all the potash used by American farmers came from Germany—an unsatisfactory state of affairs, because of the long haul from the German mine to the American farms, and because in case of war between Germany and any other large naval power oceanic shipments of potash would be interrupted and America would be deprived of her supplies of this important agricultural material.

This is what happened during the World War: German potash could no longer be imported, and the price of potash soared from 60 cents to over $6 per unit, showing how essential it is that America be rendered independent of foreign sources of potash.

Nation-wide surveys of American potash resources made by the department have revealed unlimited quantities of potash-bearing materials, including natural brines, kelp, potash minerals, and trade wastes. As they occur, unfortunately, they are not in a form suitable for fertilizers. Either they are too low in potash or else the potash which they contain is not water-soluble, or available for plant use. The problem, therefore, is to devise methods of treatment to render these potash materials suitable for the fertilizer manufacturer. Generally, it is not enough that the potash alone be extracted, but that other products of value be obtained to share the cost of the potash extraction. These are the problems which the department is now trying to solve in its potash investigations.

### Potash Raw Materials

The potash raw materials now regarded as important are the following: The giant kelps of the Pacific Ocean; the natural, desert brines of California; the potash minerals like alunite of Utah, leucite of Wyoming, shale of Georgia, feldspar of many States, and greensand of New Jersey, Delaware, and Maryland; and the industrial wastes such as cement dust, blast-furnace dust, beet-sugar molasses, and the waste waters from alcohol manufacture.

In these waste materials sufficient potash is lost each year, which if saved would supply almost all of that now required by the American farmers; whereas that contained in the natural deposits is sufficient to supply any quantity for an indefinite period. In the greensand deposit of New Jersey alone there is sufficient potash within reach of the steam shovel to last America for 1,000 years, based on the present rate of consumption. Greensand is America's largest and most favorable potash resource so far discovered.

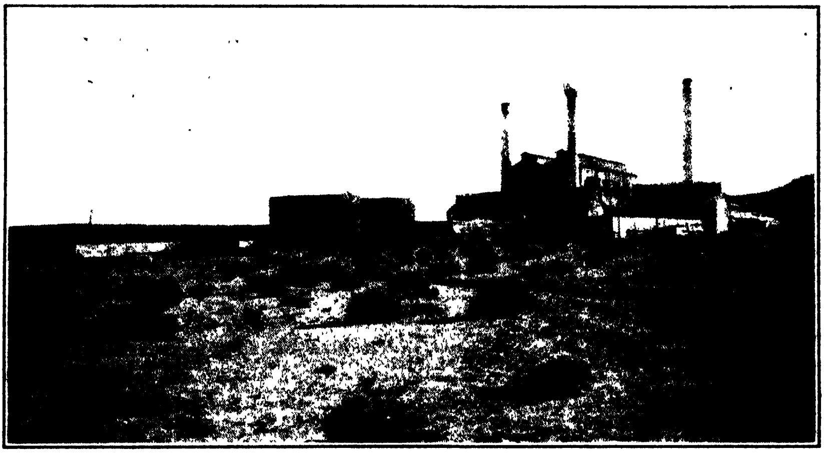

FIG. 182.—An American potash plant, Searles Lake, Calif. Here a high grade muriate of potash is produced from the salt water of Searles Lake

The American potash industry, as now established, produces about 12 per cent of the potash consumed in the United States, the other 88 per cent being imported from Europe. This domestic product is derived principally from Searles Lake, Calif., as a very pure and high-grade muriate of potash (fig. 182), and from the waste water of alcohol manufacture at Baltimore, Md., as a high-grade mixture of potash salts which may be described as "plant ash." Other smaller quantities of potash are produced from other sources. With the continued development of new processes and the establishment of new plants and the growth of those already established, there is every reason to believe that America in time will become quite independent of all foreign sources of potash. American potash should mean cheap potash, as it will be produced close to the point of consumption and it will be produced by processes yielding other valuable products to share its manufacturing costs.

J. W. TURRENTINE.

**POTATO Seed Certification** Although it is less than a decade and a half ago that a seed-potato certification inspection service was first offered to Wisconsin potato growers, the interest in the improvement of seed potatoes in seed-producing sections has been so great that such service is now offered by approximately half of the States. Since the institution of this service there has been a gradual raising of the standards of the seed stock and a greater uniformity in the certification rules under which the field inspectors operate. The current notion so characteristically held a few years ago, that the source of seed was of relatively little importance, has been largely abandoned.

In a rather recent paper by Moore,[16] of Michigan, there is embodied one of the best summaries yet presented on the relative merits of certified versus uncertified seed potatoes. These data included 15 reports from eight Canadian Provinces in which an 88-bushel per acre increase was noted in favor of certified seed. In 21 Delaware tests there was an increase of 83 bushels, and 87 reports from Pennsylvania indicated an average gain of 41 bushels. From 144 tests in Connecticut there was a 53-bushel increase, and from 31 tests in Louisiana the gain was 41 bushels; 8 tests in South Carolina resulted in 31 bushels increase, and 279 tests in Maine gave an average increase of 83 bushels; 9,740 tests in Indiana showed 44 bushels increase; 220 reports from Kentucky showed an average gain of 42 bushels; 68 tests in New York resulted in an average increase of 76 bushels, and 268 tests in Ohio gave a 48-bushel increase; 65 tests in New Jersey gave an average increase of 45 bushels; Missouri's 46 reports showed 43 bushels increase and Illinois's 15 tests averaged 47 bushels gain; Nebraska made 64 tests, which averaged 141 bushels increase, and Oregon's 3 reports resulted in 150 bushels increase; 2 reports from Montana showed an average gain of 219 bushels, and in Michigan 314 reports indicated a 73-bushel increase. In 327 tests of Michigan-grown seed in other States there was an average increase of 50 bushels per acre. The average total results in Canada and the United States, based on 11,627 reports, show an actual increase from certified over uncertified seed of 46.4 bushels per acre.

### Certified Seed Best

Assuming that the above data fairly reflect the actual average value of certified and uncertified seed, it is evident that as a rule the grower of potatoes, for either seed or table purposes, should use certified seed. The rather wide variations in the yield of certified and uncertified seed may be largely attributed to variations in the character of the uncertified seed used. The important thing to keep in mind, however, is that it pays to use certified seed potatoes. This is especially true with respect to the grower who is unable to make a summer inspection of fields with a view to direct purchase of his own seed supply.

---

[16] MOORE, H. C. EVIDENCE THAT CERTIFIED SEED IS IMPROVED SEED. Proc. Eleventh Ann. Meeting Potato Assoc. Am., p. 26–40, 1924.

Every purchaser of certified seed potatoes should carefully inspect the seed-certification tags affixed to each sack. If these tags are not attached to the sacks or leave doubt as to their genuineness, the stock should be questioned. It is suggested that a sample certification tag be requested from each certification official some time in advance of purchase of seed stock from any given State. This would permit of becoming familiar with the genuine tag.

William Stuart.

---

**POTATO Supply—Effect on Markets** It is commonly believed that a small crop of potatoes is usually worth more to the United States producers than a large crop. If the large crop of 425,000,000 bushels harvested in 1924 was valued at the reported average farm price for the season ($0.765), it would have been worth $325,000,000; whereas the small crop of 323,000,000 bushels harvested in 1925, if valued at that season's average price of $1.835, would have been worth $593,000,000. Thus 100,000,000 bushels less in 1925 than in 1924 made the crop worth $270,000,000 more. If producers had marketed as large a proportion of the large crop as they did of the small crop, the price would probably have been even lower than $0.765, and the difference in value correspondingly greater.

The reason for this contrary behavior of crop values is to be found in the habits of people with respect to the consumption of potatoes. Even when potatoes are high in price they are relatively cheap compared with other foods which make up the average person's diet, and there is no other food which will quite take the place of potatoes. For these reasons many people will pay a relatively high price for potatoes in years of short crops rather than to forego the enjoyment of their usual rations of this standard vegetable.

In years of large crops the situation is different. Though people are unwilling to decrease their consumption of potatoes when prices are high, they are likewise unwilling to increase their consumption when prices are low. There is no good substitute for potatoes in years of high prices, but according to our present standard of living neither are potatoes a good substitute for other foods when prices are low. Consequently the quantity of potatoes consumed tends to remain relatively constant, regardless of the price, which means that producers can obtain higher prices when the crop is short, but can not dispose of a large crop except at very low prices.

During the period since 1908 there has apparently been a change in the reaction of consumers to low potato prices. The reasons for this apparent change are probably to be found in the increased prosperity of wage earners since the war, which has enabled them to afford a more varied diet, and to rely less on potatoes as a staple food. It has also enabled them to save money in other ways than by living on the cheapest foods, which heretofore has stimulated the consumption of potatoes when prices were low. Another factor may be the marked increase of supplies of other vegetables often at prices sufficiently low to encourage variety in the bulky part of the diet.

The change in the supply-price relationship of potatoes is of considerable significance to potato growers. It means that the price of potatoes is now more sensitive to changes in supply, and that large crops such as were produced in 1922 and 1924 are almost certain to result in very low prices—lower than crops of the same size would have brought before the war, were it not for the increase in the general price level. The fact that a large crop is worth considerably less than a small crop, though costing more to produce, is a warning to potato growers against overplanting after a season of high prices, and overmarketing in a season of large crops.

E. M. DAGGIT.

## POTATO Yields Best From Good Seed

The significant advances which have been made in our knowledge of potato diseases during the past decade have served to emphasize more forcefully than ever before the tremendous importance of good seed potatoes. Discovery of the method of transmission of mosaic and other virus diseases of the potato from infected to healthy plants has, in a measure at least, revolutionized our preconceived notions regarding degeneration or the "running out" of varieties or strains of potatoes. The term degeneration as now used has an entirely different significance as it simply conveys the idea that the variety or strain so designated is affected with one or more of the virus diseases, such as mosaic, leaf roll, spindle tuber, yellow dwarf, or giant hill. Our old conception of degeneration or senility in plants has, therefore, been discarded. It is now believed that old-age debility does not normally occur in plants propagated vegetatively. In other words, if the potato is kept free from disease there is no reason why its propagation may not be continued indefinitely, provided it is grown under suitable environmental conditions.

The first requirement in good seed potatoes is that they be as free as possible from seed-borne diseases, at least of those which can not be destroyed by treatment in either the hot or cold corrosive sublimate or formaldehyde solutions. The stock must be true to name, free from varietal mixtures, and conform reasonably well to the type of variety. It must also possess good vigor and high productive capacity.

For many years efforts have been made to isolate superior yielding strains from our leading commercial varieties of potatoes. These efforts have been made in the belief that within any given variety bud variations or somatic changes may arise which may result in a more productive or vigorous strain of plants.

### Certified Seed Studied

With a view of determining to what extent such strains might occur in the hands of potato growers the department in 1919, in cooperation with the Wisconsin Agricultural Experiment Station, began a study of the comparative merits of different lots of certified seed potatoes for the purpose of determining the best strains of seed stock in five of the leading commercial varieties. These studies which were continued over a period of five years resulted in demonstrating rather convincingly in the first three seasons that there were outstanding differences in yield. These differences in some cases amounted to over 100 bushels per acre or nearly 100 per cent more than the lowest yielding strain. The increases were so striking as at once to arrest the attention of the growers with the result that the low-yielding strains were replaced by stock from the high-yielding ones.

The rather general acknowledgment of this principle at the present time makes possible the further improvement of seed stocks. In all such tests, however, careful observance must be made as to the presence of disease in the seed stock. There is little doubt that some of the variations in strain test yields have been largely due to the presence of disease in the seed stock used. One of the most carefully conducted strain or selection tests is that reported by Myers[17] in which a three-year average gain from selected over unselected stock of 48.1 bushels per acre was obtained.

Other examples of the value of selected seed over that of unselected or of certain strains over others might be cited, but it is felt that little would be gained by so doing.

The importance of good seed has been most strikingly demonstrated by the 300 and 400 bushel potato clubs of Pennsylvania and Michigan. In 1923, 54 Pennsylvania potato growers qualified for membership in the 400-bushel club. The average yield per acre of these 54 growers was 444 bushels, while 4 growers produced 500 or more bushels. The prize acre yielded 532 bushels. During the same season the potato growers of Pennsylvania averaged 105 bushels per acre or slightly less than one-third the average yield of the 54 growers and not quite one-fourth that of the prize acre.

### Good Seed Not Sole Factor

In the presentation of these data it is not proposed to imply that the use of good seed was solely responsible for these high yields. It is assumed, however, that all will agree that large yields can not be produced from poor seed. In other words, it will be admitted that good seed potatoes are a prerequisite to large yields. Good soil, an abundance of plant food, and excellent cultural care coupled with good seed furnish the conditions necessary to a large crop. The soil must be thoroughly prepared before planting; seed must be used liberally; preemergence tillage to prevent weed growth, and subsequent tillage of the growing crop must be performed with intelligence, and insect and fungous pests must be effectively controlled by timely applications of suitable insecticidal and fungicidal preparations if maximum yields are to be expected. The potato grower should always keep in mind the fact that it costs no more to plow or cultivate an acre of land for a good than a poor crop, and that the extra expense involved in better spraying for the control of insect and fungous pests is more than repaid in the extra bushels produced. The man who produces 400 bushels of potatoes per acre at a cost of $175 per acre will usually make a fair profit, whereas the one who produces 150 bushels at a cost of $100 per acre will usually lose money. In the one case the bushel cost is 43.75 cents, whereas in the other it is 66.67 cents.

[17] MYERS, C. H. HOW TO IMPROVE THE YIELD AND QUALITY OF SEED POTATOES BY SELECTION AND TO MAINTAIN SUCH IMPROVEMENT. Proc. Eleventh Ann. Meeting Potato Assoc. Am., p. 5–14. 1924.

The increasing demand for good seed furnishes ample evidence that the wide-awake potato grower recognizes the importance of planting good seed and is making every effort to procure it.

WILLIAM STUART.

## POULTRY Accreditation a Stabilizing Market Influence

The natural tendency toward specialization in the poultry industry and the recent rapid growth of the commercial hatchery business have made necessary improved conditions of sanitation in poultry plants and the production of breeding stock of sound, constitutional vigor. The accreditation of breeding flocks and hatcheries appears to be the only sure means of accomplishing these fundamental improvements.

FIG. 183.—A flock of standardbred Barred Plymouth Rocks. It has not only been rigidly culled on the basis of standardbred and egg-production qualities but each member of the flock will pass the rigid inspection system required in the accreditation of breeding flocks

The purposes of accreditation in general are to reduce losses in the poultry industry and to make the hatching and breeding business more efficient. The improvement begins with the quality of chicks hatched, which in turn means better-laying pullets and higher-quality eggs and poultry meat. The preamble to the uniform plan of accreditation which is being adopted by most of the States shows the fundamental aim of the work. It reads:

> Health is the foundation of successful husbandry since upon it depend successful production and reproduction. Constitutional vigor is the best insurance against ill health. Every poultryman and every hatchery man, therefore, is under obligation to maintain his laying and breeding stock in the best possible state of health by keeping only those birds which are constitutionally fit, and by keeping his premises in the best possible state of sanitation.

The accreditation program has to do primarily with the hatcheries and the breeding flocks supplying their eggs, and provides for the accreditation of breeding flocks, as well as of eggs and chicks from those flocks, and finally of the hatcheries themselves.

Among other things, accreditation rules provide for the handling of every bird in the breeding flock. This is analogous to inspection work for the larger domestic animals by official inspectors, except that in the case of poultry the inspection work is being done at the producing plant. In the second place, accreditation provides for thorough and rigid culling of the flocks for the elimination of diseased specimens as well as those birds that do not conform, within a reasonable degree, to certain standard and production requirements. All the inspectors by whom the culling is done must have had an approved course of training and they must be authorized by a responsible State agency.

### Supervision of Hatcheries

The hatcheries must be kept clean and sanitary at all times and their managers will be allowed to accept eggs for hatching purposes only from accredited flocks. Eggs received and chicks hatched are subject to inspection at any time and the management is required to keep a set of records which will give the inspectors fairly complete information concerning the operations of the hatchery. The eggs used for hatching must weigh at least 1⅞ ounces each besides being uniform in shape, color, and shell. Continuous selection of heavy eggs for hatching purposes will result in the development of strains that in turn lay good-sized eggs. Therefore the rigid enforcement of this one ruling probably will do more than any other one thing to reduce the high proportion of small eggs now going on the market.

FIG. 184.—An unculled flock that could not be used in producing hatching eggs for an accredited hatchery

Another important feature of accreditation work is that it officially recognizes those breeders and hatchery operators who take the initiative in eliminating bacillary white diarrhea from the breeding flocks. It is known that this disease takes a heavy toll not only in decreasing hatchability but in increasing chick mortality, and its elimination from the breeding flocks will undoubtedly cause a marked improvement in hatching results as well as in the vitality of chicks.

The whole problem is essentially one of education among breeders and hatchery operators, and accreditation is designed as an educational program, the benefits of which accrue to producers, distributors, and consumers. Moreover, the accreditation work as now carried on is largely self-supporting, the major costs being borne by the producers who derive the first benefits in reduced losses.

Improvement of the quality of the breeding stock lies at the very foundation of the poultry industry. A clean industry and wholesome products make satisfied consumers, less loss to distributors, and greater profits to producers.

M. A. JULL.[1]

## POULTRY Disease Prevention

The value of prevention as compared with cure is enormous in the case of poultry diseases. Much has been said about the diseases of poultry, but that subject is merely the negative side of one vastly more vital, namely, the health of poultry. The cost of poultry diseases far outweighs the price of prevention. The ravages of disease are always costly in life, longevity, vigor, and productivity, among poultry or other livestock.

The idea that disease is a necessary evil, to be grappled with when it comes, is no more true of poultry diseases than of those which affect man or other animals. The successful prevention of poultry diseases demands knowledge of their causes and effectual means of combating those causes. Diseases affecting poultry are infectious, nutritional, or environmental. Although these classes may often overlap, one or the other as a rule constitutes the real starting point of a given outbreak of disease. Space will permit only a brief discussion of the general means of disease prevention that apply to each of these divisions.

### Sanitation the First Rule

In preventing infectious disease, sanitation is the first rule. The bars are thus erected against infection. New stock is quarantined until all doubt as to its freedom from infection is removed. The flock is protected from polluted water, contaminated food, disease-disseminating birds or vermin; in fact, safeguarded from infection by every possible avenue.

Prevention of infection includes prevention of its spread. In the event that a disease makes its appearance in the flock, the affected birds should be promptly isolated until cured, or else disposed of. The latter course is frequently cheaper for the owner, and safer for the other birds of the flock. Along with isolation goes disinfection, in order that, with the removal of the infected bird, the owner may also destroy the infection which has been scattered by that bird. This disinfection process should be preceded by a rigorous campaign of cleaning, and may be governed in its details by the nature of the disease to be overcome.

---

[1] Doctor Jull, as chairman of the committee on accreditation and certification, appointed by the Poultry Science Association, has been working with the various States in the adoption of a uniform plan of accreditation and certification of poultry. About 34 States now have some form of accreditation-certification work in operation, and material progress has been made in the work.

In preventing the start or spread of poultry disease it has been found of value to shift the flock from one place to another, from year to year. This is accomplished either by the use of portable poultry houses or by providing runs on each side of the poultry house, either of which is successively used as a poultry run for one year, and alternately cultivated the following year. By this method of rotation the processes of nature have time to destroy many of the germs of disease or the eggs of parasites which otherwise may, with disastrous results, be picked up by the birds.

### Correct Feeding a Preventive

Nutritional diseases as a class are the diseases of captivity in the lower animals and poultry. Various forms of nutritional deficiency produce rather definite symptoms and lesions in birds. The nutritional disease manifestations include rickets, false roup, leg weakness, and polyneuritis (St. Vitus's dance), with more or less emaciation, anemia, and functional depression. The most common form of nutritional surfeit in poultry is gout, a disease caused by excessive protein feeding. Obesity, from excessively starchy rations, is also common in hens. The general principle of correct poultry feeding is to supply the flock with such essentials as whole and ground mixed cereals, animal protein in proper quantity, shell, grit, and abundant green feed or raw vegetables. Proved formulas issued by this department for the feeding of poultry afford adequate protection against the ordinary nutritional diseases.

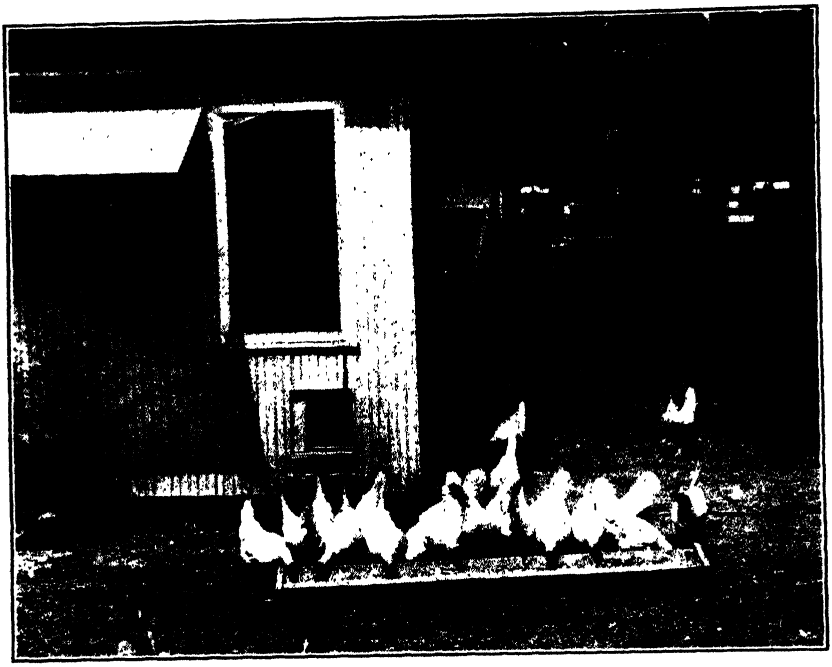

FIG. 185.—Proper selection of feeds and clean equipment will largely prevent the numerous nutritional diseases that affect domestic fowls

In close relation to nutritional diseases stands a group of conditions caused by the eating of spoiled feeds. It is needless to say that all feed supplied to poultry should be fresh, clean, and free of molds, decomposition, or contamination of any sort.

Environmental diseases in poultry are those which are traceable to the conditions under which the birds are kept. Bad ventilation and drafts or dampness in the poultry house are liable to produce definitely adverse consequences. Chilling or overheating, crowding, or lack of direct sunlight are frequently responsible for disease and death among poultry of any age, particularly young birds. Aside from the necessity of a correct type of poultry house, it is important to put the building on well-drained soil, situated so as to shelter the flock from the force of the prevailing storms.

In overcoming the disease tendency of birds caused by their habits of flocking together, it is advantageous to divide a large flock into smaller groups or units, with separate quarters. In that way the conditions of living are under better control. There is less crowding, less dissension in the flock and a more equal distribution of the daily ration allowance. Also, in smaller groups a possible outbreak of infectious disease is the more readily brought under control and relatively fewer birds are endangered.

Birds of widely varying ages should ordinarily not flock together. And finally, birds of different species should be kept from occupying common quarters, and, so far as is practicable, should be kept on separate ground.

HUBERT BUNYEA.

---

## POULTRY and Egg Production Estimates Now Made

Accurate current information concerning the production of poultry and eggs is greatly needed. The value of these products in 1925 is estimated to be somewhat over $1,000,000,000—about the same as that of all cattle.

Aside from decennial census figures, about the only information of a general nature available has been the receipts at the principal markets, the annual estimates of numbers of poultry on farms, and production of poultry and eggs as reported by the voluntary crop reporters of the Department of Agriculture. Annual reports from sample farms show the number of chicks hatched, and as this figure is related to numbers raised as reported by the decennial census, estimates of the annual production of poultry have been possible. The total production of eggs has been roughly approximated from the change in numbers of poultry during the year, on the fairly well proven assumption that conditions affecting increase or decrease in numbers tend to influence proportionately the production of eggs. The receipts of eggs at the principal markets appear to bear out this assumption.

Since September, 1924, the crop correspondents have been reporting the number of hens and pullets of laying age in their flocks and the number of eggs laid, on the first day of each month. These samples number about 20,000 and include both ordinary and commercial farm flocks, with a small proportion of town flocks. They should afford dependable information on the monthly trends of egg production. Owing to the time required for eggs to reach the market, these reported layings at the first of the month tend to synchronize with the mid-month supply of eggs at the central markets.

In constructing an index of layings per farm, difficulty has been had with the irregular reports for large commercial flocks which may be included one month and missing the next, thus introducing large variations into the averages and masking the actual trend.

### Index of Layings

The published index of layings in 1926, compared with 1925, is based upon relative layings per 100 hens. The changes from month to month in layings per hen are much more uniform and comparable than those per farm. The influences affecting layings per hen in a large number of sample flocks selected at random tend to affect in like proportion the average layings in all flocks. On the other hand, the index of layings per 100 hens is not satisfactory as an index of production, because the constant and material changes in number of birds in the laying flock are not considered. The present index is, therefore, a temporary expedient until something better can be developed.

By the exclusion of the returns of exceptional flocks, which is to be undertaken, satisfactory comparisons per farm will be possible on the basis of a large number of flocks of representative number and type. It should then be possible to estimate with reasonable assurance the monthly production of eggs per farm and hence approximate actual total production. This new basis will be established as soon as the complete figures for 1924 are available from the United States census.

An analysis of a portion of the material assembled through the monthly inquiry of 1924 and 1925 appears in the March, 1926, Supplement of Crops and Markets, and the monthly index of layings is published regularly in the same publication.

S. A. JONES.

---

## POULTRY Industry Expansion

A decided expansion in the poultry industry during the five-year period 1920–1925 is revealed by census figures. The increases are greatest in the States in which specialized poultry farms are most common and smallest in those States where production is obtained mainly from the farm flocks. Thus egg production in New Jersey increased more than 100 per cent in the five years; in Connecticut 82 per cent, in Washington nearly 100 per cent, and in California more than 50 per cent. On the other hand, egg production in Wisconsin increased only 14 per cent, in North Dakota less than 1 per cent, Iowa 11 per cent, Nebraska 12 per cent, Kansas 22 per cent, and Oklahoma 13 per cent—all of these being States in which the farm flock is predominant.

The increase in egg production has resulted from two different factors—a greater number of laying hens in the country and a greater production per hen. More farmers are interested in poultry, and there is a tendency toward greater specialization in this phase of the farm business and therefore toward larger flocks. Changes which have taken place in production methods have been largely responsible for the increased size of the producing units by reducing the labor in rearing young stock and in caring for the laying flocks. The development of mammoth incubators, by means of which larger flocks of chicks of the same age could be procured; the use of stove brooders, which made possible the brooding of the chicks in larger units; and newer information regarding feeding and management have been the principal factors working in this direction.

### Causes of Production Gain

Greater production per hen has resulted, in part, from better methods of feeding and management, but principally from the interest in and the development and wide use of bred-to-lay stock. It is logical to presume that the influence of this improved stock would be greater in the sections where specialized egg farming is prevalent than in sections where farm flocks are predominant. A rough measure of the improvement is available from the census figures.

TABLE 20.—*Eggs produced per chicken on farms, 1919 and 1924*[1]

| State | 1919 | 1924 | State | | 1924 |
|---|---|---|---|---|---|
| New Jersey | 62.9 | 80.0 | Nebraska | 50.8 | 48.7 |
| New Hampshire | 77.9 | 81.3 | Iowa | 52.2 | 53.0 |
| Connecticut | 67.9 | 83.1 | Kansas | 54.0 | 51.8 |
| Delaware | 49.4 | 56.2 | Oklahoma | 49.0 | 47.4 |
| Wisconsin | 55.6 | 55.7 | Washington | 72.2 | 93.6 |
| North Dakota | 57.7 | 48.6 | California | 73.8 | 91.9 |

[1] Number of eggs produced in 1919 divided by number of chickens on farms on Jan. 1, 1920, and similarly or 1924.

The results so obtained are inaccurate, but the contrast between the change in the rate of production for specialized States like Connecticut, Washington, New Jersey, and California, and the farm-flock States of Wisconsin, North Dakota, Nebraska, Iowa, Kansas, and Oklahoma is significant.

The development of the baby-chick industry has had a marked influence on the poultry industry. It is estimated that from 400,000,000 to 500,000,000 chicks are being produced annually in the commercial hatcheries for sale to poultrymen and farmers. The business is still growing rapidly. Many poultry keepers no longer hatch any chicks. The large hatcheries afford an excellent opportunity to improve the quality of the stock in the territory in which their chicks are sold and more and more attention is being given to this phase of the business, with good results.

### Stabilizing Egg Production

There is a definite trend toward more stable egg production throughout the year, though it has not become especially marked as yet in the entire egg crop of the country. The December receipts of eggs at the five principal markets increased from 2.3 per cent of the total for 1919 to 4 per cent of the total for 1925. The object is to increase production in the fall and early winter months when egg prices are at their highest, and success in this particular is generally accompanied by a lower production in the spring or summer, and amounts, therefore, to a shifting of a part of the normal spring production into the winter. Better laying stock, more favorable time of hatching the chicks in the spring, better methods of feeding and management and, particularly, the use of artificial light in the laying houses during the season of long nights to prolong the days for the hens are the factors which are making this development possible. Should this trend toward an evener egg production become still more pronounced, it may be expected to reduce the percentage of the annual egg crop which must be held in cold storage.

A trend toward better quality in the poultry products reaching the markets is evident. Replacement of mongrel by improved stock, better feeding and care of the poultry, a better handling of the products on their way to market, and better grading and standardization have resulted in a higher average of quality on the terminal markets.

Probably the most important trend in the marketing of poultry products is the increasing development of cooperative marketing. The eggs and poultry of large groups of producers are now being handled cooperatively on the Pacific coast, and, to an increasing extent, in the Middle Western States. Coincident with this development there has been a tendency for private poultry and egg-packing concerns to be absorbed into large organizations. At the same time the field of influence of the retail chain stores in the consuming markets as distributors of eggs has become broader and broader and with the development of volume sales these organizations are buying supplies to an increasing extent direct from large private or cooperative packers. This development is making competition sharper and the margin of profit smaller both for the wholesale receiver in the terminal markets and the packer and shipper in the country.

R. R. SLOCUM.

### PRESS Aid to Farmers Increasing

Few farmers to-day would willingly be without a farm paper. The present situation is a far cry from the early nineteenth century when the few farm papers that existed circulated mostly among scientists and among professional men who felt that agriculture was to be improved from the top, they obviously being the top. It is a far cry even from the middle of the nineteenth century, when in many a rural community the only paper taken was Horace Greeley's Weekly New York Tribune, a single copy of which was read aloud to a group at the post office on its arrival. Farmers to-day obtain from the agricultural press general farm news, reports of experiments and investigations, the experiences of other farmers, advice—much less than formerly—and general reading of an entertaining and stimulating sort.

The farm press serves, too, as it has served for a considerable time, as a forum for practicing farmers and as a spokesman for agriculture, impressing the needs of this industry upon the nation as a whole. Much of the agricultural progress so far made in the United States is due to the farm press. The Farm Journal was the pioneer among all publications in guaranteeing the advertising appearing in its columns, while it also was the originator of the movement for rural free delivery of mail. Orange Judd, the agricultural publisher, was responsible for the first agricultural experiment station in this country. Henry Wallace, editor of Wallace's Farmer, inaugurated the running of dairy, corn, and good roads trains. The Progressive Farmer was a leader in the exposure of patent medicine and stock-food frauds. E. T. Meredith, publisher of Successful Farming, was the first publisher to bring advertising experts into direct personal contact with farming and farmers in order to show farm purchasing power. J. H. Sanders, publisher of the Breeder's Gazette, was instrumental in the establishment of registries of draft and speed breeds of horses in the United States, while Farm, Stock and Home carried on a successful compaign to stamp out "stallion peddling." The abolition of bucket shops in Texas was the result largely of efforts of Farm and Ranch. The Capper Farm Press stimulated enormously the boys' and girls' agricultural club movement, being in parts of its territory a pioneer in this activity. Early promotion of the silo was carried on by the Ohio Farmer, whose "silo convention" in 1889 was a unique event.

### Agricultural Colleges Sponsored

The farm press has, further, sponsored agricultural colleges; meat inspection; the use of modern household devices in farm homes; police regulations regarding fertilizers, feedstuffs, and seeds; railroad rate regulation; rural credits; traveling libraries; cooperative marketing movements; and numerous other matters of special interest to the farmer.

Among striking developments in the agricultural press in recent years have been the increasing space devoted to matter written by farmers themselves, greater attention to agricultural organization, and emphasis on educational, recreational, and similar social features of rural life. The interest taken by women in agricultural journals has been a potent factor in the growth of the last-named class of material.

Another significant development has been the differentiation of the farm press. This is due both to the expansion of farming in general and to its increased complexity.

Farm papers to-day may be roughly divided into six groups, each of which might in turn be greatly subdivided:

1. The daily agricultural newspaper, published in a large city and dealing chiefly as a rule with livestock marketing conditions.
2. The agricultural paper issued as the weekly or semiweekly edition of a daily newspaper.
3. The general farm magazine, usually a monthly, intended to appeal to the general farmer in any part of the country.
4. The sectional farm paper, usually a weekly, designed for the farmer in a specific region or State, and consequently containing matter dealing with local farming conditions and problems.
5. The paper devoted to a special kind of farming, such, for example, as dairy farming, or a special agricultural movement, such as cooperation.
6. The breed paper, published for the specialist in a breed of livestock.

There are also numerous research journals published for scientific investigators in agriculture and related fields. Certain class and trade journals, such as those dealing with the farm-implement trade and with milling flour and grain, publish much agricultural material, although they are little read by farmers.

### General Newspapers More Interested

Increased attention to agriculture on the part of general newspapers is a notable recent development. One notes a general absence of the contempt for agriculture shown a few years ago by a large portion of the urban press, and finds instead a sympathetic interest. Agriculture has come to be recognized by editors as an essential element in national progress, and the farmer as a significant figure in national life. The emphasis laid on farming by the war stimulated the publication of agricultural matter in the urban press, although certain newspapers had been farsighted enough to give special attention to farming for many years before. To-day a large number of daily newspapers, including those published in the largest cities, employ agricultural editors and devote much space to news and feature articles about farming, either placing these in a special department or scattering them through the paper. Certain dailies with circulations as small as 5,000 have found it worth while to employ agricultural editors.

A marked advance has also been apparent in the attitude of the country weekly, the typical community newspaper, to farming. Whereas a few years ago it was exceptional to find a country paper devoting 10 per cent of its space to farm news, to-day many such papers find agricultural copy their most attractive field. A survey of reader interest made by Harry B. Potter in a typical Illinois community in 1925 showed 63 per cent of the readers interested in agricultural matter. This proportion was exceeded in the survey only in the case of certain strictly local news. A number of community newspapers have exerted marked influence upon the progress of agriculture and agricultural organization in their communities in a very short period.

### Farming Interpreted to Public

Attention to agriculture on the part of general newspapers, daily or weekly, possesses special importance to the farming industry. Not only is the farmer supplied with much interesting and useful material but farming is interpreted to the public as a whole. The effect is to promote that understanding of and that sympathy with agriculture which are essential to a permanent solution of its problems.

NELSON ANTRIM CRAWFORD.

## PRODUCTION and Consumption Surveys Useful

The increasing commercialization of agriculture makes it imperative for farmers to think of their production programs in terms of market demands; that is, the quantity and quality of products which can be sold to consumers at remunerative prices. Careful studies of the local production, distribution, and consumption of agricultural products are doing much to help focus attention on opportunities for profitable changes in the farming carried on in many areas. Such studies are particularly timely where the farmers adjacent to growing urban centers have failed to adjust their production to take advantage of changes in transportation rates and facilities.

In these studies the markets within the area are analyzed to determine the quality and quantity of products demanded, the source of supply, the prices paid, and the marketing methods followed. The markets outside the area for products that are grown or can be produced in excess of local requirements are studied in the same way. An inventory of agricultural production in the area is made, the most effective production methods and practices are studied, and an effort is made to determine the possibilities of profitable expansion in production. The primary objective is to obtain a sound economic basis for suggesting and recommending programs of production and marketing that will result in the improvement of agriculture in the area.

An example of studies of this type is the survey of the agriculture of the New Orleans trade area which was completed early in 1926. Studies in the cotton, rice, sugar-cane, truck, and dairy regions were made. In these regional studies attention was given to the factors involved in profitable production and to a comparison of practices of successful and unsuccessful farmers. The possibilities of profitable expansion of different enterprises were considered together with the limiting factors.

### Study in New Orleans

A detailed study was made of the consumption of farm products in New Orleans, of the sources of supply of these products, and of the marketing facilities available. Local producers supplied only a very small part even of products that were produced locally, owing partly to the short marketing season for local perishables and to the inadequate local marketing facilities.

Efforts have been inaugurated since the survey was completed to improve local marketing conditions and to provide local growers with better news service and marketing machinery for handling the growing truck industry in the fertile bottom lands of the lower Mississippi.

Facts were assembled showing the trends of acreage and yields in regions competing with this area. Shipments to markets during the local shipping season were analyzed to show the competing shipping districts. Facts available on how Louisiana and Mississippi growers were meeting market preferences and requirements as to grading and standardizing, preparation for market, packaging, and shipping were assembled in the report of the survey. Data on usual values per acre and usual expenses of producing were obtained and presented to furnish growers a business basis for sound farm planning.

Milk prices in New Orleans were found to be low in comparison with other southern cities. Dairying has not been profitable and distributers have had to draw part of their supplies of whole milk for New Orleans from northern producing States. A study of producing conditions in the area supplying New Orleans with whole milk indicated returns for whole milk at certain times considerably less than the butterfat value on the local price basis. It was evident that there was room for a great deal of improvement in production practices, but the poor soil conditions and unfavorable climate for growing and curing forage crops are disadvantages which are not easily overcome.

### Business Organizations Cooperate

The survey was instigated by the agricultural bureau of the Association of Commerce of New Orleans. Cooperation of Louisiana State University and Mississippi Agricultural and Mechanical College was enlisted, and through these agencies the assistance of Federal department technical workers was obtained. The Shreveport (La.) Chamber of Commerce and many other public agencies, including railroads and the city of New Orleans, made material contributions. Reports covering various phases of this survey have been issued by Louisiana State University and Mississippi Agricultural and Mechanical College. A tentative summary was published by the New Orleans Association of Commerce.

An experienced marketing expert has recently been obtained by the New Orleans Association of Commerce to work with State and Federal agencies to bring about improvements, the need of which was indicated by the survey.

Another survey, along the same general lines, of the agriculture of Idaho is being carried on. The University of Idaho Agricultural Experiment Station and extension service and the State department of agriculture initiated the survey and staffs of these public agencies and Federal department workers in that State are studying the various situations. Eight of the county agents are actively cooperating in regional surveys to obtain basis for regional and county programs. A conference of university, State, and Federal department workers met with farm and business leaders and considered the tentative survey reports after the work had been under way six months. Regional and county economic conferences of a similar nature are to be held where the facts gathered on State and national situations will be presented to local farmers and business men and adapted to local conditions.

Idaho has no large consuming centers and is obliged to seek distant markets for most of its products. The distance from market necessitates production of commodities with high values relative to transportation expenses. With its large irrigated sections Idaho obtains high yields of potatoes, wheat, small seeds, and feed and forage crops. Dairying has expanded at a high rate in the past six years. The markets for Idaho products were given a great deal of study as were the trends of production in areas competing with Idaho.

B. H. Critchfield.

---

**PROTEINS in Feedstuffs Vary Much** The value of feeds and feeding stuffs depends largely on the protein they contain. In the market, feeds are frequently bought and sold on the basis of their protein content. Recent research has shown that the quality of the protein present in the feed is quite as important as the quantity. Of two sacks of feed, one containing 20 per cent of protein and the other 45 per cent, the feed containing 20 per cent may be an ideal ration, whereas the one containing 45 per cent may be almost worthless. It all depends on the quality of the protein.

When protein is digested in the alimentary tract it is converted into some 18 or 20 substances called amino acids. It is these amino acids, not the intact protein, that are ultimately used by the animal for the formation of tissue. Certain of these amino acids are essential for the normal nutrition of animals, and not all proteins contain all of them. A protein, therefore, that is lacking in one of the nutritionally essential amino acids is greatly limited in its nutritive value. An animal depending entirely on such a deficient protein for its nitrogenous needs will not grow and develop normally, and will frequently die in a short time. Examples of such proteins are zein, one of the proteins of corn, and gliadin, one of the chief proteins of wheat, also the proteins of common navy beans, Lima beans, lentils, and cowpeas.

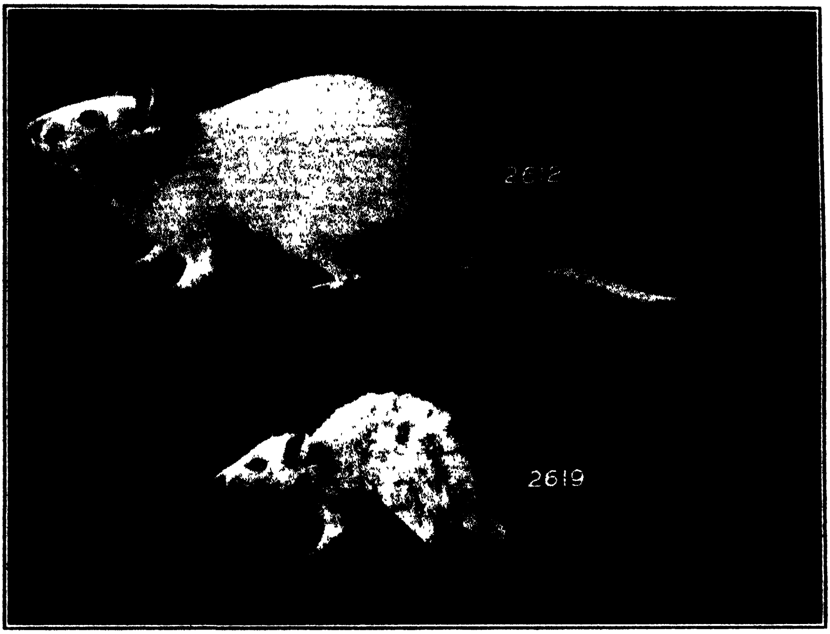

FIG. 186.—The effect on growth of the quality of proteins. A represents rat 2612; B, rat 2619. Both rats were practically the same age, and had been fed for 100 days rations the same in all respects with the exception that the ration given to rat 2612 contained protein of good quality, while rat 2619 received protein of poor quality. The protein of poor quality was deficient in the nutritionally essential amino acid cystin The difference in the nutritive appearance of the two rats is striking. The one weighed 326 grams, the other 54 grams

Figure 186 shows the contrast in the growth and appearance of two rats of the same age. One received a ration containing protein of good quality, the other, a ration the protein of which was deficient in the amino acid cystine.

### Proteins in Cereals

Cereals constitute the most extensively used class of feeding stuffs. Nearly all of the cereals contain proteins which are soluble in alcohol. These proteins are called "prolamins." Gliadin from wheat and zein from corn are the best-known examples. As a group, these proteins are of poor nutritive quality, because they are deficient in certain amino acids essential to growth. On the other hand, the proteins of most oil seeds, such as flaxseed, hempseed, sunflower seed, cottonseed, peanuts, and soy beans, are very satisfactory sources of these essential amino acids. In compounding rations with the idea of obtaining a mixture of proteins that will contain the amino acids in satisfactory proportions, it is well to remember that very little is to be gained, from the protein standpoint, by mixing different feeding stuffs of the cereal class, on account of the similarity of their protein deficiencies. Adding some of the seeds which contain in abundance the amino acids that are deficient in the cereals, however, gives a mixture that will be nutritively satisfactory from the protein standpoint.

### Qualities of Bran Proteins

The wheat kernel consists of three parts—the endosperm, the embryo, and the seed coats or bran. The endosperm is the part of the wheat which is used for the manufacture of white flour. The proteins of the endosperm and embryo have been extensively studied by various investigators, but little has been known regarding the properties of the bran proteins. Approximately 22 per cent of the protein of the wheat kernel is contained in the bran—a quantity that represents a vast amount of protein in the annual wheat crop. In view of the importance of wheat bran as a source of protein, investigations were undertaken in the Bureau of Chemistry to obtain information regarding the chemical and nutritive properties of the bran proteins.

Practical feeders of farm animals have long known that bran is highly nutritive. It is generally conceded that it is fairly well digested by ruminants, which have digestive tracts adapted for the accommodation of coarse, bulky material, such as hay and fodder. As for its food value for animals other than ruminants, particularly for man, many conflicting views have been recorded, ranging from statements that it is wholly without food value, except for roughage or bulk, to statements that it is digested by man as well as by domestic animals.

The investigations conducted in the Bureau of Chemistry showed that the proteins of bran differ essentially from the corresponding proteins of the endosperm and embryo. The bran proteins, in contrast to the endosperm proteins, are high in their content of those amino acids known to be nutritionally essential. From these results it could be predicted with a fair degree of assurance that in actual feeding experiments the bran proteins would have a relatively high nutritive value.

Feeding experiments with albino rats (fig. 187) have yielded results which confirm the predictions based on the results of the chemical studies of the bran proteins. They have also demonstrated that the ability to digest and assimilate the proteins when supplied in crude bran is not limited to ruminants, as is frequently asserted.

A large number of young albino rats soon after being weaned were fed a ration in which the protein was supplied solely by wheat bran.

They grew at an excellent rate during the first 15 or 16 weeks, the period of the most rapid development of the rat, covering life up to sexual maturity. During this period of adolescent growth, the experimental rats manifested every indication of well being and of a state of satisfactory nutrition. (Fig. 188.) With the coarse, bulky bran ration no instance of digestive disturbance was observed.

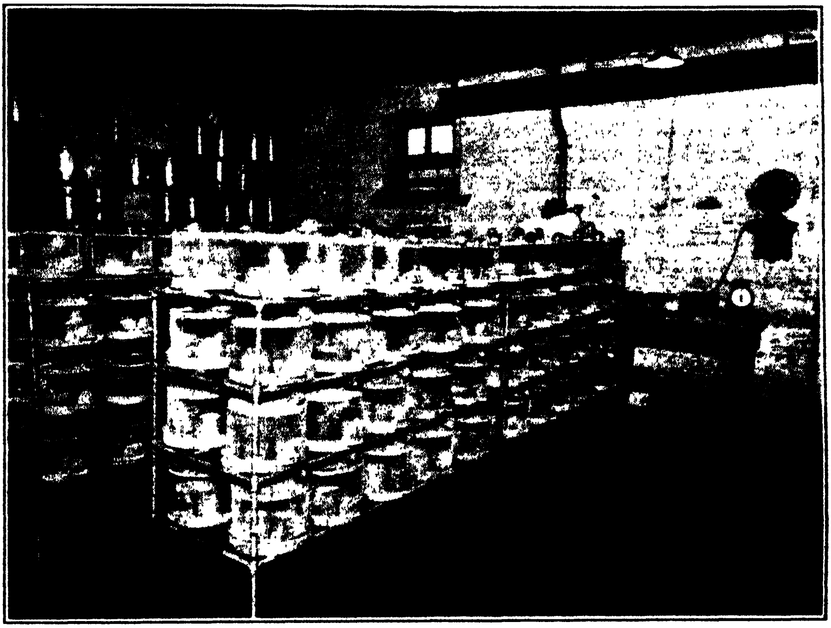

FIG. 187.—Arrangement of cages for rats used in experimental feeding experiments. Each cage contains one rat. The animals are fed diets prepared with great care and which are known to be nutritionally adequate with respect to all of the known dietary factors with the exception of the particular one that is being tested. Records are kept of the weight of the food eaten daily by each rat. The animals are weighed twice weekly. All data are carefully recorded for each rat, from which the rate of growth and other criteria used for estimating the nutritive value of proteins can be studied

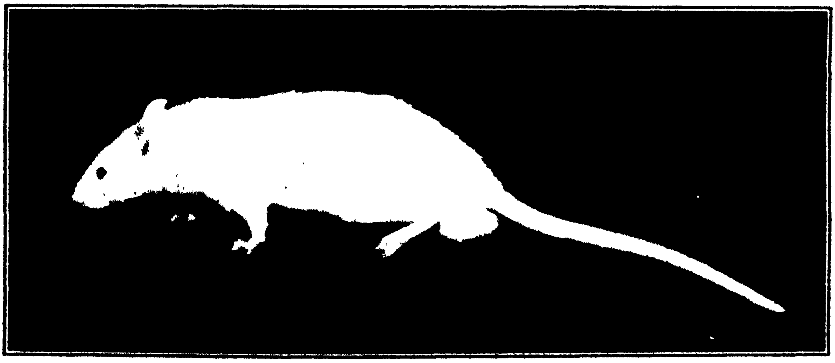

FIG. 188.—Rat 2375 received since the time it was weaned, a diet containing no protein other than that furnished by commercial wheat bran. At the time this picture was taken the rat had been on the bran ration for 88 days. During this period it had more than tripled its weight at the start of the feeding test. Note the sleek coat of fur and the animal's well-nourished appearance

The rate of growth in itself, however, does not constitute a sufficiently strong basis for the evaluation of the nutritive efficiency of proteins. We must also know how much of the protein is eaten, as no matter how excellent the quality of a protein may be, unless enough of it is eaten the animal can not grow satisfactorily.

A method commonly used in nutritional investigations to express the relative efficiency of a protein for promoting growth is to find out how many pounds or grams an animal will gain in weight for every pound or gram of protein eaten. In these experiments accurate record was kept of the food intake of the rats. It was found that during the first six weeks of the feeding tests the animal had gained an average of 1.83 grams for every gram of crude protein consumed as calculated from their food intake. Several gained over 2 grams. These figures compare favorably with those similarly obtained with other proteins known to have high food value.

### Efficiency of Bran Protein for Growth

The efficiency of the bran proteins for growth as represented by these figures is from two to three times as high as that which has been obtained in similar experiments in which the proteins were supplied solely by the patent wheat flour of commerce.

After the period of rapid growth on the bran diet the animals have not shown the growth and development that is normal for mature animals. They have done but little better than maintain their weight. Several have lived, however, for a period approximating two years, about two-thirds of the normal span of a rat's life, on the ration containing no protein other than that supplied by the bran, and are still in fair condition. Rats receiving the bran diet have produced offspring, but have had little success in rearing them. Fecundity was low.

That the unsatisfactory reproduction and rearing of young may be attributed to the same dietary deficiencies as are accountable for the unsatisfactory rate of growth of rats on the bran diet after the first 14 or 15 weeks is an interesting possibility. The high efficiency of the bran ration for promoting early growth, and the unsatisfactory results obtained with it in connection with subsequent growth and reproduction, constitute a striking example of how the nutritional requirements of an animal may vary with the changing stages of its development.

Of course, the nutritive shortcomings of the bran ration used for the mature animals should not necessarily be ascribed to the quality of the bran proteins. They may be due to a lack of some nonprotein dietary factor or to some property of the bran which has not yet been discovered. A ration that supplies all of the nutritive needs of a young, growing animal may not be adequate to meet the requirements of that same animal after it has reached maturity.

It appears that wheat bran contains in abundance the factors that meet an animal's nutritional requirements during the period of its most active growth, but is rather deficient in some other factor or factors which are required for the mature animal's normal development. The proteins of wheat bran, when considered from the standpoint of both quantity and quality, should give this feeding stuff an important place in the ration of young growing animals. Its high percentages of certain nutritionally essential amino acids that are lacking in several cereals, including corn, recommend bran as an excellent supplement to those feeding stuffs which contain proteins of poorer quality.

D. Breese Jones.

## PROVING Dairy Sires Through Daughters' Records Worth While

The cow-testing association as ordinarily conducted in this country is an organization of about 26 dairy farmers who employ a man to weigh and test the milk and to weigh the feed of each cow one day each month. From the daily records the tester computes the monthly and yearly records of every cow in each member's herd.

For more than 20 years such cow-testing association records have been used in this country to test dairy cows. They are now also being used to test dairy bulls, because production and income records of the daughters of the dairy bull, when compared with the records of their dams, test the bull as certainly as these records of production test the dairy cows.

Two bulls, born the same year in the same State, each had five daughters that completed yearly records in 1925. It was merely a coincidence that in each case the five daughters averaged exactly 350 pounds of butterfat a year when all records were figured to maturity. So far, it would appear that these two bulls were of about equal merit.

The next step in the investigation, however, showed a great difference. In the case of bull No. 1 the five dams had an average butterfat production of 381 pounds, whereas in the case of bull No. 2 the five dams had an average butterfat production of 178 pounds. Bull No. 1 lowered the production of his daughters 8.3 per cent, whereas bull No. 2 raised the production of his daughters 96.6 per cent.

Bull No. 1 was at the head of a herd better than himself. Perhaps he might have improved a poorer herd. Bull No. 2 was at the head of a herd of low-producing dairy cows. He rendered great service by almost doubling the average yearly butterfat production. Doubtless he would have improved a much better herd. It is not the records of the dams alone or the records of the daughters alone, but the records of daughters in comparison with those of their dams that make the story complete and valuable.

### Sires That Win

Cow-testing records show that some purebred sires are fit to head high-producing dairy herds, that some are able to improve the average herd, and that some should never be placed at the head of any herd of dairy cows.

In a study of the records of the daughters of 100 purebred bulls in cow-testing association herds, it was found that approximately one-third of the bulls lowered production, that one-third raised production very slowly, and that the big production gains came from the other third.

To prevent inbreeding, almost all dairy bulls, regardless of their breeding, are sent to the butcher after they have been in the herd two years. This practice is robbing the dairy industry of tens of thousands of good bulls every year.

According to the 1920 census, only one-fourth of our dairy bulls were purebred. As has already been stated, cow-testing figures indicate that only about two-thirds of these are increasing production in our dairy herds. Correspondence with the owners of these herds shows that only about one-fifth of the high-class bulls are kept until the daughters prove their worth.

No one will complain because scrub and grade bulls are sent to the block at an early age, or because the purebred bulls that lower production are doomed to an early death. It is better that these bulls should go than stay, because from them no improvement can be expected.

It is unfortunate, however, that the good bulls, those that are capable of making great improvement in dairy herds, should be sent to the butcher along with the mediocre bulls and the scrubs.

### One Every Eight Minutes

A careful estimate has shown that really high-class bulls are going to the butcher at the rate of about one every eight minutes from daylight to dark, every day in the year. How to stop this great slaughter and keep these bulls for a lifetime of service is one of the greatest problems in dairying to-day.

The cow-testing records are proving hundreds of dairy bulls, but very few of these are still alive when the results are available. As it is not worth while to prove dead bulls, some system of exchange should be started at once in order that well-bred bulls may be kept until the daughters have demonstrated their sire's true value. Eventually thousands of living bulls will be proved through the records of their daughters. From the extensive use of such purebred dairy sires a very great improvement in our dairy herds may be expected.

J. C. McDowell.

## PUREBRED Livestock Markets

Millions of dollars each year are expended for breeding stock to improve the herds and flocks throughout the Nation. Records show that during the past century prices of purebred livestock have soared to remarkable heights in some years and then in a short time have fallen to discouragingly low levels. The only market guide available before 1922 to either producer or buyer was the publication of a comparatively few auction-sale prices in breed and agricultural publications.

That such reports should fail to serve as a real index of the market for purebreds was inevitable because only a part of the auction sale transfers were published. Furthermore, auction sales have always represented only a very small percentage of the number of animals that changed hands, as shown by the transfers of ownership appearing on the books of the breed record associations. Hence the bulk of sales, which furnish the only legitimate basis for market quotations, were disposed of at private treaty and such sales were almost never published. Under such circumstances it was impossible for either the present or the prospective breeder to gain even a fair idea of the real level of prices.

Not infrequently a prospective buyer would attend an auction sale and see an animal bring $700 which, so far as anyone could discover, represented the same type, color, breeding, and degree of excellence as one which his neighbor was offering at private treaty for $75. This caused much confusion, uncertainty, and sometimes loss, and worked to the decided detriment of the purebred industry generally, and especially in times of severe depression.

### Purebred Livestock Price Reports

In view of this situation, the department began to gather and publish purebred livestock sale prices. The purpose of these reports is to give the prospective buyer, as well as the breeders who have animals for sale, an opportunity to know the average selling prices of a large percentage of the purebred animals sold throughout the country. To make the report truly representative the department gathers, compiles, and publishes prices realized at both auction and private sales. The data published are received direct from thousands of breeders scattered throughout the country.

At the beginning of each calendar year a questionnaire is sent to every breeder who during the year has registered five or more animals with his breed record association. On January 1, 1927, 45,000 breeders of cattle, hogs, and sheep were thus requested to report.

When the questionnaires are returned by the breeders the data contained therein are tabulated and averaged. The final report will show top and average prices for all of the important breeds segregated according to sex and age; also according to whether it was sold at auction or private sale.

With reliable data of this sort available it is possible for anyone to keep his finger on the pulse of the purebred industry and quickly discover any changes in trend of production, demand, or prices.

L. B. Burk.

## PYRETHRUM Powder as Insecticide

The use of insecticides, particularly arsenical preparations, for destroying potato bugs, grasshoppers, and fruit and cotton insects is well known, but few realize the enormous amount of money spent annually in the United States for materials used in the fight against household insects. One of the oldest and most extensively employed of these insecticides is insect (pyrethrum) powder, which consists of the finely powdered dried flower heads of certain species of Pyrethrum. We depend almost entirely for our supply of these flowers on foreign countries. Previous to 1914 most of the flowers came from Dalmatia, but during the World War this supply was cut off and Japan became our principal source of supply. Large quantities of Dalmatian flowers are again being imported, however, through the Italian port Trieste.

In 1920, the year of the maximum importation of insect flowers, nearly 7,000,000 pounds, valued at over $2,600,000, was brought in. During 1925 slightly over 3,800,000 pounds, valued at more than $1,000,000, was imported. The importation in 1926 will undoubtedly exceed that of 1920; during the first six months nearly 5,000,000 pounds, valued at about $700,000, was brought in. The price of these flowers has varied greatly. In March, 1920, it reached $1 a pound, while in December, 1926, the wholesale quotations for insect powder were from 23 to 27 cents a pound and the import prices for the flowers decidedly lower. The present low prices may be accounted for by the fact that the 1925 crop, both in Japan and in Dalmatia, was very large.

The dried whole Pyrethrum flowers are shipped into the United States in bales and ground into insect powder in American mills. The powder has frequently been subjected to adulteration. The most common adulterants have been powdered Pyrethrum stems and powdered flowers of the oxeye daisy, which resembles closely the species of Pyrethrum flowers from which most of the insect powder is produced. Owing largely to the activities of the Insecticide and Fungicide Board of the United States Department of Agriculture, both of these forms of adulteration are practiced very much less extensively than they formerly were. This accounts in large measure for the great increase in the use of this product during the past 10 years.

Notwithstanding the fact that insect powder has been used for more than 100 years and has engaged the attention of chemists for more than 50 years, it was not until 1924 that the exact chemical composition of the constituents which are toxic to insects was announced. In 1924 two Swiss chemists reported that they had found that Pyrethrum flowers contain two highly toxic compounds. As these compounds are exceedingly complex in their structure and constitute only about 0.2 to 0.3 per cent of the flowers, it is not surprising that scientists were baffled for a long time. Efforts to synthesize these compounds have been unsuccessful.

Experiments conducted in the Department of Agriculture and reported in 1920 showed that certain organic solvents, including the lighter fraction of petroleum, completely extract the active principles of Pyrethrum flowers. Since that time there have been placed on the market many commercial preparations consisting essentially of light mineral oil, of the nature of kerosene, containing the active principles of Pyrethrum flowers. The sale of these products, used as sprays in the control of insects, particularly house flies, has reached extensive proportions, amounting, it is estimated, to several million dollars annually.

The Department of Agriculture is frequently asked why the United States does not grow its own Pyrethrum flowers, as the plant which bears these flowers is closely related to our common oxeye daisy. In former years insect flowers were produced commercially in California, and field experiments are now being made by the department to determine whether insect flowers of the required potency can be grown elsewhere in the United States at a cost which would permit their cultivation on a commercial scale.

C. C. McDONNELL.

---

**QUETTA Nectarine—A New Fruit of Indian Origin** The nectarine has very aptly been called a peach with a smooth skin. Like the peach, it is a child of the Orient where, in some parts at least, it is more generally cultivated and used than it is in this country.

The Quetta nectarine (fig. 189) is one of the many plant immigrants brought to this country as a result of a systematic world search for new and promising crops. Quetta is one of the outposts of the British Empire located in Baluchistan, northwestern India. Through the courtesy of an English army officer, the Office of Foreign Plant Introduction was enabled to obtain a number of fruit seeds from that country. Among the lot were a few nectarine seeds. "I am sending you these seeds," wrote the officer, "because it is about all I can find here. I am sure you must have better nectarines. The only point in their favor is that they stand cold and the trees do not get much water, as no rain falls here from April to December."

The records show that summer temperatures in the valley where Quetta is located frequently reach 100° F. in the shade, while in the winter they drop below zero, with severe frosts continuing for weeks at a time. The valley has an elevation of about 5,500 feet with an annual rainfall of about 10 inches. The seeds, which came as a small parcel post shipment, were planted at the Chico, Calif., plant introduction garden, and in due course a few small trees were produced from them. A few years later the seedlings bore fruit, some poor, some fair, and one very good. As fruits like the nectarine, peach, and plum do not come true or reproduce their kind from seed, it was necessary to propagate the good nectarine by budding. Buds from the selected tree were worked or made to grow on a Chinese wild peach stock known to be quite hardy, and thus good, strong, vigorous trees were obtained. In accordance with the usual practice, this new fruit was given seed and plant introduction (SPI) No. 34685. Later it came to be called the Quetta nectarine after the country of its origin.

### Characters of Tree and Fruit

The Quetta nectarine, when grown on the Chinese wild peach stock, is a vigorous tree with compact head. It is a comparatively early bloomer and makes a handsome ornamental when the mass of flowers are at their best. The fruit is large for a nectarine, being from 2¼ to 2½ inches in diameter. The color is yellowish green, speckled and irregularly streaked with carmine. The skin is smooth and not easily broken, which adds to the shipping qualities of the fruit. The flesh is yellowish white and streaked with red near the seed, to which it clings. The fine texture and firmness of the flesh are especially noticeable; also its juiciness and sprightliness. A most striking feature is its rich aroma which lingers for a considerable time on the hands and whatever else the fruit has touched.

The Quetta nectarine has all the qualities of a first-class peach with the added advantage of having a smooth skin, handsome coloring, and a rich aroma. In the dietary then it will take the place of the peach, being especially agreeable when eaten out of the hand, or as a sliced breakfast fruit. Although no elaborate tests have so far been made in the drying and canning of this fruit, there appear to be no reasons that would preclude its use for those purposes.

The Quetta nectarine has been extensively propagated at the Chico plant introduction garden and distributed from there to all the States in the Union, except Maine, New Hampshire, and Rhode Island. The largest number of trees have been established in California, the records showing nearly 6,000 trees and more than 4,000 buds as having been placed in the hands of growers there. Something over 1,200 trees have been distributed in the Atlantic and Gulf Coast States, and several hundred more in Midwestern States. Practically all of the propagation has been accomplished by budding the trees on the Chinese stock already mentioned. This has, without doubt, added to the hardiness of the tree, as the Chinese wild peach is known to be more resistant to cold than the ordinary peach.

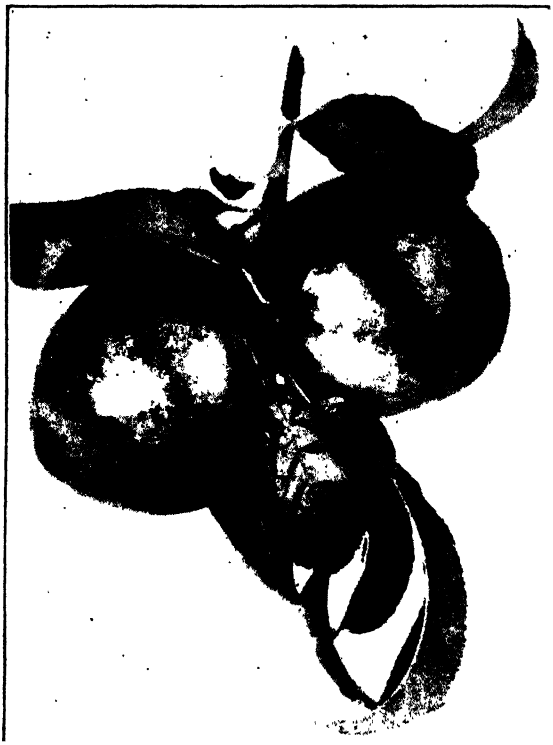

FIG. 189.—The Quetta nectarine. A promising new fruit from northwestern India. About two-thirds natural size. The skin is smooth and the flesh is sweet, sprightly, and as finely flavored as a high-grade peach

### Commercial Production Reviving

The commercial production of nectarines practically ceased in California a few years ago, but is now coming to the front again.

The Quetta seems to be leading in this matter, records showing nearly 100 acres planted for commercial use. Its chief value to the California growers is found in its high quality, handsome appearance, and ability to stand long-distance shipments. The last is important, as most nectarines are poor shippers. From all the reports at hand the fruit would seem to have found a place in California as a commercial introduction. Throughout other sections, including most of the cotton-growing States, Missouri, Illinois, Indiana, Ohio, Kentucky, and Tennessee, this fruit would seem well worthy of culture in the home fruit garden and for small orchards where the products are for local consumption. It is believed that the Quetta nectarine has passed the experimental stage and might profitably be taken in hand as a promising commercial nursery product.

B. T. GALLOWAY.

## RABIES Becoming More Prevalent in United States

Indifference and lack of fear, together with misguided sentiment and distance from the scene of infection, are factors that may reasonably be held responsible for the prevalence and increase of rabies. Children probably make up the greatest number of victims in homes where rabid animals have been kept as pets. If the malady actually affects a person, it is not curable; but it is preventable, in most instances, by proper vaccine inoculations.

Rabies among dogs, throughout the eastern part of the country at least, is on the increase. This, of course, results in a greater menace to man and to farm stock. There is need to overcome the apathy of the public as to the situation. To have general knowledge about a disease puts one on the alert for its presence. To have definite knowledge about it frequently means also the ability to avoid its occurrence or to prevent its spread should it appear.

Rabies is essentially an acute, degenerative disease of the central nervous system, due to infection. In this disease the functioning of the brain is utterly abnormal, resulting in an acute insanity. The disease in dogs is manifested either by an acute mania known as furious rabies or by a lethargic mania known as dumb rabies.

The disease in animals is practically always transmitted by the bite of an affected dog and by dogs affected with the furious form of the disease. The dumb form of rabies may be preceded by a more or less acute or furious form of the disease. There is the possibility, therefore, that any rabid dog at large, although having the dumb variety of disease, may have had opportunity to transmit the disease so that all dogs with which he may have been in contact should be regarded as possibly exposed and should be handled accordingly.

### Symptoms Shown by Rabid Dogs

A dog that fairly suddenly develops defective vision, changes its usual attitude toward dogs and animals or man, that appears to have a bone in its throat, has inability to swallow, seems unusually snappish, runs away or is unable to run on account of apparent paralysis, exhibits fear or unusual aggressiveness, should be examined by a veterinarian in order that a diagnosis may be made and that proper precautions may be taken to forestall mischief. The symptoms mentioned above are often indications of the presence of rabies.

It is a duty in many research and public-health laboratories to examine the carcasses and brain tissues of animals, principally dogs, that are suspected of having been affected with rabies. When the disease is found, proper precautions may then be taken to prevent its spread by animals that have been exposed to the rabid one. Preventive treatment may be given by a family physician to persons bitten by the animal. Occasionally, preventive treatment is given to exposed dogs also. The examinations are for the purpose also of fixing quarantines for the protection of other dogs and domestic animals. Losses from rabid cattle, horses, sheep, and swine, in the aggregate, are large.

The large number of animal carcasses submitted for examination to the Bureau of Animal Industry laboratories in Washington, D. C., shows that the disease in this vicinity has been steadily and greatly on the increase. During the last year in the pathological laboratory of the bureau 289 suspected cases were examined microscopically for evidence of rabies. Of this number 146 were found to be positive cases of the disease. All these cases originated in Washington, D. C., or in the suburbs. This number is about three times as great as occurred four years ago. From other evidence also there is abundant proof of a rather general increase in many communities.

The number of dogs in the country without doubt is larger than at any previous time. This fact, together with the custom of allowing the dogs to roam at large without muzzles or other restraint, unquestionably explains in part the rabies situation of to-day, since the disease is transmitted from dog to dog or from dog to man and domestic animals almost exclusively by the bites of rabid dogs. In man, rabies may be accidentally transmitted in the laboratory by accidental wounds in which the rabies virus from a dog is being manipulated in examination; however, this is of rare occurrence.

If a person is bitten by a dog and rabies is suspected, tie up the dog (if this can be done safely) instead of killing it. This will facilitate diagnosis of the suspected disease. Consult a physician without delay.

JOHN S. BUCKLEY.

## RADIO Aids in Distribution of Market News

Broadcasting crop and market news reports by the radio stations of the country has been in effect since early in 1921. The greatest expansion of that service was in 1922. Beginning the year with authorizations to nine broadcasting stations to release market reports originating in the then Bureau of Markets and Crop Estimates the service grew till by the end of the year 81 stations were regularly releasing scheduled reports, and it was estimated that over more than half of the area of the nation daily reports could be heard by those having fairly good receiving equipment.

During 1923, 1924, and 1925 the area covered by the service expanded somewhat, particularly in the western half of the country. Some stations discontinued broadcasting, others merely changed their plans and discontinued the regular scheduled broadcasting of market reports. The losses to the service were small, and where a station of somewhat indifferent ability discontinued the service others that were more efficient were found to take up the work. During the three years that the service of market reports by radio was becoming stabilized surveys were made to obtain, if possible, some idea of the number of farm homes that were equipped with radio sets so that if market reports were wanted they could be obtained. The results of the 1923 surveys showed an estimate of 145,000 sets on farms: 1924 gave an estimate of 365,000,' while in 1925 the number estimated was 553,000.

With an assured audience that was rapidly increasing the use of radio as a means of reaching the largest possible number of producers with the current market reports took its place in 1926 as a well-organized part of the market-news distribution machinery. Ninety-five stations carried regular programs during the year.

### New Stations Added in 1926

Although the number of new stations added to the service during 1926 was small, being only eight in number, there were three rather important market-news programs set up to serve areas that were not being well supplied. At Hastings, Nebr., a complete market-news program was provided by the establishment there of a branch office of the leased wire telegraph system of the bureau which made available all the market reports that passed over the western circuit of the system. Cooperation with local agencies, including the local chamber of commerce and the radio station KFKX, provided the necessary machinery for the handling of the reports. The radio station at Hastings is very powerful and the reports were heard over a wide area in Nebraska, Kansas, Colorado, Wyoming, Montana, and South Dakota. No less than 5,000 complimentary letters received in the first three months of the arrangement at Hastings proved that the material broadcasted was reaching farmers.

At Ames, Iowa, an arrangement similar to that at Hastings was made, except that the local cooperation was provided by the Iowa State College extension service and the radio station owned by the college. The leased wire was extended to Ames and broadcasting of the complete reports began in July, 1926.

Although the leased wire passed through Oklahoma there were no available cooperating agencies and satisfactory broadcasting station which could be obtained for the development of a radio market-news program. However, with the increase of the power and facilities of station KFJF at Oklahoma City and the increased interest of local agencies, arrangements were made for the establishment of a branch of the leased wire at Oklahoma City and the broadcasting of the information thus made available by the state marketing commission over station KFJF.

## RECREATION for the Farming Population

Various elements in rural society are according increased value to recreation. Education recognizes it through enlarged playgrounds, school athletic leagues, and the opening up of buildings to community use. Religion recognizes it by making recreation a part of its rural church program, both outside and inside the church building. Rural social organizations evidence its greater importance by promoting rural community field days, pageants, athletic badge contests, and athletic leagues, and by establishing community centers. Farm economic organizations demonstrate it by making recreation a part of their balanced community programs. Social and recreational cooperation is becoming a valuable building stone in economic cooperation.

Significant in rural recreation are recent Pennsylvania laws authorizing county and township boards of recreation. Chester County, under its superintendent of recreation, is training rural recreation leaders. Some of the results are development of athletics, neighborhood social evenings, new community halls, school recreation under leadership, provision for recreation at fairs, promotion of Christmas programs, and establishment of recreation clubs.

In Butte County, Calif., the county recreation director furnishes recreation programs to the recreation director of the farm bureau centers, organizes recreation evenings for farm bureaus and other organizations, organizes community players, community play days, Christmas festivals, farm bureau picnics, and Camp Fire Girl circles. Every farm bureau in the State has a recreation committee.

According to studies made, farm communities are taking adva steps in both indoor and outdoor recreation features. The bureaus of Kendall and Whiteside Counties, Ill., Weber Cou Utah, and three California counties formed baseball lea Farmers' outdoor swimming pools were constructed in Gage Cou Nebr., and Phelps County, Mo. The farm boys' band of Harr *Township, Boone County*, Iowa, and the boys' band organized by grange at Concord, Minn., are examples.

### History Taught in Pageants

Local history is taught and preserved through rural pageants. The rural people of Kittson County, Minn., presented five homemade, home-staged pageants one year. Eight farm bureau centers of Kern County, Calif., produced local plays in 1925 sponsored by the community theater committee of the bureau. In Iowa 149 township farm bureaus produced plays and 109 farm bureau debates were held.

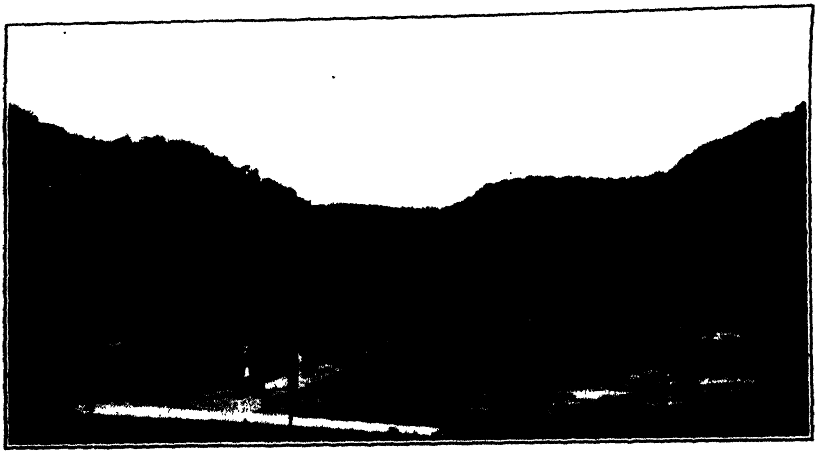

FIG. 190.—The 1926 picnic of the Winona County, Minn., farm bureau was attended by 8,700 people. Community picnic grounds, a tract of 27 acres, was donated to the farm bureau and has been equipped for picnics and recreation. More than 20,000 people attended picnics here during three summer months of 1926

The little country theater is strongly featured in North Dakota and New York. Farm bureaus in 792 Iowa townships averaged three showings each of moving pictures in 1924. An old farm barn was converted into a successful moving-picture house in Albemarle County, Va.

In Alabama in 1924 there were 21 boys' and girls' camps and 4 for women, each with a recreation leader. Recreation as a county demonstration project was featured in 16 counties in New York, including training schools for leaders and a three-day rural-dramatics institute.

Farmers' picnics on special farmer-owned picnic grounds are popular. The farm bureau picnic held in the picnic grounds of the Winona (Minn.) County farm bureau in 1926 was attended by 8,700 people (fig. 190). Rural people are establishing their own parks and playgrounds. A notable example is near Smith Center, Kans.

Rural indoor recreation is centered primarily in special community buildings found in most counties, or secondarily in churches or schools or club buildings especially planned for community recreation features.

In 1925 the Lewiston Park Community Club near Hopkins, Minn., procured the plans and specifications for a community building, prepared by the Department of Agriculture, and recently completed their building, financed by community entertainments. It is the home of the county branch library, Boy Scouts, boys' glee club, community chorus, boys' and girls' club work, women's home project course, and community club. Activities are local plays, suppers, dances, card games, and lectures by the county agents and others.

### Department Bulletin Plan Used

The farmers of Fabius Township, Marion County, Mo., recently erected their building from floor plans published in Farmers' Bulletin No. 1173 through voluntary contributions of labor, material, and money. It is headquarters for the county agents, farm bureau, girls' sewing society, boys' pig club, ladies' musical society, community orchestra, glee club, baseball association, and other organizations, and has the usual social activities. The 25-room community building at Emden, Ill., population 462, was recently completed after inspection of the Brimfield, Ill., building, and publication of the plans in Farmers' Bulletins Nos. 1173 and 1274. It was financed by stock sales to 192 people and contributions of money and labor amounting to $50,000. Activities include motion pictures, Chautauquas, local plays, traveling theatricals, musicals, dancing, luncheons, lyceum courses, basket ball, indoor baseball, volley ball, and roller skating.

WAYNE C. NASON.

## RED Clover Seed's Origin is Important

A Wisconsin farmer would not think of planting Missouri-grown seed corn, but until recent years clover seed has been judged solely by its purity and germination, irrespective of the place where the seed was produced. Extensive trials for several years past have shown, however, that clover seed is not always equally fitted to assure a successful stand, one that will not only live over winter but that will survive the attacks of disease organisms and, if medium red, produce two cuttings in the second season.

Assuming that the soil is fit for the growth of clover and that no unusual drought kills the young stand, the remaining important element in getting and keeping a stand of red clover is the seed. In the United States two factors tend to destroy a stand of red clover—one is severe winter weather, the other disease.

A winter of steady low temperature need not be hard on clover, provided the ground is covered with snow, and conversely a winter with alternate spells of severe cold and thawing weather may be much harder on clover than one of steady cold. From present information, the geographical limits of the areas where severe winters may be expected can not be exactly defined, but in general such sections as Iowa, Minnesota, and New York have winters severe enough to cause destruction of clover, while in the Lake States, Ohio, Pennsylvania, and southward, clover does not commonly suffer from winterkilling due to cold.

The disease factor operates both directly and indirectly; directly in killing the seedlings or the plants after the June hay crop has been cut, and indirectly in weakening the seedlings so that they fall prey to other diseases or to winter weather, in which case the result is often ascribed to winterkilling alone.

### Anthracnose Causes Damage

The disease which causes the damage, or at least by far the greater part of the damage, in the eastern clover belt is anthracnose. Two fungi are responsible for this disease, one most active in the southern part of the clover belt and known botanically as *Colletotrichum trifolii*, the other known as *Gleosporium caulivorum*, most active in the northern part of the clover belt. Since the most severe damage so far observed has been due to the southern form of anthracnose, *C. trifolii*, most of our information concerns the damage done by this organism. Although the external symptoms of the disease are alike in both cases, the fungi are different and behave differently toward temperature and other conditions.

Like all plants, red clover has tended to become adapted to local conditions and in the regions of severe winters the less hardy plants have been killed out and by natural selection a strain better able to endure the winters has developed. The consequence is that, when seed grown in Oregon or in Tennessee is sown in Minnesota, a larger proportion of plants are winterkilled than is the case when Minnesota seed is sown. Farmers in such sections, therefore, need to sow northern-grown seed. As far as trials have been made, no imported seed of any kind has been found to produce plants as resistant to Iowa or Minnesota winters as home-grown seed or as American-grown seed generally. In Iowa and Minnesota, 90 per cent or more of the plants raised from Italian seed and from 50 to 60 per cent of those raised from French and Chilean seed have been killed by cold, while in the same winter and on the same fields only 10 to 15 per cent of the plants from northern-grown American seed were killed. Russian red-clover seed has not been adequately tested. Farmers in any section where the winters are hard on clover or wheat should therefore use American-grown red clover seed and, if possible, that from the Ohio Valley, the Northern States, Iowa, or Canada.

### Southern Form of the Disease

In the southern part of the clover belt, approximately south of an east-and-west line along the southern border of Pennsylvania, the southern form of anthracnose causes much loss of the young plants during the first season or kills the older plants after the June crop of hay has been cut. Clovers produced in various sections differ in their susceptibility to this disease, plants raised from seed grown in the South being usually less susceptible than those from imported or from northern-grown seed. Plants from Italian seed are more susceptible to this disease than any others and many are commonly killed during the first year. Those that survive, if any, often die out during winter and the few that survive are sure to die after the first cutting. Plants of several of the best European strains, as Silesian and Bohemian, which are highly regarded in Europe, appear to be rather more susceptible than most French or Chilean strains, though plants of all imported strains, even Russian, are decidedly more subject to this disease than are plants from American seed. Figure 191 shows how a stand of clover which was good in August of one year disappeared before May of the next year. Plants from Oregon, Canadian, and Wisconsin seed have been found more susceptible than those from Ohio seed and in some cases the same has been true of Minnesota seed. In one case, however, the plants from Minnesota seed have been little injured.

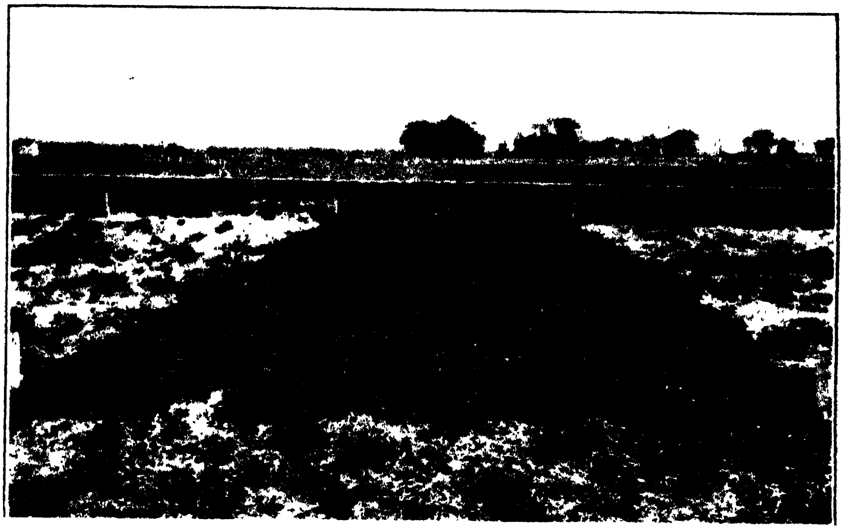

FIG. 191.—Effect of anthracnose on the stand of red clover. Center, perfect stand of Tennessee anthracnose-resistant clover; left, plot seeded with Italian; right, that seeded with Bohemian seed. The plot in the foreground is seeded with Oregon seed. All plots had a good stand in early August, 1922

As far as tried, seed produced by plants grown in Virginia, Maryland, and in southern Ohio have withstood this disease better than any except those of the selected anthracnose-resistant Tennessee strain.

### Practical Lesson Gained

The practical lesson from the information so far gathered is that in sections of severe winters American clover and preferably northern-grown seed should be used. In the southern part of the clover belt, an effort should be made to produce a local source of supply, preferably of a strain or of strains known to be resistant to anthracnose. Until such seed is available, seed produced in the southern part of the clover belt or in the Ohio Valley should be given preference.

A. J. PIETERS.

### RED Clover Strains—How They Behave

All red clovers are derived from the wild form of *Trifolium pratense*, a low-growing plant with branches lying nearly flat on the ground. From this, two main types have been developed—the single cut or late clovers, and the double cut. In the United States the single cut is known as mammoth, and the double cut as medium or June red.

These two types are distinguished mainly by the fact that the single cut is in full bloom two to three weeks later than the double cut and produces but one crop of stems in a year, while the double cut produces two crops of stems. The mammoth also has coarser and more hairy stems, but the development of this character depends somewhat on the soil and weather conditions. In the fall of the first year's growth the mammoth is lower growing and more compact than the medium red and rarely produces stem growth. True American mammoth is grown only in North America. Imported "mammoth" or "sapling" has, in the department's trials, invariably proved to be European double-cut clover. The American mammoth is a single-cut clover like the European single cut but is a very different strain, being coarse, strong growing, and very hairy, whereas the European type is smooth or with appressed hairs. The Altaswede, developed in Alberta, Canada. is a very good hardy type of European single-cut clover.

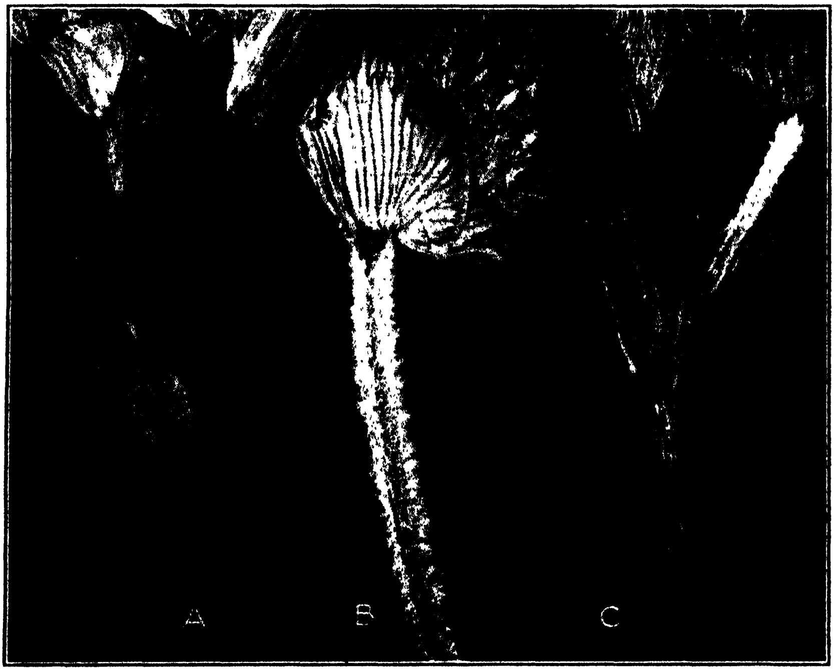

FIG. 192.—Young parts of red-clover stems showing characteristic hairiness. Enlarged to show hairiness. A, Italian, smooth. B, American, rough hairy. C, English, appressed hairy

While these two main types, single and double cut, are common to red clovers in Europe and in America, the American type, though derived from the European, has developed characteristics of its own by which it may nearly always be known.

### American Red Clovers Hairy

The American red clovers, whether single or double cut, are hairy, and the hairs stand at right angles to the stem (fig. 192). The stems are relatively coarse and the flower heads larger than those produced by European clovers, at least under American conditions. The European clovers are either nearly or quite as smooth as the Italian or the hairs lie flat against the stem and point up, as in English and French clovers. There is some variability in this character of hairiness, the American clover sometimes being very hairy and sometimes little hairy, but the characteristic appearance of the hairs can nearly always be seen on the young parts of the stems, especially just below the flower heads. It is very rare to find a plant of genuine American clover with smooth stem or with the hairs appressed to the stem. When such plants occur in numbers in any field it is certain evidence that mixed seed has been sown.

Besides the above characters visible to the eye, American clover is in America more winter hardy and more resistant to disease than the European type of whatever origin so far tested. Russian clovers have not yet been thoroughly tested. South American clover, at present imported only from Chile, is of the European type.

One American strain, the Tennessee anthracnose-resistant clover, has been selected for resistance to this disease, but in appearance is precisely like other American clovers. American clovers, whether grown in Canada or in any of the United States, are all alike in appearance, though there is some evidence that they are not all equally hardy or resistant to disease.

A. J. PIETERS.

## REINDEER in Alaska Thrive and Multiply

A third of a century ago there were no reindeer in Alaska. To-day more than 350,000 are grazing on the ranges and more than 100,000 additional have been utilized for a generation's food and clothing. Such surprising production in a comparatively few years indicates something of the vastness of the infant reindeer industry in our Arctic regions.

The original stock of 1,280 reindeer, from which have come the present herds, was imported from Siberia over a period of 10 years beginning in 1892, under the direction of the Bureau of Education of the Department of the Interior. That bureau also brought Laplanders from northern Europe to instruct the Eskimos in their new mode of gaining a livelihood, but the Lapps lacked the knowledge of coping with the parasitic and other diseases that began soon to develop among the animals.

About two-thirds of the reindeer are now owned by natives and one-third by whites. The latter, realizing the need of expert assistance for the welfare and improvement of the herds, especially as evidences of deterioration became manifest, appealed to Congress for aid, with the result that in 1920 an appropriation was made for necessary investigations by the Biological Survey.

From the outset both the Eskimo and the white owners have taken the greatest interest in the reindeer investigations and are rapidly adopting the recommendations that have been made by the parasitologists, veterinarians, and grazing experts engaged on the work. To give a clear idea of the accomplishments and the work still in progress, the problems studied may be conveniently grouped under four heads, having to do with improvements (1) in the control of diseases and parasites; (2) in the condition of the herds and methods of herd management; (3) in grazing and range management; and (4) in facilities for transporting carcasses and marketing the meat.

Determinations have been made of the parasites and diseases of the reindeer and of successful methods of control in many cases. The studies are still in progress.

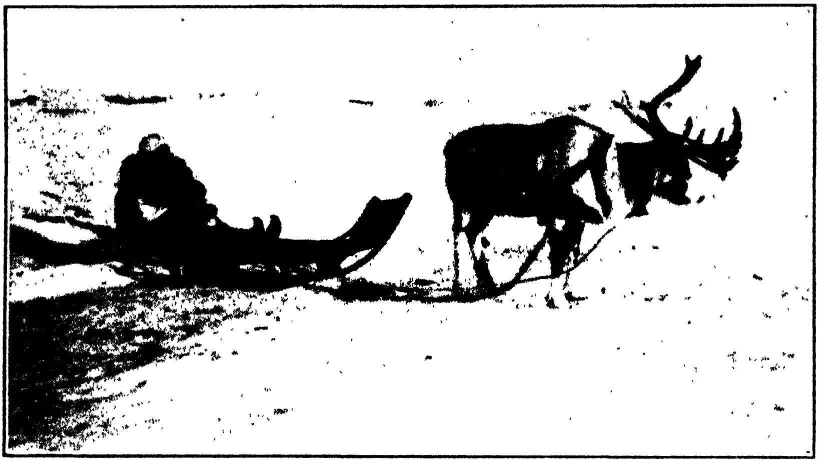

FIG. 193.—Lapp woman driving sled reindeer in Alaska. The line for guiding the reindeer is shown leading back to the sled. Lapps came from Europe at the time reindeer were first brought from Siberia to instruct the Eskimos in their new industry

### Herd Requirements Studied

The requirements of herds of increasing size have been investigated and practical methods are being worked out for handling reindeer on the range, at round-ups, and at the times of counting, marking for ownership, and castration of surplus bulls. Open herding and seasonal changes of pasture are being adopted, following recommendations of the investigators, and in round-ups the use of modern corrals with wing fences, chutes, and squeezes are found far superior to the rough and crude practices formerly followed. Castration methods are now employed with exceedingly beneficial results, compared with former barbarous customs. On Nunivak Island cross breeding with the larger caribou, captured on the upper Yukon and transported there for the purpose, is under way, and the animals produced should be larger, more stocky, and superior meat producers, and have fewer accidents from broken bones.

The range itself has received a full share of study, and as a result the distribution and abundance of the lichens are being ascertained as a requirement for the conservation of lichen areas for winter use.

The summer and winter grazing needs of individual herds, whether large or small, the yearly carrying capacity in different sections, and the delimiting of unit areas are being worked out. Recommendations also have been made for preventing the destructive fires that threaten seriously to curtail the grazing capacity of the ranges.

Studies are being made to determine the most satisfactory methods of slaughter and of dressing reindeer carcasses for shipment. These include the improvement of cold-storage and transportation facilities and the establishment of grazing units near waterways or along the Alaska Railroad or other arteries of travel. It is fully realized that for its highest development the reindeer industry must have facilities for marketing the meat and that these must keep pace with the increasing numbers of reindeer. Officials of the Alaska Railroad are cooperating heartily in solving this problem.

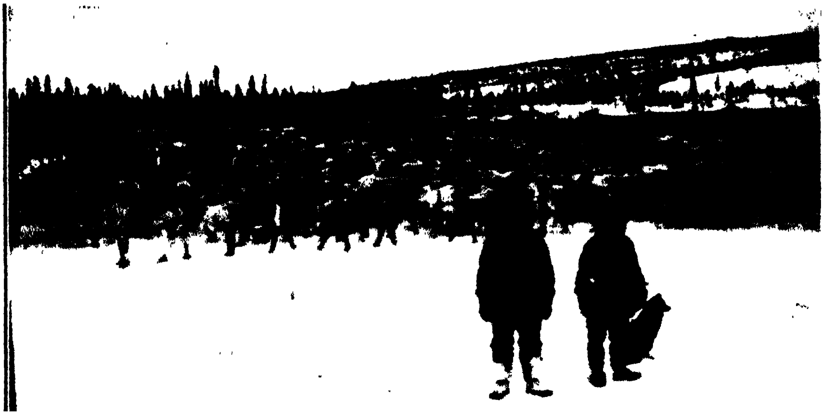

FIG. 194.--Reindeer held on winter range. Part of more than 350,000 reindeer on Alaskan ranges, the offspring of the original 1,280 animals introduced about 30 years ago. In the foreground are shown a reindeer owner, a herder, and one of the dogs used in corralling the reindeer

### Experiment Stations Maintained

Reindeer experiment stations have been maintained by the Biological Survey from the very beginning of these investigations, and arrangements have now been made for conducting the experimental work from a station near Fairbanks, in cooperation with the Alaska College of Agriculture, with a substation possibly at Broad Pass, on the Alaska Railroad. All former investigations will be continued, including experiments in feeding grains and other rations, with a view to developing sled reindeer able to transport freight and supplies in areas where lichens are not available.

E. W. NELSON.

## REPORTING Service on Markets Is Country-Wide

The collection and distribution of "to-day's markets to-day" by the market news service of the Bureau of Agricultural Economics was extended during 1926 by the addition of five collection points and two distributing points.

The department now has a total of 35 offices outside of Washington, extending from Boston on the east to Jacksonville on the south, and to San Antonio, Tex., and San Francisco on the west. The system now comprises nearly 8,000 miles of leased wire which is operated each market day, supplemented by a large use of commercial wires, in collecting information on shipments, receipts, and prices, etc., from field stations.

The service now covers in a comprehensive way the following staple agricultural products: Livestock and meats, wool, fruits and vegetables, dairy and poultry products, hay, feed and seeds, cotton, and a weekly review service on grains. Farmers and others who desire to receive the market news reports issued by the bureau may write to their nearest branch office as shown on accompanying map (fig. 195), or to Washington. This market news service now furnishes the principal part of the market news and reports used by news associations, the farm press, country newspapers, and for radio broadcasting.

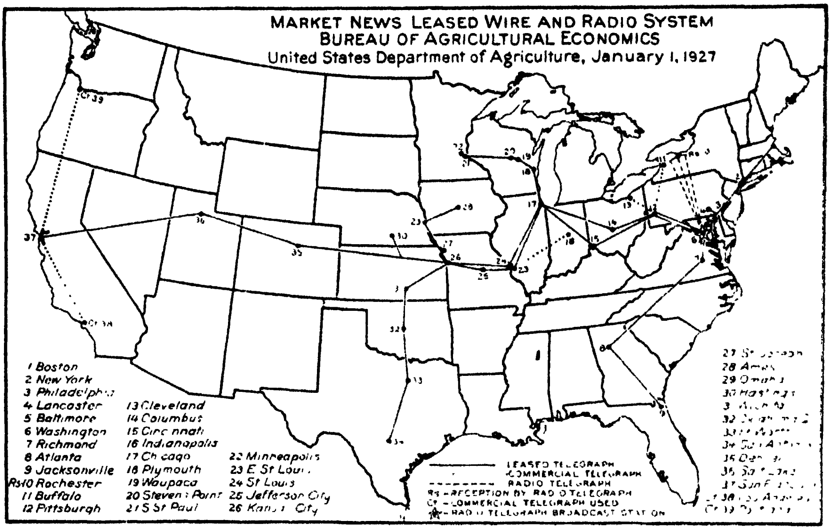

FIG. 195.—Location of stations having the market news service of the Bureau of Agricultural Economics

J. CLYDE MARQUIS.

## RESEARCH Pays Dividends in Unforeseen Ways

It is often difficult to determine in advance what is and what is not worth while in scientific research. This fact occasionally causes the suggestion to be made that research work should be tested by its immediate utilitarian results. Such a standard of values would be entirely inadequate. Frequently the simplest and apparently the most unimportant observations turn out to be of great value. This has been so often demonstrated that it is never safe to call a scientific discovery useless, no matter how hard it may be to imagine any practical application for it. New truth generally proves useful eventually. The history of scientific conquests is full of instances. A good example is the way in which the Bureau of Plant Industry of the United States Department of

Agriculture found uses for an apparently unimportant discovery made nearly half a century ago by Karl Wilhelm von Nägeli, a brilliant Swiss-German botanist, in the course of a study of one of the fresh-water alga belonging to the genus Spirogyra, popularly known as " green slime " or " frog spittle."

This alga grows in ponds and slow streams and looks to the naked eye as fine, long, green silk thread. Under the microscope, the thread is made up of cylindrical-shaped cells placed end to end, with spiral bands of green cholorphyll and the protoplasm and nucleus showing clearly. It is thus easy to see the living cell in operation and von Nägeli planned to study its life processes under the microscope with the hope of learning just how they took place. He prepared aquaria with carefully compounded food solutions required by the Spirogyra, but after repeated trials he could not get the alga to grow. However, when he brought water in from the spring they grew beautifully. Here was a question, apparently not of great importance, but he wanted to know why the alga would not grow in his synthetic solution. To make a long story short, he finally traced it to the water which he drew from a bronze faucet in his laboratory and then to the faucet itself. He discovered that the water passing through the bronze faucet took up enough copper from the bronze to kill the Spirogyra.

### Copper Solution Killed Algæ

After repeated tests he found that 1 part of copper in 50,000,000 parts of water was sufficient to cause the green spiral chlorophyll band to contract, turn brown and, later, the cell to die. This phenomenon he described as the oligodynamic effect of copper on Spirogyra. It opened up a new field of study as to the physiological effect of dilute poisons and their selective effect. Most plant and animal tissues would not react at all to such dilute solutions. The facts were printed in a small report. They were considered of scientific interest, but probably of no practical importance.

About 20 years ago the Bureau of Plant Industry received a letter from a cress grower up in the Alleghany Mountains asking help in controlling a pest that was destroying his cress. Cress growing in the district was quite a well-developed industry, representing large investments. The bureau sent a physiologist to examine the trouble. The pest proved to be Spirogyra. The conditions in the cress ponds were so favorable for the growth of the alga, as well as the cress, that the former smothered out the latter. In seeking a remedy, the work of von Nägeli was recalled and tests of copper sulphate, 1 to 50,000,000 parts, were tried. This small quantity completely destroyed the Spirogyra without in any way harming the cress. At a cost of a few cents this pest was easily controlled. Here, then, was demonstrated a highly practical result of work, which, at the time, appeared to be of no value, at least from a dollar and cents standpoint. The use of this knowledge is saving the cress growers many thousands of dollars annually.

The remarkable results obtained suggested that copper might be used to control other forms of algal infections of city and town water supplies. Certain forms of algal growth made the water in large city reservoirs almost impossible to use at certain times of the year, causing not only great inconvenience, but great loss, as it was impossible to control the trouble. As a result of these investigations, it was found that all of these pests could be eliminated at small cost and with absolute safety to the users of the water. This saved not only many millions of dollars a year, but greatly added to the health and comfort of those who used the water. Hundreds of supplies were cleaned up, not only in the United States, but in foreign countries.

### Mosquito Larvæ Killed Also

During this work it was discovered that the larvæ of certain species of mosquito were destroyed by these copper treatments, which also destroyed algal growth. A method of destroying these pests was, therefore, at hand that could be used in water supplies, including tanks, wells, and cisterns where it was not practicable to use oil. The method was used with great success in a yellow-fever outbreak in New Orleans and later during the construction of the Panama Canal.

During these studies it was observed that certain species of bacteria, which are, in fact, microscopic plants, were also destroyed by these dilute solutions of copper. Careful studies were therefore made of the effect of copper on pathogenic species like those causing typhoid and paratyphoid fever and Asiatic cholera. It was discovered that they were highly sensitive to copper and could be cleaned out of a water supply as easily as the algæ without the slightest danger to the users of water, if properly applied. Water supplies contaminated with typhoid were disinfected and made perfectly safe at small expense and the method has now become a standard sanitary engineering procedure.

As a result of this work the use of chlorine was similarly standardized and has also become a standard treatment for infected supplies. The copper treatment has been used in India, China, and the Philippines for disinfecting supplies contaminated with Asiatic cholera organism and amoeboid dysentery organism. The value of this is almost beyond computation. It may fairly be said to be the outgrowth of von Nägeli's studies so many years ago. It demonstrates how important it is to make such studies, even though they may not at the time appear to be of practical value. If von Nägeli had not asked the question, "Why do my algæ die?" and worked till he found the answer, we might never have had the knowledge we now possess.

One other example will be all that space permits. In 1883, a French botanist, Millardet, was studying a fungous disease of the grape, or the "vine," as they call it in France. He had some trouble in keeping the boys from stealing the grapes, and to scare them off he sprinkled on the vines a mixture of copper and lime, which made a bluish coating on the leaves and fruit. The boys thought this was poison and let the grapes alone. Millardet noticed, to his surprise, that the leaves and fruit on which he had sprinkled this copper and lime mixture were free from the disease, while the parts not treated were destroyed by the disease. This led to the discovery that dilute solution of copper destroyed the fungus causing the disease without in any way injuring the vine or the fruit.

From this discovery of Millardet was developed our modern knowledge of Bordeaux mixture and its uses in controlling fungous diseases of fruits, vegetables, and plants in general, saving hundreds of millions of dollars annually.

Research in other fields such as soils, fertilizers, plant breeding, animal breeding, animal diseases, insect pests, chemistry, meteorology, forestry, nutrition, and economics has yielded and is yielding and promises to yield facts of great possible value. We can not afford to lessen our efforts in research, but we must increase them if we are to meet the demands of the future. No investment made by the Federal Government and the States has paid larger dividends in the past and none is likely to give a larger return in the future.

### The Scientific Method

Some one has said that research is the golden key that opens the portals to progress. It is the constant aim of all educational agencies to cause the human mind to develop in such manner that it may learn how to distinguish truth from error and how systematically to go about the job of finding the truth. This is research, and the method is the scientific method. It may be applied to the simplest things about us or to the most complex problems. It always proceeds from the known to the unknown. The known factor, to begin with, may be the merest clue, apparently worthless, but if it is the only known fact it must be the starting point to gain others through the processes of observation, analysis, and experiment or testing. These processes are frequently very slow and expensive, but there is no royal road to truth.

If we would know the truth we must be ready to make the sacrifice necessary to find it. The history of science is full of romance and self-sacrifice. Because of this spirit our modern world enjoys a well-being not dreamed of as possible, even to the most fortunate. Our knowledge of chemistry, physics, biology, geology, astronomy, and mathematics gives us a control of ourselves and of our environment that was undreamed of a few centuries ago. Still, we are only on the threshold of great new realms of knowledge and power to come within our grasp through the patient continuance of research.

A. F. Woods.

## ROTATION a Sure Way to Reduce Production Cost

If you had land which produced low yields as the result of exhaustive one-crop farming would you simply buy fertilizers and continue the one-crop system, or would you diversify and practice a good rotation of crops? To be sure there are other decisions you can make; but to decide wisely in profitable soil management, you must know certain facts, among which are the following:

A one-crop system of farming ultimately leads to disaster.

Diversification and crop rotation lead to well-organized and profitable farming.

Soil productiveness can best be maintained when intertilled, small-grain, and leguminous or grass crops are grown in the order named and in recurring succession on the same land.

The largest crop yields are possible only when crop rotation and the use of manure or fertilizers are practiced together.

Crop rotation increases the returns from farm manure and fertilizers; and manure, fertilizers, and lime increase the returns from rotation.

Crop rotation does not cost any money, but it rivals the use of manure and fertilizers in maintaining and increasing crop yields.

A good rotation is a most effective means for increasing yields and lowering crop-production costs.

WILBERT W. WEIR.

## ROUNDWORMS of Swine Prevented by Sanitation

Although it has long been known that the large intestinal roundworm (*Ascaris lumbricoides*) is one of the commonest and most injurious of the parasites that infest swine, the precise nature of much of the damage caused by this worm has been discovered only during the last 10 years. Up to about 10 years ago ascarids were considered to be injurious to swine largely because they were known to produce various digestive disturbances, to interfere with growth and development, and to bring about unthriftiness in other ways, especially among young pigs. Their greatest threat to life and one outstanding capacity for doing harm were brought to light, however, when their life history was fully determined.

Before 1916 the life history of *A. lumbricoides* was thought to be comparatively simple. It was known that the eggs produced by the female worms were discharged into the intestine of the pig and passed out with the droppings. Under favorable conditions the eggs were known to complete their development on the ground in about two weeks, at the end of which period each normal egg contained a small, coiled larva. On the basis of knowledge then existing it was believed that if the egg was swallowed by a pig, the larva contained in the eggshell would be liberated in the digestive tract, would remain in the intestine, and grow slowly to maturity.

These eggs of the roundworm were also known to be very resistant to unfavorable conditions and to be able to withstand more or less drying and other seemingly injurious effects to which they might be subjected in nature. On account of this marked resistance of the eggs of the roundworm, the problem of preventing infestation of pigs with ascarids was regarded as a very difficult matter.

### Earlier Views Modified

As a result of discoveries first published in 1916, previous conceptions regarding the life history of these parasites became considerably modified. It was first shown by F. H. Stewart, a medical officer in the British Army, and later confirmed and considerably extended by the late B. H. Ransom and others, that the young worms after hatching in the digestive tract do not settle down at once in the intestine, as had been believed.

It was found instead that the young worms enter the blood stream and are carried by the circulation first to the liver and then to the lungs. It was further discovered that the young worms make their way from the lungs to the windpipe by upward migration, thus reaching the back of the mouth, from which they come down again through the esophagus and stomach into the intestine, where they settle down and develop to maturity. The roundabout journey of the young worms through the blood stream and the air passages requires about 10 days for its completion, after which their growth to maturity occurs in about 10 weeks.

In passing through the lungs the young worms were found to injure that organ, and if many worms passed through at the same time, a serious pneumonia was produced, which frequently terminated in death. These observations were first made on small, laboratory animals, such as mice, rats, and guinea pigs, and later on pigs. In the course of experiments with pigs it was found that animals did not fully recover from the setback that they received as a result of the lung injuries produced by the migrating young worms. They became stunted and in many other ways failed to develop at a normal rate.

Observations on lung troubles in pigs as a result of the migrations of young roundworms were first made on animals experimentally infected with ascarid eggs in the embryo stage. In these experiments it was found that very young pigs, from a few days to a few weeks old, were most susceptible to infection with the worms and that they suffered more severely as a result of it than did older pigs. Pigs several months old or older were found to be only slightly, if at all, susceptible to infection with the roundworm.

Observations on lung trouble in pigs due to migrating ascarid larvæ were soon extended from pigs used in experiments to pigs on farms, that had acquired a natural infection with roundworms. In naturally infected animals, a form of lung trouble commonly known as " thumps " was found to be due in many instances to ascarid larvæ going through the lungs, thereby affording a sound explanation for this condition which had previously been explained by various theories now known to be inaccurate for a large proportion of these cases.

## Method First Tested in McLean County, Ill.

On the basis of these newly discovered facts concerning the life history of the large intestinal roundworm of swine, the Bureau of Animal Industry, through the efforts of Doctor Ransom and his coworkers, devised a method of preventing losses among swine by keeping down the infection with these parasites. Because the method was first tested under actual farm conditions in McLean County, Ill., it has come to be known as the McLean County system of swine sanitation.

Essentially the method consists in keeping young pigs away from old hog lots and other places that have been exposed to contamination with swine manure, and away from older and infected animals, other than their mothers, until they are old enough to have developed a resistance to the roundworms. In actual practice it has been found that pigs 4 months old are highly resistant to ascarid infestation, and if raised free from worms up to that period they will continue to develop normally.

The method of handling sows and pigs so as to reduce infection with roundworms is briefly as follows:

Before farrowing time all litter is removed from the farrowing pens. The sides and floors of the pens, which should be of sanitary construction, are thoroughly scrubbed with boiling water and lye. (Fig. 196.) Before being placed in the clean pens and several days before farrowing, the sows are washed with soap and water, particular attention being paid to washing the udders thoroughly. This removes, for practical purposes, the worm eggs and disease germs which may be swallowed by the young pigs with the first few mouthfuls of milk. After farrowing, the sow and pigs are not allowed out of the farrowing pens until they are taken to pasture. When the pigs are about 10 days old the sow and litter are hauled to pasture in crates on a sled which may be backed to the door of the pen. (Fig. 197.) The pasture should not be a permanent pasture, but one that has been under cultivation and sown at the proper time to a suitable forage crop, preferably a legume crop, and no other pigs should be allowed access to it. The pigs are thus kept away from contamination until they are at least 4 months old, after which they are not likely to suffer seriously even though exposed to worm infestation.

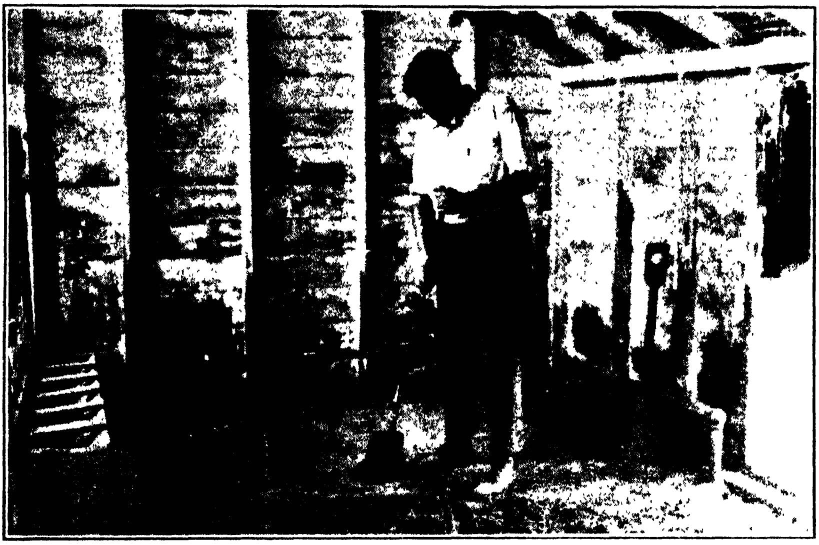

FIG. 196.—Cleaning farrowing pen. Note guard rail which aids in saving pigs. Following cleaning of the pen, it is disinfected and the sow is washed thoroughly. Thus the pigs when born have slight chance of acquiring roundworm infection

### Prevents Other Filth-Borne Diseases

In actual practice if pigs are reared in accordance with the precautions outlined above, they not only escape infestation with the roundworm, but they are also likely to escape many other filth-borne diseases, such as bullnose, sore mouth, and certain forms of diarrhea. This system of swine management should not be depended upon as a preventive of hog cholera, and hence hog-cholera immunization should be continued in accordance with the approved methods of hog-cholera control.

When the system of raising swine so as to reduce roundworm infestation was first put to an actual test under farm conditions in McLean County, Ill., 20 farmers cooperated during the first year. During the third year about 10,000 pigs were raised in the same county under this system. In 1925 more than 600 farmers in 61 counties in Illinois used the system and reported that they raised more than 90 per cent of their pigs. The pigs averaged 7.1 pigs per litter when 4 months old, in comparison with litters averaging 5.1 pigs when raised without precautions to reduce roundworm infestation. The average weight of pigs raised under the sanitation system in 1925 in McLean County was 96 pounds per head when 4 months old, whereas pigs of the same age raised without special regard to sanitation averaged only 68 pounds per head in the same localities. In 1926 about 1,000 farmers in 78 counties in Illinois, about 200 farmers in Nebraska, and many farmers in Iowa and in other regions in the Corn Belt were raising pigs in accordance with the plan described. This system of swine management is now being experimentally developed in the South by the Bureau of Animal Industry.

FIG. 197.—The sow and young pigs are hauled to a pasture recently sown to a suitable forage crop. and no pigs from worm-infected lots are allowed in the pasture

Briefly the results have demonstrated that enormous losses among pigs, caused by deaths in infancy and by stunting as a result of disease early in life, are preventable by a feasible system of sanitation. This has had a beneficial effect on the swine industry by restoring the confidence of farmers and has convinced them that swine management based on sanitation is a successful and profitable undertaking.

BENJAMIN SCHWARTZ.

## SAUSAGE—the Real and the Imitation Kinds

In preparing the carcasses of meat animals for the market, there are produced large quantities of materials which are best utilized in the form of sausage and other prepared products. Conversion of such materials into a tasty and nutritious product such as sausage is not only an important source of profit to the establishment but is of economic importance and of substantial benefit to producer and consumer alike.

There are, however, certain practices connected with the manufacture of sausage and meat food products which are of doubtful benefit to the producers, the consumers, or even to the manufacturers themselves. These practices involve the manner of utilizing organs and parts possessing inferior palatability and food value, the use of flour and other binders, the addition of excessive water, and the dyeing of casings.

Since the ingredients of sausage and other products resembling sausage, such as "imitation," are ground fine, it is possible to utilize, without ready detection by consumers, a considerable proportion of organs and parts not commonly used for food as such. Organs and parts of this type are not recognized as meat in the true sense of the term but as "meat by-products." By chemical analysis such organs and parts are found to contain somewhat less protein and considerably less fat than is contained in meat. Their food value is inferior to that of meat for the reason that their protein is largely incomplete and can not, therefore, be used in its entirety for the repair of body waste or the building of new tissue.

### Why Cereals and Water Are Added

On account of lack of flavor and lack of suitable binding qualities it is not possible to make from meat by-products an article simulating sausage which is acceptable to consumers without the use of a certain proportion of meat. By the addition of cereal or vegetable flour as a binder the proportion of meat by-products may be increased. When meat by-products are used in any large proportion it is also necessary to incorporate a considerable quantity of water in addition to that normal to the meat and products used in order to make a product of acceptable consistence. The addition of flour and water can not be detected by ordinary physical examination, although the appearance of smoked and cooked products differs from that of sausage made wholly from meat in that the imitation product does not develop that rich color in smoking which is characteristic of sausage consisting of meat. With the application of artificial color to the casings this difference is made to disappear.

Sausage of good grade made wholly from meat may be expected, therefore, to contain more protein, more fat, and less added water than the product made in part from meat by-products and containing cereal as a binder. The difference in food value is greater than that shown by analysis on account of the fact that the proteins of the high-grade product are complete proteins and can be utilized by the body for the repair of waste and the building of new tissue, while the proteins of the inferior product are in part incomplete and therefore are not utilized by the body to the best advantage.

### Comparison of High-Grade and Imitation Sausage

It is contended by some manufacturers that the utilization of organs and parts not commonly used for food of and by themselves together with cereal and large quantities of added water is justifiable because it furnishes a supply of wholesome and nourishing product at a low price to consumers who can not afford to purchase meat. In view of this contention the following comparison of five typical samples of Frankfurter-style sausage of the highest grade and nine typical samples of product made in imitation of Frankfurter-style sausage illustrates the doubtful degree to which the manufacture of imitation product is beneficial to the consumer:

Fig. 198.—Portion of a Federal meat-inspection laboratory. Trained chemists readily determine the true value of many meat products and ingredients submitted for analysis

TABLE 21.—*Comparative cost and value of Frankfurter-style sausage and of "imitation"*

| Item | | Genuine Frankfurter-style sausage; average of 5 samples | Product made in imitation of Frankfurter-style sausage; average of 9 samples |
|---|---|---|---|
| Cost of materials | per pound | $0.098 | $0.052 |
| Selling price: | | | |
| Wholesale | | $0.24 | $0.17 |
| Retail | | $0.32 | $0.25 |
| Analysis: | | | |
| Moisture | | 56.4 | 65.4 |
| Fat | | 24.3 | 12.1 |
| Protein | | 14.5 | 13.3 |
| Added water | | 1.2 | 12.1 |
| Calories | per pound | 1,259 | 813 |
| Cost of 1 ounce protein: | | | |
| At wholesale price | | $0.109 | $0.079 |
| At retail price | | $0.136 | $0.113 |
| Cost of 100 calories: | | | |
| At wholesale price | | $0.019 | $0.021 |
| At retail price | | $0.025 | $0.031 |

Comparison of the results of chemical analysis shows that the difference in the percentage of protein contained in the two types of product is not great. The high-grade sausage has a slight advantage in the actual proportion of protein but this advantage is not enough to overcome the difference in the selling price. The cost of an ounce of protein in the form of imitation product is slightly less than in the form of genuine sausage. Comparison on the basis of protein alone is not fair to the high-grade product, since the imitation product contains a substantial proportion of incomplete protein which is of less food value than the complete protein in the high-grade product.

### Superior Product Shows Its Worth

The percentage of fat in the genuine sausage is more than twice that in the imitation product. This difference is further shown by the comparison of calories per pound and cost of 100 calories. It may be noted that the sums of the percentages of water and fat in the two classes of product are nearly equal, as also are the sums of the percentages of fat and added water. This shows substitution of water for fat through the use of materials low in fat and muscle tissue and the addition of water to give the imitation product a consistence similar to that of genuine sausage.

All the products included in the comparison were produced and sold in the same localities and the prices quoted are those prevailing in the same market and at the same time. Three of the five samples of genuine sausage were collected from establishments also preparing imitation products included in the comparison. All the samples were typical of the product represented. The comparison shows clearly, therefore, that the manufacture of imitation product is not so much a means of supplying consumers with a wholesome and nourishing meat food product at a low price as a means of selling water and flour at the price of meat.

Robert H. Kerr.

## SEED Import Control Law Strengthened

Red clover is the most important soil builder throughout the humid regions of the United States outside the Cotton Belt, and alfalfa, long important in the drier areas, both with and without irrigation, is now successfully grown in every State. The United States does not, on the average, produce enough seed of either of these basic crops to meet the seeding requirements and substantial importations of seed from surplus-producing countries are necessary. It is obviously important to safeguard the quality of these imports.

Table 22 shows the imports of seed of red clover and alfalfa by years and countries from which exported to the United States.

**TABLE 22.**—*Alfalfa and red clover seed permitted entry into the United States under the seed importation act by fiscal years and by countries exporting*

[4] All of Chilean origin except 22,000 pounds.

Until about 25 years ago the quality of imported seed of agricultural crops was given little consideration. Seed of yellow trefoil was frequently imported into the United States only to be used as an adulterant of red clover and alfalfa seed.

Through an arrangement with the United States Customs Service, samples of all imported lots of forage-plant seeds have for many years been furnished to the United States Department of Agriculture for examination for quality. When these examinations were begun many importations were found to be worthless for seeding purposes, as they were composed largely of screenings which did not find a ready market in Europe, although this material was imported into the United States to be sold to our farmers. The country which does not scrutinize its imports naturally gets the poorest the world has to offer in seeds, as in other commodities.

A series of purity and germination tests of alfalfa and red clover seed imported during 1906 showed many lots containing large proportions of weed seeds, the live seeds present being small and shriveled and some lots contained few or no live seeds. Public sentiment at that time was concerned mostly with adulteration and the presence of weed seeds, and relatively little attention was given to germination.

The seed importation act of August, 1912, was intended to prohibit the importation of adulterated forage-plant seeds as well as those containing large proportions of weed seeds. It prohibited the importation into the United States of the seeds named in the act when adulterated or when they contained more than 3 per cent of weed seeds, and seed of clover and alfalfa when it contained more than 90 seeds of dodder per pound. Dodder was particularly discriminated against, as it is a destructive parasite in both clover and alfalfa fields. The effect of this act was to keep out of the United States the weedy screenings of alfalfa and red clover which had previously been imported. It did not, however, prevent the importation of seed which was dead, when it was relatively free from weed seeds, nor the importation of orchard grass and other kinds of chaff containing little or no seed, although these commodities could only be used for purposes of adulterating farm seeds.

### Proportion of Pure Seed Required

On August 11, 1916, the seed importation act was amended by requiring that each lot of bluegrass imported should contain at least 50 per cent of live pure bluegrass seed and that each lot of other kinds of seeds should contain at least 65 per cent of live pure seed of the kind imported. Although these requirements are low, there have been shipments of most of the kinds of forage-plant seeds subject to the act prohibited entry into the United States on account of low germination. .

Imported forage-plant seeds that are not fit for seeding purposes, within the meaning of the act, can not now be brought into the United States and sold to our farmers.

In recent years, the question of adaptability of forage crops has been given increasing attention. Comparative tests carried on in many States and extending over a period of years shows that the expected crop is largely dependent on the region of production of the seed. The most extensive work along this line has been carried on with red clover and alfalfa. It has been shown that red clover seed from Italy is strikingly unadapted to general use in the United States, as is alfalfa from Turkestan and South Africa. The belief in the superiority of domestic seed and the wide difference in adaptability of imported seed from various sources of production has so influenced the seed market that domestic seed often has a market value one and one-half times that of imported seed. This has resulted in much imported seed of red clover and alfalfa being sold to farmers as domestic seed and at the price of domestic seed. The situation was most unsatisfactory, both from the standpoint of the farmer and the honest seed merchant. The only way in which it could be effectively remedied seemed to be to provide a method by which the ultimate consumer, the farmer who sows the seed, would always have certain definite information as to its origin, which information would be carried by the seed itself.

### Seed Must Be Colored

With a view to making information of this kind available, the seed importation act was again amended April 26, 1926, providing that all seed of alfalfa and red clover be colored at the time it comes into the country. Ten per cent of all the seed from those regions which the Secretary of Agriculture has found to produce seed unadapted to general agricultural use in the United States, as well as seed of unknown origin, will be colored red. One per cent of seed from Canada will be colored violet, and 1 per cent of seed from other regions will be colored green.

This coloring will be done with alcohol-soluble stains, and if in any case there is doubt as to whether the seed has been stained, the fact can easily be determined by putting a tablespoonful of the seed in half a glass of wood alcohol or denatured alcohol and stirring it. The alcohol will show the characteristic color if the seed was imported.

This coloring provision with respect to imported alfalfa and red clover seed will automatically provide without expense a nationwide field test as to the crop-producing value of imported and domestic grown seed.

All but five States within recent years have passed laws regulating the sale of agricultural seeds within those States. A State can not control the movement of agricultural seeds into the State, so without reference to State laws and in the absence of Federal legislation it has been possible for a seed merchant in one State to ship into another State agricultural seeds which were prohibited sale in the State into which they were shipped. In order to supplement State laws with respect to interstate shipments of agricultural seeds, the seed importation act, as amended April 26, 1926, makes any seeds which are wilfully misbranded and shipped in interstate commerce subject to seizure and confiscation.

### Farmer Has More Protection

The Federal seed act, the title under which the seed importation act, as amended, is now known, gives the American farmer a greater measure of protection with respect to imported forage-plant seeds than he is given with respect to the same seeds of domestic production.

All seeds subject to the act meet the following requirements before they are permitted entry into the United States:

1. Contain not to exceed 5 per cent of adulterants.
2. Contain not to exceed 3 per cent of seeds of weeds.
3. Contain not to exceed 90 seeds per pound of dodder in the case of clover and alfalfa.
4. Contain not less than 65 per cent of live seed of the kind. In the case of bluegrass 50 per cent.
5. Seed of alfalfa and red clover will be colored to indicate origin, as follows:
   (*a*) Seed declared by the Secretary of Agriculture to be unadapted to general use in the United States and seed of unknown origin will be colored 10 per cent red.
   (*b*) Seed from Canada 1 per cent violet.
   (*c*) Seed from all other sources 1 per cent green.
6. Seed shipped from one State to another will be subject to seizure and confiscation if wilfully misbranded.

In short, all imported seed subject to the Federal seed act will be fit to sow. The colored seed in alfalfa and red clover will indicate its origin. State laws regulating the sale of agricultural seeds will be supplemented by preventing wilfully misbranded seeds from being shipped from one State to another.

EDGAR BROWN.

## SEED Improvement Associations in United States

Seed improvement has been one of the most important aids in recent years in obtaining larger yields and more economic production. Getting good seed into general use in any community has depended largely on four main things: (1) Development in the State of new varieties of crops, or the improvement of old varieties already in use, (2) determination in what section of the State these varieties are best adapted, (3) development of adequate seed supplies of such varieties locally within the community, the county, or the State, and (4) a well-organized means for the distribution of improved seed supplies, so that many farmers can readily obtain the improved seed.

FIG. 199. Field inspection of potatoes at blooming stage for mixture of varieties

The developing of new varieties or improvement of old varieties is mainly done by the State experiment stations cooperating with the United States Department of Agriculture. The Federal and State experiment stations work with the cooperative extension service in studying and determining the localities to which the new and improved varieties are suited. Developing supplies of seed of these varieties adequate to meet the demand of farmers wanting such seed can not be handled by the experiment stations, since their work is restricted to investigation. This has led in a number of States to the development of a State seed-improvement association composed of active farmers cooperating with the extension service. The distribution of seed, it has been found, is best carried on by the State or seed-improvement association, although their main purpose is to standardize production rather than to serve as marketing agencies.

The business transactions of the association are carried on by the officials of the association, dealing direct with the organized seed trade, farmers' cooperative organizations, or individuals wishing to obtain improved seed.

The organization of State seed or crop-improvement associations has been the outstanding development in the program for getting improved seed used in new communities. The associations owe their existence very largely to the activity of extension workers working with their respective State experiment stations on a crop-improvement program. Such associations have been developed and are in operation in 34 States. Through cooperation with such associations it is possible for the extension service to take the improved seed that has been developed in a limited quantity by the experiment station, have it grown under careful supervision, kept free from varietal mixtures, noxious weeds, and injurious diseases, and save the largest possible quantity of this seed for distribution to the farmers in various communities of the State.

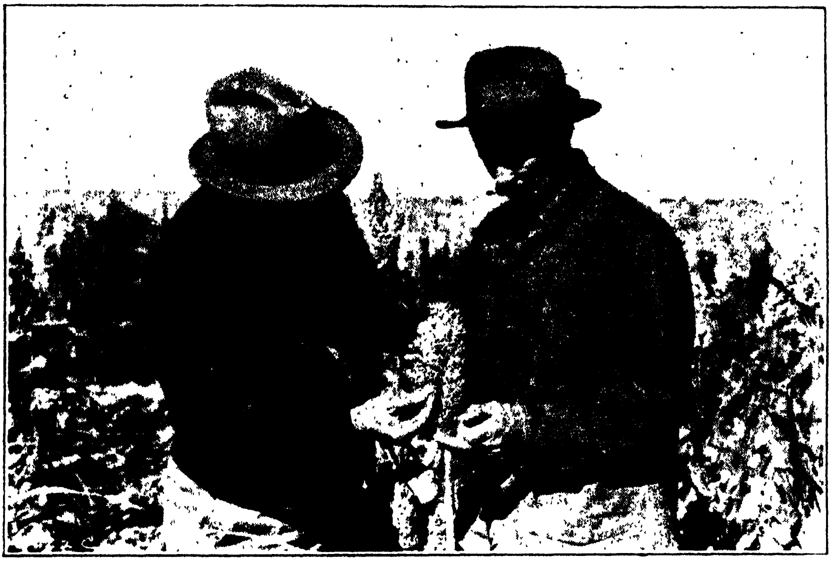

FIG. 200.—Field inspection of corn for off type plants

### Standardization of Varieties

In a number of States the crop-improvement program is based largely on the standardization of the best varieties of grain grown in the State. Such standardization has been found practical only when the State seed or crop-improvement association has cooperated closely with the extension service and the experiment station. For example, Oregon reports as high as 90 per cent of the entire wheat acreage in some of its eastern counties is seeded to one variety. In Maine, where seed-improvement work in growing potatoes was started in 1922 by the experiment station and the extension service, 65 per cent of the total acreage of potatoes in the State is now reported seeded to improved varieties.

Through the development in recent years of seed-improvement work, farmers have been able to put to much wider practical use the results of the work carried on by the experiment stations in developing and improving crop varieties. The State experiment stations can not enter the commercial field. Neither do their funds and limited facilities permit of developing more than a limited supply of seed of any one crop. Through the cooperation of the extension service and the State seed-improvement associations this deficiency is being supplied and adequate supplies of good seed have been provided in several thousand communities where a farmer, if he desires, can now obtain pure seed of approved varieties at a reasonable price.

O. S. Fisher.

## SEED Records Win Support of Seedsmen

In the days of kerosene lamps and of planting potatoes by the light of the moon, seeds were sold like salt and coal. Nature produced the seeds, so why try to change them. That apparently was the theory on which early seed dealers worked. So long as the seeds were plump and of good color, no further questions were asked. Time, however, has wrought changes, slowly at first but rapidly in comparatively recent years. The "appearance" stage was followed by the "purity and germination" stage and finally by the "origin" stage. To-day, of course, the finished product embodies the best things in these stages and they are rapidly being amalgamated in such a way that seeds are coming more and more to be sold on an intrinsic-value basis.

### Farmer Now Has Truer Yardstick

Seed laws, tests conducted by State colleges and experiment stations and the United States Department of Agriculture, and higher prices for seed, land, and labor have paved the way largely for this metamorphosis. The farmer has kept his eyes and ears open and is demanding better and better seed. He now has a truer yardstick with which to measure the real value of seed.

The progressive seedsman has not stood idly by, but has changed his business to meet changing conditions. To be in a position to supply information quickly and accurately regarding origin, he has found it necessary to keep more and better records. Of course there are other reasons for keeping records but perhaps nothing in recent years has contributed more to impressing upon seedsmen the importance of stock records than has the agitation regarding origin.

### Lots Are Bulked Together

The modern seedsman bulks 2 to 25 or more lots together, usually before recleaning, because he finds it advantageous to do so. Upwards of 5,000 country lots of seed may be received by the larger seedsmen in a season. It would be impracticable to sell these lots separately for a number of reasons. Most of these seedsmen, however, can tell from their bulking, milling, or dump records which lots were used in making up a given bulk lot.

With the finding that origin of growth of certain kinds of seed is of great importance has arisen the problem of verifying origin.

Although the presence of certain weed or other seeds, or of inert matter characteristic of the region in which a given kind of agricultural seed has been produced, frequently furnishes a clue to the source or origin of this seed, such examination is futile in too many cases.

The Bureau of Agricultural Economics has given considerable study to this problem during the past year. About 60 seedsmen have been visited and approximately 250 record forms have been obtained from them. These forms have been studied and some of the best features have been incorporated in tentative forms, such as receiving, milling, stock, and invoice records. This bureau has reached the conclusion that a system of records which preserved the identity of seed from the time it entered the seedsman's warehouse, together with outside—preferably voluntary—supervision, would go a long way toward insuring that the correct information as to origin would be passed on to the buyer.

### Verification System Practicable

That a system of verification of origin based on stock records is practicable, is evidenced by the fact that fully 90 per cent of the progressive seedsmen are now keeping complete stock records. The second seed marketing conference held November 30, 1926, in Chicago, the International Crop Improvement Association at its annual meeting the following day, and the Wholesale Grass Seed Dealers' Association at its midwinter meeting the following week indorsed the studies on seed-stock records that this bureau has made and recommended that they be continued, and that this bureau devise a complete system of inspection and verification of stock records of seed handlers wishing to sell "verified-origin" seed.

The big objective of this whole movement is to improve the marketing of certain kinds of seeds, principally alfalfa and red clover, the origin of which is of considerable importance. Staining, as provided for under the amendment to the seed importation act, protects the alert buyer against the substitution or misrepresentation of foreign red clover or alfalfa for domestic seed. It is just as important, if not more important, that he be protected effectively against misrepresentation of domestic seed. The buyer is entitled to know where the seed which he is buying, whether it be imported or domestic, was produced.

The Bureau of Agricultural Economics will issue in the near future revised forms for receiving, bulking, and shipping records, which, together with the sample of seed and the lot number on the tag, would provide a chain of evidence that would afford an effective check on statements of origin. These forms would tend to stimulate interest in the keeping of better records and to bring about greater uniformity in those being used by many seedsmen. Seed bearing a "verified-origin" tag doubtless would command a premium sufficient to cover possible additional expenses in the keeping of records and costs of inspection or supervision. This would tend to facilitate the distribution of seeds adaptable for the various States to the betterment of the agriculture of the country.

### SHEEP Acres Test Pastures at Beltsville

Sheep Acres is the name used to designate a portion of the animal husbandry experiment farm at Beltsville, Md., which has been set aside for the study of sheep production under intensive conditions typical of the South Atlantic region of the United States. This tract, consisting of approximately 100 acres of tillable land, has been improved with a well-planned system of pasture rotation and modern sheep equipment. (Fig. 201.)

Although there had been some sheep at the Beltsville farm since 1911, the work as now outlined was begun in the fall of 1915, when 53 purebred Southdown ewe lambs, bred at the United States Morgan Horse Farm, Middlebury, Vt., were shipped to Beltsville.

#### Advantages of Forage-Crop Pastures

One of the main lines of work conducted at Sheep Acres is the development of a practical system of forage-crop pastures whereby sheep can be pastured longer and moved from field to field more often than when kept by the usual permanent-pasture method. This makes it possible to keep the farm flock on less cured feed, which is rather expensive in this region. In addition, sheep can be kept in larger numbers on a given area, because the danger of serious infestation and loss from internal parasites—one of the principal drawbacks to the sheep industry along the eastern seaboard—is greatly reduced. The results of this work are discussed in Farmers' Bulletin 1181, "Raising Sheep on Temporary Pastures."

FIG. 201.—General view of Sheep Acres, a 100-acre tract devoted to sheep experiments at the animal-husbandry experiment farm, Beltsville, Md.

Another problem of general interest which is being studied at the farm is the effect of different degrees of nourishment of the ewes at breeding time on the percentage of twins in the lamb crop. Results covering 10 years' work show an advantage of 16 lambs per 100 ewes in favor of the highly nourished ewes compared with those kept on short feed during breeding season. Work on this experiment is reported in Department Bulletin 996, "Flushing and Other Means of Increasing Lamb Yields."

#### Growth of Lambs Studied

The study of various phases of growth in lambs is another problem being investigated at Sheep Acres. Weekly weighings are made on all lambs until 1 year of age and all mature stock is weighed at intervals of two weeks. Studies are made on the growth of lambs as related to birth weight, gain of dam during gestation, weight and age of dam, and size of sire. Further data are also obtained from periodical measurements on representative lambs of each of the breeds. These data consist in measurements of width and depth of chest, length from shoulder to hip, circumference of the middle of the body, and length from nose to the end of the tail dock.

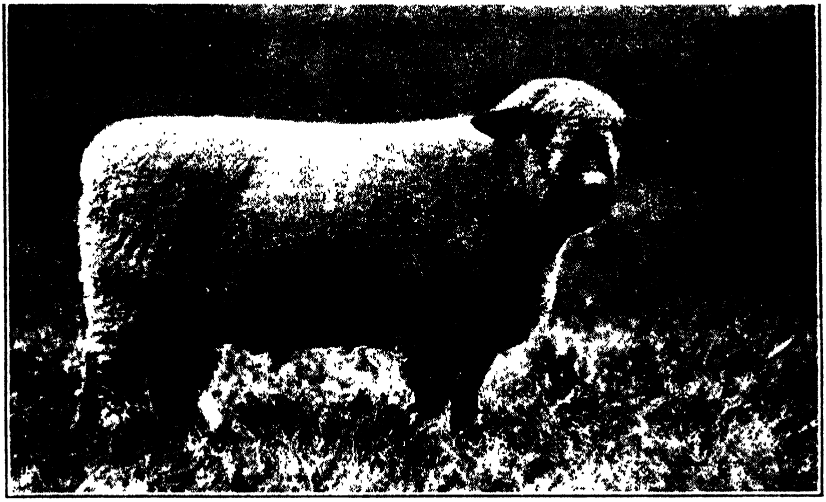

FIG. 202.—Hampshire stud ram used at Sheep Acres

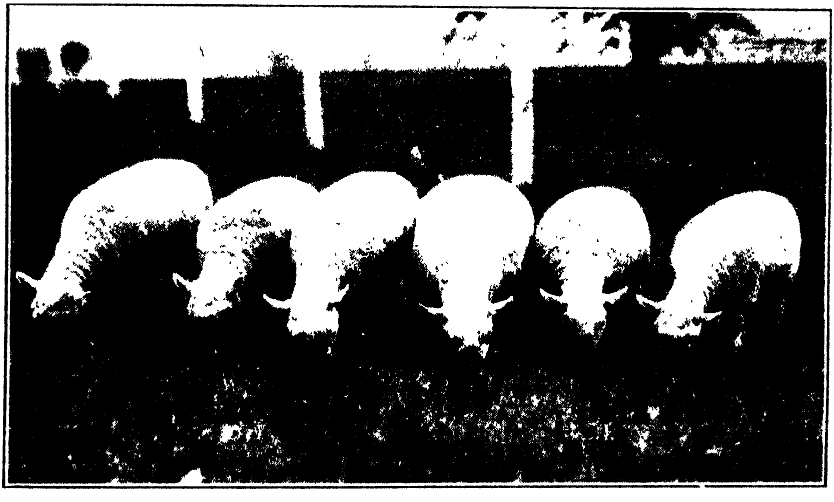

FIG. 203.—Yearling ewes of the Southdown breed, raised at Sheep Acres

Type fixing in purebred sheep is carried on at this station by selective breeding. The matings are made as a result of information obtained from the bureau's scoring system, which consists of five numerical scores on the mutton conformation and five scores on the wool of each individual sheep. Corrections are attempted in the matings by use of rams which show by their offspring that they are especially excellent in their ability to transmit characteristics in which a ewe shows, by her offspring, that she is lacking. Controlled breeding is practiced and by using a rather large number of tested sires much has been accomplished in the elimination of undesirable characteristics in the progeny.

### How the Flocks Are Improved

The flocks at Beltsville, December 1, 1926, consisted of 48 Southdown, 30 Shropshire, 27 Hampshire, and 30 Corriedale ewes of breeding age, 12 stud rams, 30 ram lambs, and 40 ewe lambs of the various breeds. These flocks are maintained on a basis of one-quarter replacement each year by the addition of ewe lambs produced at the farm.

Room is made for the ewe lambs by the selection of ewes of various ages for disposal each year. None of the best ewe lambs are ever sold. By this process it has been possible to set the type and fix the characteristics of each of these flocks far beyond what the average sheep breeder can do if he depends on apparent individual excellence of the breeding stock rather than on a careful study of the strong points and weaknesses in breeding ability of individual sheep as shown by their offspring.

C. G. Potts.

## SHEEP Experiment Station at Dubois, Idaho, is Unique

In 1915 President Wilson signed an Executive order creating a reservation of 28,160 acres of sheep-grazing land near Dubois, Idaho. This land was an undeveloped sagebrush range typical of vast areas of the intermountain regions of the West, where about half of America's sheep are produced. Congress then appropriated funds for the establishment of the United States Sheep Experiment Station on this tract. (Fig. 204.) In 1917 a band of about 1,000 Government-owned sheep began grazing there, and the construction of the necessary equipment was begun.

Most of this reservation lies far from running streams or any other natural body of water, so that the first important step in the development work was the digging of a well. The elevation at headquarters, where the well had to be dug, is more than a mile and the soil is of lava-rock formation. In order to insure an abundant supply of good water the well was dug through rock to the depth of 750 feet.

After the construction of necessary barns, silos, houses, and water reservoirs and the building of 40 miles of fencing a definite program of experiments in the problems of range-sheep men was promptly put into operation.

It was found necessary to have an area for summer grazing definitely assigned to the station. For this purpose President Harding, in 1922, signed an Executive order setting aside 16,650 acres near the Continental Divide, about 40 miles northeast of Dubois, for use in summer grazing experiments with sheep, making a total of 44,810 acres for range-sheep experiments, all within 60 miles of Yellowstone National Park.

### Results Apply to Practical Range Problems

All operations at this station are kept in line with good range practice, and the results of the experiments apply directly to the practical problems of sheep producers, especially of the intermountain ranges. Approximately 16,000 acres were fenced in the fall of 1920, thereby excluding all roaming livestock from that area. During the next five years an average of 3,100 sheep were grazed on the area each spring and fall for a combined season of 120 days. During this five-year period grazing was not started quite so early in the spring as formerly, and the camps and temporary watering places were moved frequently to avoid overgrazing local areas. In June, 1925, a careful survey was made of the vegetation and its grazing value on this protected area and on similar but unprotected grazing lands just outside the fenced area. It was found that the protected area had a carrying capacity of 160 sheep per square mile for a 120-day period and the unprotected range a capacity of only 135 sheep per square mile for the same period. Thus the protected range was 18.5 per cent better than the unprotected range as a result of controlling the number of sheep and the use of the range during a more appropriate grazing season.

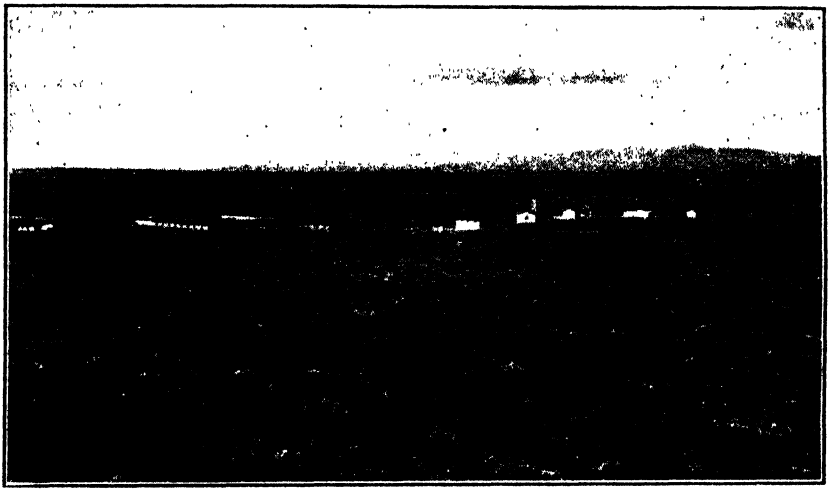

FIG. 204.—Headquarters of the United States Sheep Experiment Station at Dubois, Idaho. The foreground shows the sagebrush type of range where the sheep graze during the spring and fall. In winter they are trailed 40 miles to the deep, protected canyons of the mountain ranges in the background

### Columbia Breed of Sheep Developed

The development of the Columbia breed of sheep is another result of the station's work. The foundation of this breed is the Lincoln-Rambouillet crossbred. The crossbred ewes have been mated continuously with crossbred rams, until now the type is fairly well established. The Columbia sheep yield heavier fleeces and heavier lambs than any other breeds tested under similar conditions by the department. Other experiments show that Rambouillets yield good feeder lambs and excellent, fine wool, and that Corriedales produce splendid quality in both lambs and wool.

One outstanding discovery in the station's wool experiments is the fact that length of staple in Rambouillet fleeces has a very important influence on the total weight of clean wool. Recent results show that on a normal market each addition of 1 inch in the length of staple results in an increase of from $1.25 to $1.50 per fleece. Western woolgrowers who keep sheep by the thousands are finding such information of great practical benefit.

Lamb-production experiments show that the use of Hampshire rams with Rambouillet or Corriedale ewes under conditions of the intermountain range results in lambs of greater weight than purebred Rambouillet or Corriedale lambs at market age. However, Corriedale lambs have averaged the higher in quality of meat produced. A band of 1,200 ewes is used in this experiment.

FIG. 205.—A band of Corriedale and Columbia ewes on spring range just before "bedding down" at sundown. The camp wagon is the herder's home

### Annual Field Day Held

Each spring a field-day meeting is held at the station and is well attended by stockmen and workers of the surrounding States. Shearing is then in progress and the results of the various experimental projects are demonstrated. The visitors go out over the range and see at first-hand how the grazing value of range vegetation can be improved and how the usefulness of dry ranges may be extended by methods of supplying stock water. Displays of mounted plants tell important stories about the forage resources of the ranges. Graphic charts and tabulations on exhibit at the sheep pens tell facts of practical application illustrated by the sheep themselves. State and Federal investigators also discuss at this meeting the technical phases of the work and exchange views on plans for future work.

So far as department workers are able to learn, the United States sheep experiment station is the only experiment station in the world that is devoted entirely to the solution of sheep problems under practical range conditions. It is dedicated to a study of the efficient use of intermountain ranges which are adapted only to grazing purposes—a conservation measure of national importance.

## SHOE Soles From "Bend" of Hides Most Durable

Our bill of about $1,500,000,000 for over 300,000,000 pairs of boots and shoes each year makes the quality and wear of shoe soles a matter of real economic importance, both individually and collectively. Most of our shoe soles are made of leather. As the result of various factors, however, leather soles are not all alike in either composition or wear.

### Thickness

Quite naturally the wear of a pair of soles depends largely upon their thickness. In general, thick soles are made from the best heavy steer hides, as distinct from the lighter-weight cowhides, from which many thin soles are obtained. Thick soles contain more leather substance, generally of a better fiber, and not only last longer but afford more protection to the feet against the weather and against injury from pebbles and rough surfaces.

In the leather trade the thickness of soles is measured by a unit known as the "iron," which is one-forty-eighth of an inch. Consequently one-quarter of an inch is 12 irons. The United States Army specifies outsole leather of part of hide used at least 9 irons for soldiers' shoes.

Another important factor in the wear of soles is the part of the hide from which the leather is cut. Experimental work done in the Bureau of Chemistry indicates that this is more vital than the kind of leather, so far as the present-day tannages, such as oak, union, or hemlock, are concerned. An animal's hide varies widely in texture and fiber. Consequently some sections of it make much better leather than others. The sections into which sole-leather hides and "sides" are divided are the head, shoulder, bend, and belly, as shown in Figure 207, which is an outline of a side, or one-half of a hide, obtained by splitting the hide down the backbone line. Hides are usually split this way before tanning. The bend is about 48 per cent, or very nearly one-half, of the side; the belly is about one-fourth; and the shoulder is about one-fifth.

### Soles That Give Greatest Wear

The best-wearing soles are cut from the bend, approximately a rectangle of leather extending 50 to 55 inches from the root of the animal's tail toward the head and about 25 inches from the backbone line toward the belly. The exact size of a bend is determined by the "breaks," or soft spots, at the fore and hind flanks. The cut that separates the bend from the belly is nearly parallel with the backbone edge and passes through the top of the two "breaks." The cut that divides the bend from the shoulder meets the belly cut at the "break" at the fore flank.

Bends of sole leather can often be seen in shoe repair shops. The leather in the bend is dense, firm, and thick fibered; that in the belly is flabby and more open fibered. Wear tests conducted by the Bureau of Chemistry have shown that soles from the bend wear about twice as long as soles from the belly and nearly one and one-half times as long as those from the shoulder. Often when one sole of a pair of shoes wears out very much faster than the other it is because the poorer sole was cut from a poorer section of the hide.

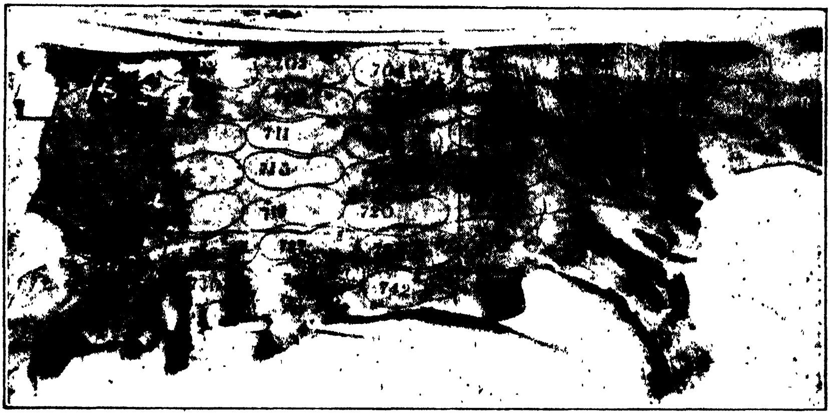

FIG. 206.—Sections of a side of sole leather

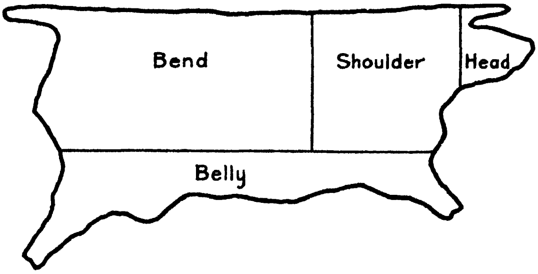

FIG. 207.—Layout of test soles for determining the wear of different parts of the hide

### Tannage Used

A third important factor in the wear of soles is the kind of leather. The sole leather that the public knows best is vegetable tanned. It is made by treating hides with infusions and extracts of barks, woods, nuts, and leaves, all products of the vegetable kingdom, which is responsible for the name, "vegetable-tanned leather." Its natural color is tan, varying in shades from fawn to reddish brown, depending upon the materials used and the treatment.

Among other tanning processes is one known as mineral tannage, in which products of mineral origin are used. The most important and most widely used mineral-tanned leather is called "chrome leather," which is tanned with chromium chemicals. Although chrome leather has been made for 20 years or more, it is extremely modern as compared with vegetable-tanned leather.

Most shoe upper leather of to-day is chrome tanned. Practically all such leather is dyed, but often the natural and very characteristic pale blue to green color of chrome leather can be seen by closely examining an exposed edge.

At present the quantity of chrome sole leather made is relatively small. Natural or unwaxed chrome sole leather is used to some extent on gymnasium and other athletic shoes for indoor wear. Unwaxed chrome soles are very porous and readily absorb moisture, which makes them unsuitable for outdoor use except in dry regions. To increase its water resistance and thus make it more suitable for general wear, unwaxed chrome sole leather is filled with waxes and oils, producing what is known as "waxed" chrome, which is generally dark green or nearly black. Such leather is used to some extent in men's and boys' shoes and in work shoes.

### Soles That Wear Longest

Recent wear experiments conducted by the Bureau of Chemistry with soldiers and civilians show that unwaxed chrome sole leather is the longest wearing sole leather made. Waxing to impart water resistance sacrifices some of the wear, but even then the resulting product wears longer than vegetable-tanned sole leather.

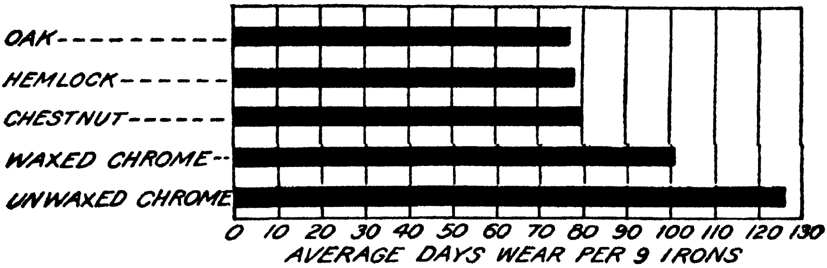

FIG. 208.—Summary of wear tests on Army shoes soled with different kinds of leather

Figure 208 graphically summarizes the results from a set of experiments conducted with soldiers. The days' wear for a standard thickness of 9 irons is directly proportional to the length of the heavy black line. For these experiments all soles were cut from bends. Unwaxed chrome soles showed an average wear of 126 days and waxed chrome soles one of 102 days. Vegetable-tanned sole leathers, of oak bark, hemlock bark, and chestnut wood tannages, showed from 78 to 80 days' wear. These experiments showed also that loading such leathers with glucose and epsom salts adds nothing to their wearing quality.

Chrome sole leather presents some difficulty to the shoe manufacturer, often requiring special handling through certain factory operations. It is sometimes slippery and has a tendency to spread, producing an uneven and slightly frayed edge. Although at first it is rather stiff, especially if heavily waxed, the stiffness usually disappears after a little wear. Chiefly for such reasons chrome sole leather has not been more generally adopted by the trade. Chrome soles are particularly serviceable when wear and not extreme refinement in appearance is the first consideration, as, for example, in men's outing and work shoes and in boys' shoes.

Recently efforts have been made to combine the desirable properties of vegetable-tanned leather and of chrome-tanned sole leather in a product known as chrome retan leather. In this process the hides are first tanned with chromium and then retanned with vegetable materials. Experiments are now under way to determine the relative merits of such a leather for shoe soles.

**SIRUP "Sugaring" Preventable by Use of Invertase** Cane sirup and sorgo sirup often "sugar," or crystallize, and sometimes maple sirup does. The principal sugar of these three sirups, and the one which separates during crystallization, is cane sugar, the chemical name for which is sucrose. Crystallization occurs when the quantity of this sugar in the sirup is too great to dissolve in the water present at the prevailing temperature. Sucrose is less soluble in cold than in warm weather. The presence of crystals of sugar gives sirup an unsightly appearance, which often detracts from its market value. Unfortunately, the thicker sirups preferred by many people have a greater tendency to undergo crystallization than those of more common density. The crystallization of sugar also increases with the ratio of sugar to the total solid material in solution in the sirup. This ratio increases with the degree of maturity of the sorgo and sugar canes and is generally higher in first-run maple sap than in last-run sap.

If a portion of the cane sugar (sucrose) is transformed into invert sugar the tendency to crystallize is greatly reduced. Advantage may be taken of this fact to prevent crystallization, even in very thick sirups. "Invert sugar," a mixture of the two sugars dextrose and levulose in equal parts, has about the same degree of sweetness as sucrose. The transformation of sucrose into invert sugar is called "inversion" and has practically no effect on the sweetness of sirup.

Some invert sugar is normally present in cane and sorgo juices and in maple sap. Sorgo juice contains more invert sugar than cane juice, which, in turn, contains more than maple sap. The standards of the Federal Government and of most States require that not more than 30 per cent of water be present in cane and sorgo sirups and not more than 35 per cent in maple sirup. If sirups contain no more than these specified amounts of water, crystallization of sugar does not often occur. If the sirups are evaporated to lower contents of water, however, sugar usually separates on standing, the crystallization increasing as the water content decreases. Under such conditions there is usually not enough invert sugar present to prevent crystallization and separation of sugar.

Cane and sorgo juices and maple sap contain acids which cause some inversion during evaporation. The amount of cane sugar inverted increases with the time required for evaporation, but it is not advisable to prolong evaporation for this purpose because of its harmful effect on the color and flavor of the sirup. Evaporation should be conducted just as rapidly as possible. Inversion of cane sugar can be increased by adding acid to the juice or sap, thereby preventing crystallization. This is not advisable, however, because of the effect of the acid on the flavor. Fortunately there is another method by which enough cane sugar can be inverted to prevent crystallization without affecting the flavor. This is by the use of invertase, a substance belonging to the type of substances called enzymes that are widely distributed in nature in both plants and animals. For instance, the sugar of the nectar of flowers consists largely of cane sugar which is transformed by bees, by means of the enzyme invertase, into invert sugar, the sugar of honey.

### The Use of Invertase

The Bureau of Chemistry has developed a method whereby the sugaring of cane, sorgo, and maple sirups may be prevented by the use of invertase. Briefly, this method is as follows: In making cane and sorgo sirups it is best to add the invertase at an intermediate stage of the evaporation, say at a density corresponding to about 20° Baumé (when the sirup is about two-thirds evaporated). Invertase is destroyed at fairly high temperatures and should not be added directly to the boiling sirup. The partially finished sirup is allowed to cool to about 150° F., the invertase is added, and the sirup is allowed to stand over night. It is then evaporated the next day to final density. Two evaporators can be used conveniently in the process. This also increases the total daily output and justifies the expense of the second evaporator. One evaporator is used for bringing the partially finished sirup, treated with invertase, to final density while the other evaporator is concentrating fresh juice to partially finished sirup. If the second evaporator does not seem desirable, a single evaporator can be used by discontinuing grinding while the partially finished sirup treated with invertase is being evaporated to final density. A tank is provided for holding the partially finished sirup during the overnight treatment with invertase.

In making maple sirup all that is necessary is the addition of the invertase to the finished sirup as soon as it is cool and at the end of a certain period, depending upon the amount of the invertase added, heating the sirup to about 185° F., so as to destroy the invertase and prevent any further action. If the maple sirup is to be held in bulk before canning, it may receive the invertase treatment during the storage period. The heating required to destroy the invertase may be done at the time the sirup is canned.

Under certain conditions invertase can be added to finished cane and sorgo sirups instead of during evaporation. This is conveniently done in connection with the operation of a canning plant, the sirup being warmed to 150° F., invertase added, and the sirup allowed to stand for about 36 hours, after which it is heated to the required temperature for canning.

The cost of invertase is about one-half cent per gallon of cane and maple sirups and about one-fourth cent per gallon of sorgo sirup. Full directions for using invertase, including names and addresses of manufacturers, may be obtained from the Bureau of Chemistry, United States Department of Agriculture.

H. S. Paine.

**SIZE of Farms Important on Irrigated Land** Size of farm materially influences the effectiveness with which capital and labor can be used in the organization and operation of irrigated farms. Considerable light was thrown on this subject by a four-year study of irrigated farming in southern Idaho, which makes it possible to compare groups of 40-acre and 80-acre farms.

The two groups were classified as "general cash crop farms," very little of the income being derived from the sale of livestock and livestock products. The proportional part of the total farm land of the two size-groups that was tillable or was in crops differed very little. There was some variation in the percentage of the crop area that was devoted to the respective crops during the four years of the study, 1919 to 1922. This, however, is not sufficient to account for the difference in the crop acres handled per horse and per month of man labor used by the two groups.

The following are some of the outstanding points of interest brought out in comparing the results obtained on the 40-acre and 80-acre farms during the four years of the study:

The 40-acre farms had, in round figures, an average of 5 per cent more of the total capital tied up in buildings and equipment than had the 80-acre farms. In other words, a greater percentage of the capital of the 80-acre farm was in land that could be used for producing crops.

The average yield of all crops for the four-year period for the two groups of farms differed but little, the 40-acre farms ranking a trifle the highest. The yields of alfalfa hay, sugar beets, dry field beans, and alsike-clover seed averaged highest on the 40-acre farms, while the yields of wheat, potatoes, and red-clover seed were highest on the 80-acre farms.

### Net Return to Capital

The net return to capital for the four-year period averaged $453 for the 40-acre group and $1,341 for the 80-acre group. That is, the latter is 296 per cent of the former. The average net return to real estate for the period covered by the study was $6.50 per acre greater for the 80-acre farms than for the 40-acre group.

The 40-acre farms kept an average of 3.5 horses per farm, whereas the 80-acre farms kept 4.6. A work horse handled one-half more crop acres on the 80-acre farms than on the 40-acre farms. For each month of man labor used, 2.8 acres of crops were taken care of on the 40-acre farms as compared with 4.2 acres on the 80-acre farms.

Thus, it is evident, 80 acres is a more desirable size for this particular type of farming (general cash crops) in the area studied than is 40 acres. Other things being equal, the acreage devoted to each crop is about twice as large on an 80-acre farm as on one of 40 acres. For this reason practically all field operations can be performed more economically on the former than on the latter. A few illustrations should suffice to make this clear.

Much less time is consumed per crop acre in turning while performing the cultural and harvesting operations on 80-acre farms than on those of 40 acres. It requires about the same length of time to repair the haymaking equipment and assemble a haymaking crew for 15 acres of alfalfa as for 30 acres. One man can irrigate about twice as many acres in a given time on an 80-acre farm as he can on one of 40 acres, because he has twice as large a volume or head of water with which to work. Thus, under general crop farming, the 80-acre farmer can use the various factors of production to better advantage than can the 40-acre farmer.

Byron Hunter.

## SKIM Milk in Dry Form Has Various Uses

Approximately 806,487,000 pounds of skim milk was used in 1925 in the manufacture of over 73,000,000 pounds of dry skim milk. This was approximately 2 per cent of the skim milk resulting from the manufacture of butter.

Although the quantity of milk used in the manufacture of dry skim milk represents but a small percentage of the total milk production, it should be remembered that the manufacture of dry skim milk is one of the more recent developments in the dairy industry. The relatively low production is partly due to a failure to realize the food value of skim-milk solids and the advantages this product possesses over fluid milk.

The conversion of surplus skim milk into the dry product, which can be shipped, stored, and handled with little danger of spoilage, makes dry skim milk valuable from the standpoint of convenience and a ready source of skim-milk supply in various industries wherein its use is advantageous. This is especially true for the nonmilk-producing areas of the country. It offers an opportunity for greater conservation of an excellent food supply for humans and animals and incidentally increases returns to the producer.

### Food Value

An analysis of dried skim milk shows the constituents to be as follows: Proteins, 38 per cent; lactose, 50 per cent; salts, 8 per cent; fat, 1 per cent; and moisture, 3 per cent.

An analysis of average whole milk indicates that the ratio of protein to fat is approximately 1 to 1, while the ratio of sugar to fat is approximately 5 to 3.5. Assuming that each constituent is 100 per cent digestible and assimilable, the relative total caloric value of the constituents as foods would be as shown in Table 23:

Table 23.—*Relative total caloric value of food elements in milk*

| Constituent | Parts per 100 parts of milk | Heat of combustion; calories per gram | Relative total caloric value | Approximate percentage of total |
|---|---|---|---|---|
| Fat | 3.5 | 9.54 | 33.39 | 45 |
| Protein | 3.5 | 5.65 | 19.78 | 27 |
| Sugar (lactose) | 5.0 | 4.19 | 20.95 | 28 |
| Salts (ash) | .7 | | | |

The figures in the table indicate that a considerable portion of the energy value of milk is contained in the skim milk and that dry skim milk is extremely valuable as a food. Energy values alone, however, do not indicate the value of the skim-milk solids as a food. Foods are needed not only because they furnish energy but also because they furnish material with which old tissues are repaired and new tissues are formed. The salts in milk are especially valuable foods in this respect though lacking in caloric value.

Foods differ in the ease with which they furnish these materials. The almost completely digestible and assimilable milk proteins and the readily metabolizable calcium and phosphorous compounds in dry skim milk make it especially valuable as a constituent of the diets of children, adults, and the feeds of growing animals.

The drying of skim milk does not seem to destroy the vitamins present.

It is difficult to state to what extent higher concentrations of lactose are utilized for energy requirements,[18] but it is known that they have a marked beneficial physiological effect in regulating the intestinal flora.

### Uses in Bread

The need of increased nutritive values of human foods can be and is being met by increasing the various desired constituents through the addition of milk. When fresh milk is not available, butter and dry skim milk may be used.

The addition of dry skim milk to bread dough supplements the protein of flour with one of greater nutritive value. The readily assimilable salts of added dry skim milk furnish mineral constituents essential to proper development and growth. Added dry skim milk also improves the flavor and many of the physical characteristics. It has been found that the use of dry skim milk in bread-dough mixes to the extent of 4 per cent of the weight of the flour, produces a marked improvement in the size, weight, and texture of the loaves and adds greatly to the palatability of the product.

The different flours respond in varying degrees to the action of a dry milk. By using a good grade of flour the volume of the loaf is increased by approximately 10 per cent and the weight by approximately 4 per cent. It may be stated that cases wherein the volume increase is not marked, the weight of the loaf as well as other physical characteristics are enhanced. The extent to which the volume of loaf may be increased, depends largely upon the treatment of the milk prior to its manufacture into the dried form.

Results of investigations in the research laboratories of the Bureau of Dairy Industry show that dry milk from milk heated to 65° C. for varying lengths of time produced no increase of volume when used as an ingredient. Dry milk from skim milk heated to 95° C., when added to bread-dough mixes, produced loaf volume increases up to 10 per cent.

In general, it may be said that the added cost incurred by use of dry milk is balanced by the increase in yield per barrel of flour.

---

[18] Approximately 90 per cent of the lactose of a diluted milk is utilized for energy requirements. G. Lusk. Science of Nutrition, 3d edition, p. 339. 1917.

Dry skim milk insures a source of clean skim-milk solids of uniform good quality which is economical in handling and storage and convenient in its uses. These advantages over fluid skim milk make it a valuable asset in the ice cream, the milk chocolate, and other industries wherein skim-milk solids are used. This is especially true in the areas of low milk production.

The many advantages of the product already recognized by industries are also being recognized by smaller units of trade. Its convenience and the ready availability of a skim-milk supply meet the fluctuating demands for fresh skim milk in hotels, clubs, and aboard ships.

There is also a need of increased nutritive value in the proper feeds of various animals. The use of dry skim milk as a supplement to other feeds for calves, pigs, and other animals insures them of a highly nutritive diet. The discovery that the incorporation of dry skim milk in the diets of growing chicks prevents coccidiosis has resulted in a marked increase in the use of this product in poultry feeds.

## SMUT Control by Disinfectants in Growing Favor

The losses caused by cereal smuts amount to several millions of dollars annually in spite of the fact that seed treatments have been recommended for many years. Seed treatment has not been practiced as generally as the needs seem to demand, especially in case of certain of the cereal smuts which are easily controlled. This is due, to a certain extent, to the fact that seed injury often is caused by the generally recommended formaldehyde and copper-sulphate-lime treatments.

### Factors That Influence Treatment

Several factors now are known to influence the effects of the treatment on the seed. Among the more important of these factors are the kind of seed, the variety treated, the conditions under which the seed is grown and subsequently handled, and the local soil and weather conditions existing where the treated seed is sown. In addition, variations may occur in the material, its preparation, and its application. The striking need for disinfectants which will control the smuts and at the same time cause no seed injury under these various conditions has led to intensive investigations during the past decade by scientific and commercial organizations. Out of these studies a few new materials of importance have become known. The more important of these are copper carbonate and some of the organic mercury compounds.

The dry copper-carbonate treatment was used successfully for the control of stinking smut of wheat in Australia in 1917. It was first used in the United States in 1920 by the United States Department of Agriculture and the California Agricultural Experiment Station. It was found to be much more satisfactory for the control of stinking smut of wheat than other treatments. Since that time copper carbonate has become the most popular treatment for the control of stinking smut in the United States.

Recently the Kansas Agricultural Experiment Station, cooperating with the Department of Agriculture, has found this treatment to be satisfactory for the control of covered-kernel smut of sorghum.

The copper-carbonate treatment consists in the thorough application of 2 to 2.5 ounces of copper carbonate, specially manufactured for seed-treating purposes, to each bushel of grain. To be effective, each kernel should be completely coated with the dust. Machines of the rotary type are best for mixing the dust with the seed. A simple type of homemade mixer is shown in Figure 209. A dust mask or wet handkerchief should be worn over the nose and mouth while the grain is being treated. Copper carbonate should not be mixed with grain by shoveling over on the floor. The dust gets into the air and causes irritation and nausea or even severe sickness if inhaled.

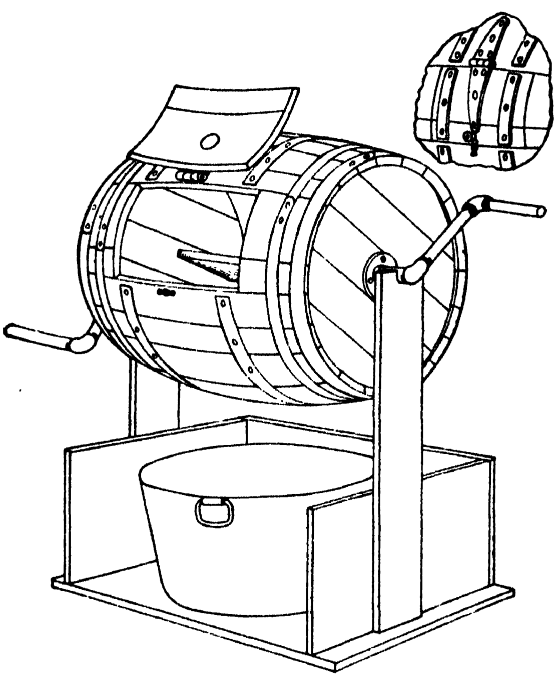

FIG. 209.—One type of homemade barrel mixer for applying copper carbonate to the seed. One or two boards 3 or 4 inches wide, the length of the barrel, should be nailed edgewise inside it to serve as agitators

### Advantages of Copper Carbonate

Copper carbonate has many advantages over the old liquid treatments. (1) It does not injure germination (2) Seed can be treated whenever convenient and stored without injury. (3) Dusted seed can be sown at any time in dry or moist soil. (4) It requires little labor and expense to treat seed for large acreages. (5) Copper carbonate protects stored grain from attacks by weevils. Rats and mice will not eat treated grain unless forced to it by hunger.

The organic-mercury seed disinfectants were used in Germany as early as 1912. There has been a rather rapid development of these compounds in Europe and America since that time. During the past five years the Department of Agriculture has conducted experiments with these organic-mercury compounds and many related and unrelated materials. Both dusts and liquids were included in the materials tested. Many of these compounds have proved worthless, while others have shown considerable merit. Among the more promising of these are: Chlorphenol-mercury (including chlorophol, semesan, and uspulun), cresol-mercury (of which germisan is an outstanding representative), and ortho-nitro-phenol-mercury (including corona 620 and others).

These mercury compounds, applied either in dust or liquid form, control the stinking smut of wheat, but none of them has proved as satisfactory as copper carbonate. In limited experiments, the solutions have given promising results in the control of the smuts of oats. It is still doubtful if they will prove more satisfactory than formaldehyde for the control of oat smuts. In the control of barley smuts several of the organic mercury compounds, including chlorophol, corona No. 620, germisan, semesan, and uspulun, when used in solutions, have given excellent results. The seed is soaked for 1 hour in solutions containing 0.2 to 0.3 per cent of the compound.

### Mercury Materials Effective

The results with these mercury materials have proved to be superior to those obtained with formaldehyde, from the standpoint of seed germination, smut control, and yields of plants from treated seed. Both the loose and covered smuts were controlled in the varieties of barley used in the experiments conducted by the department.

The mercury compounds are more expensive than formaldehyde. The additional expense may be more than compensated by the increased germination and yields. There is also a possibility of saving seed by sowing less of the treated seed. The mercury compounds are very poisonous and care should be used with treated seed to prevent poisoning of animals.

The trend of the investigations on seed disinfectants seems to be along promising lines. From the investigations now under way materials which are even more satisfactory may be obtained.

W. H. Tisdale.

## SOIL Types and How They May Be Recognized

In view of the fact that modern agriculture has come to recognize that soil type is an important factor in determining crop adaptations and the needs of a soil, it is pertinent to ask: Do you know your soil types? To say that it is red clay, or "gray, pine-woods sandy land," or "gumbo," or "buckshot," or "loam" means little or nothing. Gumbo, for example, may be soil which ranges from the highly productive, limy, black clay found in the bottoms of such streams as the lower Missouri River to the unproductive gray, salty clay occurring in low positions in the Gulf coastal plain. The term "loam" is loosely applied to numerous soils having widely varying properties, cropping values, and cultural requirements.

These local names vary so much in meaning from one locality to another, and with the persons using them, that they can not be relied upon to convey correct ideas; and those who cling to them, failing to acquaint themselves with the important soil types of their localities, are at a distinct disadvantage, in that they are not in a position to understand the best use of the fertilizer, and the cultural and crop-variety tests carried on by the experiment stations of the country. Everyone knows that what one soil needs or what crops are best suited to it may not correspond in the least with the requirements and adaptations of another type. One side of a field may need potash for cotton or corn, whereas the other side may need a phosphatic fertilizer only.

Throughout the country fertilizer and other tests are made more and more upon the important soil types, as established by State and Federal soil surveys. In order to apply the results of these tests with greater certainty of getting the most effective response, it is necessary to know that your soil is of the same general class or type as that upon which a particular experiment is conducted.

### Value of Soil Surveys

This adjustment between soil types and agricultural methods is going to be brought more and more into the foreground of American agriculture, so that it is important that the up-to-date farmer familiarize himself with the prominent soil types of his locality.

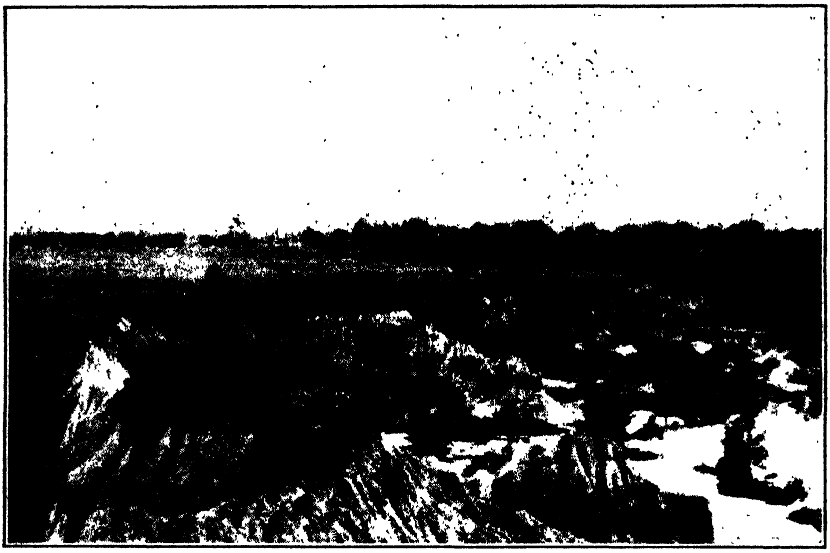

FIG. 210.—The great land destroyer, erosion, at work

This can be done by studying the soil-survey reports and maps now being published by the United States Department of Agriculture.

Where reports are not available the State experiment stations frequently will be able to advise farmers as to the kinds of soils occurring in their respective localities.

Soil surveys usually are made of counties. In this work the entire acreage of the county is gone over, and the soils are classified according to standardized methods of identification. The different soils are given local names, the same name being applied to the same soil wherever it is found. The Orangeburg sandy loam, for example, was first mapped near the town of Orangeburg in Orangeburg County, S. C. Since its discovery it has been mapped in hundreds of counties of the Atlantic coastal plain, from North Carolina to the Brazos River in Texas. It is a brown sandy loam, from 8 to 12 inches deep, underlain by bright-red sandy clay of a friable nature. This type of soil usually is in need of complete fertilizers which should be applied in moderate quantities. It is especially well adapted to peaches, pecans, and tobacco; and in addition, cotton, corn, peanuts, oats, velvet beans, and a number of other crops give good returns when properly treated.

This is the kind of information that is contained in soil-survey reports; and this is the kind of information that the leading farmers want. Of course, the exact needs of all soils can not be determined at once. Some States have already accumulated much information relating to the fertilizer needs of their important soil types. On the basis of such information soil-management recommendations are given to farmers, thus eliminating much guesswork. That this kind of definite soil knowledge is valuable to the farmer and to the State is shown by the remarkable agricultural advances made in those States which have advanced the farthest in this direction.

Different soils often interfere in the helpful interchange between farmers of methods and ideas, sometimes resulting in losses to one farmer because he, trying to follow the practices of another, did not know of unsuspected soil differences.

### Surface Appraisal Inadequate

Many farmers know only the surface of their land. If the surface looks good, it is assumed that the soil is all right. Such appraisal is wrong probably as frequently as right. It is an assumption that does not regard the disadvantages of clay pans, hardpans and other impervious and impenetrable subsoils which not only seriously retard underdrainage and the upward movement of soil moisture. but which resist root penetration also. Soils having such subsoils become excessively dry when rain fails, and remain soggy for long periods when there is an abundance of rain. On them low yields result from late planting, too little or too much summer moisture, or from the imperfect development of plant roots.

The farmer often puzzles over his poor crops, when the real cause would be obvious if he better understood each of his soil types from top to bottom. He sometimes undertakes, usually without success, to correct with fertilizers or cultivation what might be accomplished by a better adjustment of crops and methods to his varying soils. Some types of soil, for example, frequently will grow redtop, but on which alfalfa, peaches, or apples can not be expected to give even ordinary returns, regardless of the intensity of fertilization or cultivation.

Tiling will not always correct the evils of poor drainage. Open ditches sometimes will prove beneficial on soils when tile may prove ineffective. This is true of those soil types which have subsoils consisting of dense, impervious clay which closes around the tile, sealing them as with paraffin or wax.

Shallow soils which are underlain by gravel, sand, or upturned beds of shale or other stratified rocks, usually are excessively droughty, and erode badly. On some slopes soils which have substrata consisting of loose materials are generally extremely susceptible to erosion, and as a rule should be used only for timber or grass. (Fig. 211.) Once a gully has cut down into the friable material, the land "melts" away almost like sugar. A soil which has a thin surface layer over heavy, plastic clay, such as the shallow phases of the Susquehanna types, quickly loses its surface soil by rain wash, when brought under cultivation, and becomes fit only for the growing of trees. Soils of high susceptibility to washing should not be cultivated at all unless they are adequately terraced. Most of them could be more profitably used for grass or timber.

### Soil Destruction by Erosion

It is estimated that 10,000,000 acres of land formerly cultivated already have been permanently destroyed in this country by erosion or made unfit for farm crops. In one county alone 50,000 acres, once largely cultivated, were found by actual survey to have been ruined by washing. This land could have been saved if the owners had understood its strong tendency to erode, and had protected the slopes with terraces, using the steeper ones for wood lots and pastures.

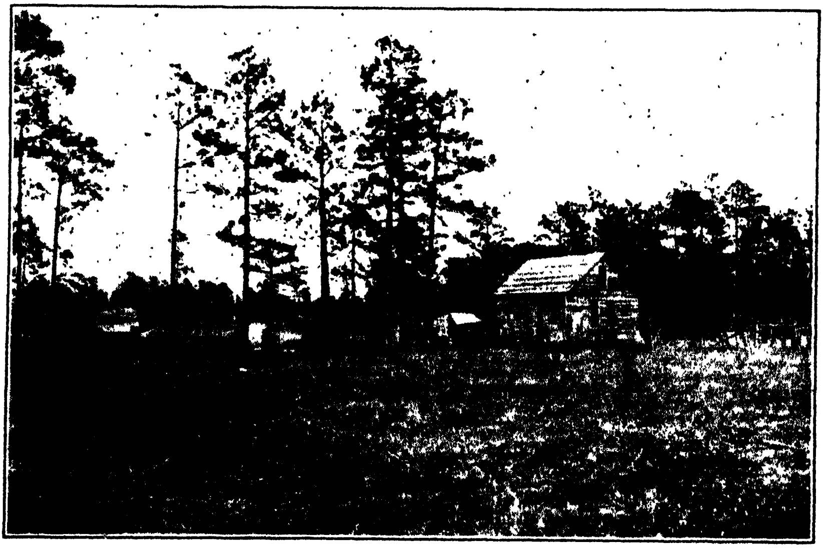

FIG. 211.—Abandoned farmstead on an inferior soil on the Gulf coastal plain. This land was purchased by a hopeful farmer who was new to the locality. There was too much soggy land like that in the foreground, which would not grow even trees. Failure was foreordained by the unfavorable soil—it looked good, but was not

Those heavy clays and shallow soils over heavy clay, which are subject to severe erosion and are difficult to till, seldom can be farmed profitably. They should generally be recognized as timberlands and utilized in forestry. Here and there a farmer is eking out a living upon unfavorable ground, but he usually is forced to supplement his farm income by working elsewhere when he is not busy with his discouraging crops, or else he leads a precarious existence. By failing to understand the exceptional obstinacy of his ill-chosen soil, he often misinterprets the situation, wrongfully ascribing failure to mysterious causes or to his own inability to do things in just the right way. Thus feeling he has " lost the touch," he frequently moves to town or to some other locality to start over again.

In regions of low rainfall, where salts accumulate in certain heavy soils and in situations of imperfect drainage, disastrous mistakes are frequently made in attempts at farming. Sometimes a soil that looks good contains enough salt to prevent the successful growth of any crop. The writer recently saw land of this kind planted to grapefruit and cotton. The trees showed no indication of ever bearing, and the cotton would yield not more than 10 pounds of lint to the acre. For this land the owner, thinking it looked good, had paid $300 an acre. Actually it was not worth $5 an acre, because of its high alkali content and the extreme difficulty of improving it by drainage. In immediate contact with this worthless land was excellent soil, without alkali and without danger of ever being seriously affected by alkali. Had the purchaser consulted the soil-survey maps of the region, he would have been on his guard, and probably never have bought the land. His case is but one among thousands in which failure is foreordained by soil inferiority.

All the advantages that may be gained from getting better acquainted with your soil types can not be given here. The time has come when you should lay aside the old way of the indiscriminate use of all kinds of land for all kinds of crops, or applying the same methods in all fields regardless of the soil type. This is too much on the order of hit-or-miss farming. It will be better for you and the Nation if you will set about to get better acquainted with your soil types, so that you may cultivate those of better quality only, adapt your soils to the right crops, practice proper methods, and devote your inferior land to timber or grass.

H. H. BENNETT.

---

## SOY-Bean Output Increasing in United States

Although introduced as an unknown immigrant from the Orient many decades ago, not until recently has the soy bean won a recognized place in the cropping system of American farmers. The great interest shown in the soy bean and its products and the largely increased acreage and production during the last decade indicate that it is destined to become a crop of considerable economic importance in the United States.

In 1917 less than 500,000 acres were devoted to soy beans for all purposes. In 1924 there were 2,500,000 acres, of which about 1,000,000 acres were grown for hay, about 1,000,000 acres for pasture and silage, and more than 500,000 acres for seed production. About 2,283,000 bushels of seed were produced in 1917, while in 1924 nearly 10,000,000 bushels of seed and 1,360,000 tons of hay were produced. Although the increase in acreage has been general over the eastern half of the United States, the most marked increases have been in the Corn Belt States and in a few of the Southern States. In 1924 the five leading States for total acreage were Illinois, 747,000; Missouri, 400,000; North Carolina, 255,000; Indiana, 210,000; and Tennessee, 167,000; and for seed production North Carolina, 2,560,000 bushels; Illinois, 1,548,000 bushels; Missouri, 1,379,000 bushels; Ohio, 728,000 bushels; and Indiana, 650,000 bushels.

The soy bean can now be grown successfully in any climate suitable to corn or cotton. The Department of Agriculture during the past 10 years has developed, through introduction and by breeding methods, varieties which have extended the range of profitable soy-bean culture far beyond what were at first considered its limits. The principal uses of the soy bean are hay, pasture, silage, grain, oil and oil meal, and human food. With such a wide range of uses the production of the soy bean is no longer localized and its increasing importance is assured.

### Gaining Favor as Forage

As a forage crop alone, it is not likely that the soy bean will become a major field crop in the United States. However, even as a forage crop it has gained steadily in favor as indicated by the increased acreage from year to year. The forage is preserved either as hay or silage, or cut and fed green as soilage. It is also pastured extensively with sheep and hogs. Not infrequently, the soy bean is employed as a green manure or summer cover crop in orchards. Unlike most other legumes the seed is rich in oil which makes the soy bean an important source of vegetable oil. Although the soy bean will no doubt continue to grow in importance as a forage crop, indications are that the future increase in soy bean acreage will be largely for the production of oil and oil meal. During the past few years, oil mills in the Corn Belt States and some of the Southern States have crushed fairly large quantities of domestic beans, and found ready markets for the oil and oil meal.

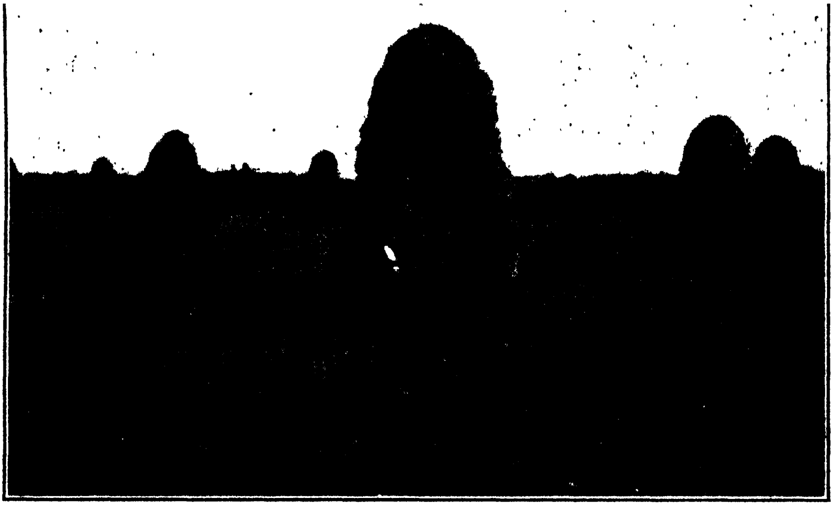

FIG. 212.—Best results in making soy-bean hay are obtained where the vines are piled in tall, narrow cocks

Soy-bean oil is used largely in the manufacture of soaps, paints, varnishes, linoleum, enamels, lubricating oils, printing ink, waterproof goods, salad oils, and substitutes for rubber, lard, and butter. The oil has now an important place in the world's trade and commercial utilization of vegetable oils. The cake or oil meal remaining after the oil is extracted is a highly concentrated and nutritious feed, and is relished by all kinds of livestock.

As an article of food the use of the soy bean in the United States has been very limited. For many years a few food companies have manufactured special soy-bean flour products. The number of such concerns producing soy-bean food products has increased to a considerable extent during the last few years. Soy beans are now being made into breakfast foods, crackers, wafers, soy sauce, bean curd, soy flour, and special flour preparations for various purposes. One of the most recent developments is the manufacture of soy sauce and bean curd from domestic grown beans. This has been found a most profitable industry in some parts of the Corn Belt, and soy sauce has now a fairly extensive market in the United States.

### Improved Production Methods

Increased acreage and greater utilization of the soy bean have brought about improved methods in planting, culture, and harvesting. Implement manufacturers, who in the past took no interest in the soy bean, are now actively engaged in a study of the planting, cultural, and harvesting problems of the crop. The development of an efficient method of harvesting the seed crop has been one of the serious problems connected with the production of soy beans. Many types of machines are now on the market, ranging from the single-row harvester to broadcast harvesters of the beater type and the combine harvester like those used in harvesting wheat and other small grains.

Because of this rapid increase in the importance of the soy bean, State experiment stations have greatly extended their investigations of the different feeding problems, such as the value of soy-bean silage, hay, grain, pasture, and oil meal. One of the most outstanding results of this work has been the use of a mineral mixture with the grain and meal. Extensive feeding trials with hogs and poultry have shown that when minerals are added to a soy-bean ration the results compare favorably with those from a ration of tankage and meat scrap.

In the last decade the soy bean has advanced from a position of minor to one of major importance. Previously soy beans were grown only occasionally, usually as a substitute crop when clover or some other crop failed. At the present time the plant is grown regularly for hay, grain, and pasture, and with corn as silage.

W. J. Morse.

## SOY-Bean Rotation Increases Rice Yields Greatly

Crop rotation has not been a factor in developing the rice industry in southwestern Louisiana. The pasturing of rice fields after several years of cropping has been the only recognition of the principle of crop succession in this section. Experience has shown that this method is not effective in controlling weeds, especially red rice, the worst weed of the southern rice fields. Red rice seed may remain viable in the soil for at least four years and will germinate only when brought near the surface by plowing and other tillage operations.

Experiments conducted for a period of 14 years at the rice experiment station, Crowley, La., show that weeds can be controlled and may be eradicated by growing rice in rotation with soy beans. The success of weed control depends upon thorough cultivation. Cultivation that permits weeds to produce seed is not effective. Tillage that is necessary to prepare land for soy beans also aids greatly in reducing weeds. The land should be plowed during the previous winter to a depth of at least 5 inches and disked several times in spring before seeding. By repeated light diskings several germinations of red rice may be obtained and destroyed before the soy beans are sown.

Experiments and the experience of rice farmers who are using this rotation indicate that the Biloxi is better adapted to rice field conditions than any other variety of soy beans that has been tested. (Fig. 213.) This variety should be sown in rows 4 feet apart at the rate of 30 pounds per acre. Seeding may be done with an ordinary corn planter adjusted to drop one or two seeds from 2 to 4 inches apart in the row. The seed should be sown just beneath the soil surface. Deeper seeding is likely to result in a poor stand. Sow not earlier than the last week in May and preferably not later than June 15. Thus sown, the plants are relatively short and bear short limbs that fruit rather heavily. Such plants are easily cultivated and can be harvested with machinery without appreciable loss. Early seeding has little effect on date of maturity, which with the Biloxi normally occurs in early November.

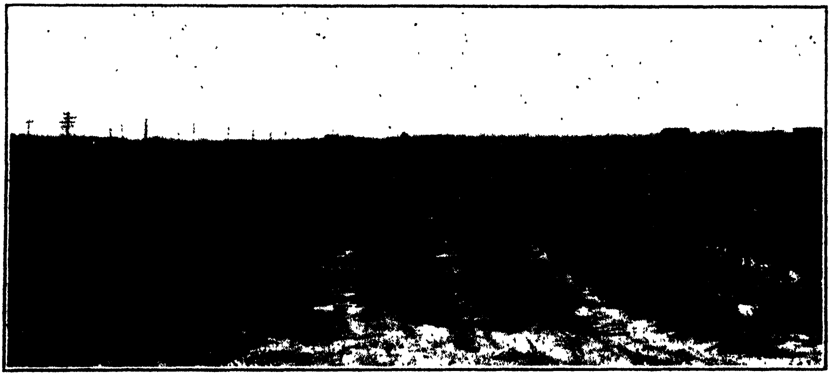

FIG. 213.—A field of Biloxi soy beans growing on typical rice soil in southwestern Louisiana. This field has been so thoroughly cultivated that there are no weeds in it

Cultivation should begin as soon as the plants can be readily traced in the row. It may be done with a riding cultivator. By using the disk and other attachments alternately this implement will keep the soil in a condition that will promote the germination of red rice and other weed seeds, the growth from which can be easily killed by later tillage. Cultivation should be frequent and continue as long as weed growth is noticeable.

Weed control is not the only advantage of the soy-bean rotation. Plowing under the soy-bean plants after the beans are harvested adds to the soil a large quantity of organic matter which decomposes rapidly when drainage is good. The upturned soil under these conditions readily responds to tillage in preparing a suitable seed bed for rice. Good seed-bed preparation insures a more thorough destruction of weeds, better germination, a better stand, a stronger root growth, and larger yield. When the soil is deficient in organic matter such a seed bed is not easily obtained even with extra tillage. Soil fertility also is greatly increased by the decomposed vegetable matter. On the typical rice soil of Louisiana the soy-bean rotation is giving an average acre increase of 10 bushels of a better grade of rice, which is a greater return than is being obtained by the use of commercial fertilizers.

Charles E. Chambliss.

## SOY-Bean Standards Promulgated for Commercial Crop

The phenomenal increase in the production of soy beans during recent years has created widespread interest in this commodity. Production in the United States increased from 2,500,000 bushels in 1920 to 6,517,000 bushels in 1926. With this increased production the saturation point in the demand for soy beans for seed purposes has been reached, especially of the staple varieties.

The commercial possibilities of the soy bean, however, offer a potential outlet for a supply many times the present surplus above seeding requirements. Several mills are now crushing soy beans for oil and meal and others are being built or equipped for this purpose. Research chemists are studying the value of the soy bean and its products for food and other uses, together with methods of converting them into the proper form for such uses. The extent of these commercial uses seems to be limited principally by the supply of the raw product. Production above seeding requirements is increasing steadily and, with the general employment of more efficient and economical methods of growing and harvesting the crop and preparing it for market, the annual supply available for industrial uses should be increased manyfold.

With the commercial supply of a comparatively new agricultural product increasing there naturally arises a problem in marketing. Although there may be an adequate outlet or market for the crop, a definite basis for price quotations is essential in order to insure more equitable returns to the producer and to expedite movement of the crop from the farms. Uniform quality standards are the key to the solution of this problem.

### United States Standards Issued

After extensive studies of the various phases of the soy-bean industry, United States standards for soy beans were issued in September, 1925, and recommended for use in the grading and marketing of this commodity. These standards were used as a basis for Federal inspection of the 1925 crop of soy beans at original shipping points in eastern North Carolina with gratifying results. Favorable reaction from growers, shippers, wholesale seedsmen, and oil mills to this initial use of the standards resulted in a demand that the inspection service be expanded in North Carolina and that it be extended to other producing States.

Based on the use of the standards and further studies of the industry, slight revisions were made effective September 1, 1926, chief of which is the addition of a supergrade to take care of extra high-grade stock for which there is a demand at a premium, especially from the seed trade, and which growers are now producing under normal conditions. Wholesale seedsmen are finding it expedient to purchase their supplies on the basis of the two high grades provided in the standards, and shippers and State agencies are cooperating with Federal inspectors for the purpose of furnishing buyers with authentic supplemental information as to variety and germination whenever requested. Oil mills are buying their soy beans on the basis of the United States No. 2 grade, with a scale of discounts for the lower grades and premiums for the higher grades.

The use of the standards in the purchase and sale of soy beans removes much of the uncertainty regarding values of lots of varying qualities. It eliminates the necessity of submitting samples, which delays a transaction, and speeds up sales. It tends to encourage better farm preparation for market, resulting in larger net returns and more equitable returns to the grower, and to improve the quality of the finished product to the consumer and manufacturer. As a result, impetus is being given to an industry in the making and greater confidence is being shown by farmers in this promising cash crop.

J. E. Barr.

## SOY-Bean Varieties Newly Developed for U. S. Farms

The acreage of soy beans in the United States increased from about 500,000 acres in 1917 to over 2,500,000 acres in 1924. This enormous increase in the use made of soy beans in this country has been largely due to the development of better-adapted varieties. The number of real or supposed varieties has increased very rapidly in the United States during the past few years, resulting in much confusion concerning varietal names and characters. In many instances disappointment and loss have been caused to the grower by the lack of reliable information, and the soy bean brought into disfavor in some localities. At the present time about 60 varieties of soy beans are handled by growers and seedsmen in the United States. Varietal names greatly exceed the number of true varieties, for different varieties are often sold under the same name, and different names are often applied to the same variety. It is therefore essential not only to know the name of a desired kind, but also its varietal characteristics in order to prevent substitution in purchasing seed.

Varieties of soy beans are differentiated largely by the color and size of seed, though they also differ in time of maturity, habit of growth, disposition to shatter their seed, disease resistance, oil and protein content, and in yield of forage and seed. They vary also in their adaptation to climate and soil. Some varieties are especially suitable for fertile land, others for less productive land; some for early planting, others for late planting; some for a seed crop, others for forage; some for planting with corn, others for planting with Sudan grass and sorghum. One may find a few varieties or even a single variety adapted to the climate of a certain section which will fill all the local requirements of the crop. No single factor has greater influence upon the success of the crop than the selection of the right variety to meet the needs and the conditions of the section where it is to be grown.

### Only Eight Varieties Grown in 1898

Previous to the numerous introductions made by the United States Department of Agriculture, beginning in 1898, there were not more than 8 varieties of soy beans grown in the United States, namely, Mammoth Yellow, Ito San, Butterball, Guelph or Medium Green, Eda, Ogemaw, Buckshot, and Kingston. All of these varieties were rather limited in adaptation, and at present the Ito San and Mammoth Yellow are the only ones grown to any appreciable extent. In 1907, 23 varieties of soy beans were being grown, and of these 15 were introductions made by the department prior to 1905. Vigorous efforts were inaugurated about 1907 to obtain additional varieties through consuls, agricultural explorers, foreign seedsmen, and extensive correspondence with missionaries and others until in 1909 the department had in its trials about 200 distinct varieties; by 1913, 400 varieties; by 1919, 600 varieties, and by 1925, about 1,200 varieties.

FIG. 214.—Field trials of varieties of soy beans at Clemson College, S. C.

The records of introduction indicate that every Chinese village has its own distinct varieties. There is no seed trade in China, consequently local varieties are never widely disseminated. Undoubtedly numerous varieties are yet obtainable from the agriculturally unexplored villages of China, Manchuria, Korea, Japan, and India.

When new introductions are received they are thoroughly tested at Arlington Experiment Farm the first year, and if mixed, single plant selections are made for the second year's test. After three years' work with these selected strains, those giving the best results in comparison with standard varieties are disseminated among the State experiment stations, where they are grown again under careful observation and test conditions. Finally seed is distributed among farmer cooperators who assist the department in its practical field investigations. Varieties that appear promising in these field trials ultimately are assigned suitable varietal names and made available for general use and distribution in the localities to which they are adapted.

### One Thousand Varieties Introduced

During the past 20 years more than 1,000 varieties have been introduced into the United States from China, Japan, Manchuria, India, Korea, Siberia, and the East Indies. Several of these have become established in American agriculture, either as direct introductions or as selections from introductions. Others, introduced in the past year have proven so valuable in trials that they are deemed important acquisitions and doubtless will become widely grown. It is universally appreciated and acknowledged by all soy-bean authorities that the annual introductions of soy beans into the United States have been of fundamental importance in the rapid rise of the crop in public favor.

FIG. 215.—A field of Otootan soy beans, one of the newer introductions by the United States Department of Agriculture

The soy bean lends itself readily to improvement. Considerable breeding work is being carried on by the department, several State experiment stations, and a few soy-bean growers. Although the Orient abounds with varieties, it is evident that they are the result of natural crossing and selection, as very little breeding work has been done. Introductions, for the most part, are admixtures, containing two or more varieties. The progeny of individual plants has shown decided differences in yield of forage and seed, in tendency to shatter, in maturity, and in oil and protein content. Many new varieties have been introduced into the seed trade of the United States as a result of selection work. Some of these varieties originated from natural hydridization and a few are almost certainly mutations or sports. The most important of such varieties are Chestnut, Dixie, Goshen Prolific, Hamilton, Herman, Illini, Ilsoy, Lexington, Mikado, Minsoy, Peking, Sooty, Soysota, Virginia, Wilson-Five, and Wisconsin Black. Introductions without selection have given us the following important varieties: Biloxi, Black Eyebrow, Chiquita, Columbia, Haberlandt, Hahto, Hoosier, Laredo, Manchu, Mandarin, Morse, Old Dominion, Otootan, Southern Prolific, Tarheel Black, Tokio, Wea, and Yokoten.

### Work Justified by Results

The results that have been obtained by this wholesale search have justified the work and expense many times over. When the department work began, the soy bean was a very minor crop, and of importance only in limited areas, owing primarily to the lack of suitable varieties. To-day, its culture, due to a wide range of excellent varieties, is widespread and lends substance to the belief that the soy bean will become one of our major crops.

Table 24 shows the total value of soy-bean seed and hay produced in 1924 by varieties introduced and developed by the department. These data, which do not include the value of the soy beans pastured or fed as silage, indicate that over half (52 per cent) of the total soy-bean hay and seed produced in the United States was obtained from these new varieties. The wide use that is being made of these varieties shows most conclusively the effect this introduction and breeding work has exerted on the development of the soy-bean industry in the United States.

TABLE 24.—*Value of seed and hay of the principal new soy-bean varieties introduced and developed by the United States Department of Agriculture*

| Variety | Year introduced | Estimated value [1] | | | Per cent of value of all soy-bean hay and seed |
|---|---|---|---|---|---|
| | | Seed | Hay | Total | |
| Biloxi | 1908 | $883, 680 | $374, 360 | $1, 258, 040 | 3.0 |

[1] Values given are based on yields of seed and hay in 1924 and the percentage of varieties grown in the different States in 1923. Data obtained from reports of the Bureau of Agricultural Economics.

W. J. MORSE.

**STARCHES and Other Finishes for Fabrics** Starch and other materials are used in the laundry in the attempt to restore to washed fabrics the finish given by the manufacturer to the new goods. Of course, in many cases he applies an elaborate mixture and uses heavy hot rollers. Thus he gives a finish that can never be reproduced in the home or even by the small establishment that refinishes damaged and soiled fabrics. These attempts, however, would be far more successful if more were known about the different starches and materials for finishing and how they act on different fabrics. Then instead of fabrics looking "laundered," as they often do now, they would look and feel much more as they did when new.

An ideal laundry starch should give the desired "feel" and stiffness, should adhere strongly and penetrate well into the material, not cause white materials to appear muddy or yellow, and not dull the colors of dyed fabrics. The starches used in laundry work are corn, wheat, rice, potato, and occasionally sago and tapioca. In the United States, corn is by far the most widely used because of its great abundance, although the others are frequently employed where special finishes are desired. However, there are a number of varying ideas and opinions as to the results obtained by the different starches used alone and in combination. Statements have been made attributing rice-starched fabrics with a peculiar harsh "feel," whereas another group recommends it heartily for use on infant's garments and dainty lingerie. Terms ranging all the way from a "soft," "full," "mellow" to a "harsh," "rough," "boardy" feel have been used to describe the effect of wheat sizing. Potato starch forms a very clear paste and is thought by many to give a transparent finish which is especially desirable for dyed fabrics.

### No Testing Instruments

At present there are no instruments available for testing these properties of starch. In fact, the very terms describing the effect of the different size mixtures are so vague that they convey conflicting ideas. "Soft," "pliable," "harsh," "boardy," "smooth," and "crisp" are some of the words by means of which an attempt is made to compare different finishes. None of them carries a definite meaning to the person who is judging. Standard terms for describing the physical properties of textile fabrics and an instrument to measure each of these properties are needed to study the starches now on the market as well as the newer types such as canna and tree fern which are being introduced. With but a few tests their suitability for fabric sizing could then be determined. The work being done in the department will be a contribution along this line.

Starches have been prepared from corn, wheat, potatoes, and rice of known variety and grown under known conditions. Fabrics starched with paste made from these have been tested for stiffness. Wheat starch caused the greatest stiffness. Fabrics starched with rice and corn were less stiff than those starched with wheat, although they resembled one another very much. The addition of a little borax added greatly to the stiffness of fabrics starched with corn starch. When used alone borax gave no apparent stiffness to the fabric, although it has been recommended by some as a good stiffening agent. The addition of fats, oils, and waxes to the starch paste resulted in a less stiff fabric.

Sometimes starched garments look mussed almost as soon as they are put on, for one reason because the starch is not pliable. The pliability of the different starches is therefore being measured as well as the stiffness. Starch paste, typical of that used in laundry work, is prepared and spread over a very smooth surface to dry. The thin, dry film formed in this way is peeled off and cut into narrow strips which are folded by an instrument devised for that purpose. The number of folds which can be made before the strip breaks is recorded and gives a means of comparing the different starches and starch mixtures.

In many cases materials other than starch are more desirable to restore a crip new finish to the fabric. A very dilute solution of gelatin, made by dissolving 1 ounce of gelatin in 1 pint of water and finally diluting this solution 8 to 15 times, is an excellent dressing for silk, wool, and cotton materials such as organdies, voiles, and batistes. A dilute glue solution is also good but can not be used on white or light fabrics because of its color.

### Glue and Gelatin for Dark Stuff

Both glue and gelatin, because of their transparency, are to be preferred to starch on dark fabrics where the starch usually leaves undesirable white splotches. One ounce of gum arabic dissolved in 1 pint of water and this solution diluted with from 5 to 10 parts of hot water is a very satisfactory finish. A gum tragacanth solution, one-sixth ounce to the pint of water and diluted 8 to 12 times accomplishes the same purpose. Too much of the gelatin, glue, or gums will, however, cause the fabric to feel sticky.

Other properties of the typical starch pastes and finishes used for laundry work will be studied. As a result methods will be found for laundry starching that will restore so far as possible the finish that fabrics had when new.

Esther C. Peterson.

## STINKING Smut of Wheat—Progress in Its Control

A new era in the control of stinking smut of wheat began in 1917 when an Australian investigator announced that he had successfully prevented this disease by dusting seed wheat with copper carbonate. This treatment not only killed seed-borne spores of the fungus which causes this disease, but did not injure germination of the seed wheat. The United States Department of Agriculture, in cooperation with the California Experiment Station, tried this method and found it more satisfactory than either the copper-sulphate-lime or formaldehyde treatments formerly used.

Realizing the importance of this discovery, plant pathologists throughout the wheat-growing sections of the United States began active research in order to determine whether or not copper carbonate would give satisfactory control under varying local conditions. As this work progressed and it was found that the treatment was an improvement on the methods formerly used for disinfecting seed grain, the effort was made to bring it into common use. For example, in 1921, the extension pathologist for the State of Washington arranged for ten 1-acre demonstrations. The treatment was so successful that by 1924 over a million and a half acres were sown with treated grain in that State. The good news spread, and soon many farmers in Oregon, Montana, and Idaho had discarded the wet seed dips and were using copper carbonate.

As a result of the experience gained from practical farm trials in the Western States and from experiments of plant pathologists knowledge concerning this treatment and convenient methods for its application grew rapidly. It was found that in addition to being an effective agent for killing the smut spores carried on seed wheat, the copper carbonate treatment has certain other advantages. W. H. Tisdale, pathologist in the Bureau of Plant Industry, outlines several of these in Department Circular 394:

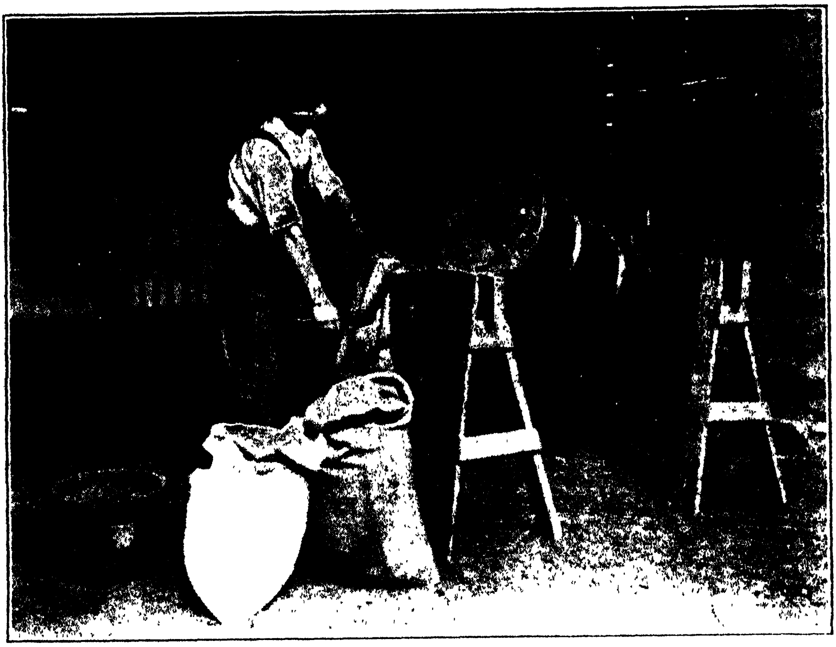

FIG. 216.—When treating seed wheat with copper carbonate for stinking-smut control a mask must be used to avoid inhaling copper dust

> It does not injure germination. In fact, treated seed often germinates better than untreated seed.
>
> Seed may be treated whenever convenient and stored without injury. The wet methods do not permit this.
>
> Dusted seed may be planted at any time in dry or moist soil.
>
> Very little labor or expense is required to treat seed for large acreages.
>
> Copper carbonate protects stored grain from attacks by weevils. Rats and mice will not eat treated seed if there is untreated grain in the storehouse on which they can feed.

In the same circular warning is given with regard to limitations of copper carbonate and certain precautions are outlined to observe in its use.

The development of this improved method of treating seed wheat was most timely. Deep concern with regard to the wheat smut situation has not been limited to farmers. It has been felt by all who have an interest in the handling of wheat or the manufacturing of wheat products, since the quantity of smutty wheat received on the market has steadily increased during recent years.

This means a threefold loss. As wheat marked "smutty" under the Federal grain standards can not satisfactorily be ground into flour until the smut has been removed by the use of special machinery, discounts on such grain range from a few cents to 20 cents or more per bushel, the price being determined by the amount of smut present. This, however, is only the final effect of the disease.

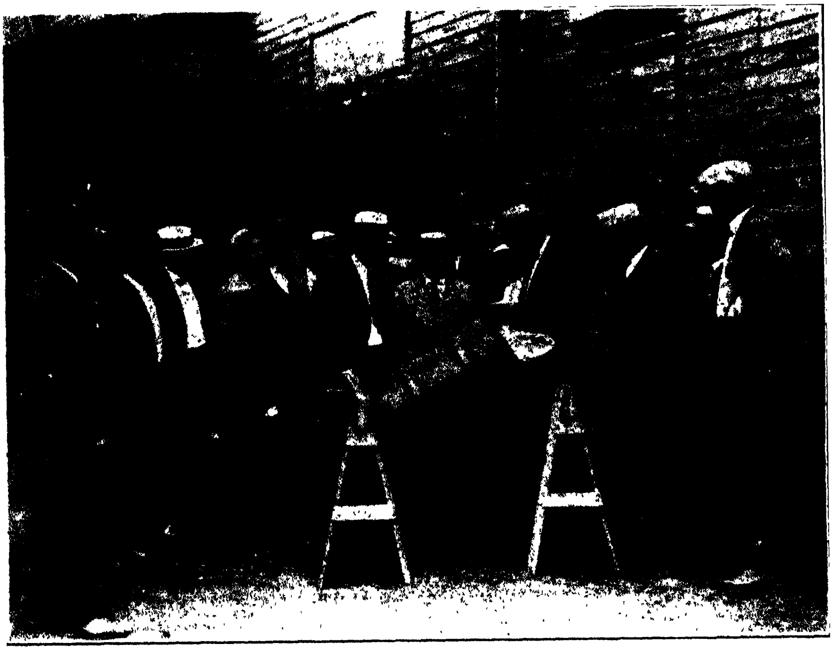

FIG. 217.—Community demonstration in treating seed wheat with copper carbonate to control stinking smut

### Threshing Machine Explosions

Back on the farm there is the danger of threshing-machine explosions during the harvesting of crops with a high percentage of disease. Separator explosions at threshing time owing to the ignition of clouds of smut dust in the separator may result in heavy property damage.

The initial loss due to the disease, however, is felt directly by the grower in a marked reduction in yield. Estimates of this type of damage caused by stinking smut in wheat during the years 1917–1924 indicate that losses in the United States approximate from

5,000,000 to 26,000,000 bushels a year. The average estimated reduction in yield during this period was over 14,000,000 bushels annually. The highest loss was in 1924 when something more than 26,000,000 bushels of wheat were destroyed in the field by stinking smut.

### Control Method Widely Accepted

Considering these inroads which smut makes in the farm income, it is not surprising that wheat growers are adopting the new and better control method with great enthusiasm. In 1858 when a dilute solution of copper sulphate was first recommended for treatment of wheat seed, and again in 1897 when formaldehyde came into use, there were no county agricultural agents to assist farmers in learning to use the chemicals. Years passed and yet many growers were unacquainted with methods of using them.

As a contrast to this we have the work done during 1926. Under the leadership of extension pathologists and agronomists and supported by farmers' organizations, railroad agricultural development groups, wheat improvement associations, millers' associations, chambers of commerce, newspapers, and other business agencies, over 500 county agents set to work with the aim of decreasing losses due to stinking smut of wheat. Farmers were taught to build and use treating machines. Assistance was given to millers, grain dealers, elevator managers, and others who desired to render service to their communities by doing custom treating. Manufacturers of copper carbonate and treating machines have kept pace with the demand created so that the acreage sown with treated grain increased materially in both spring and winter wheat areas. A disease-control method which seven years ago was unknown to farmers in this country has now come into widespread use.

FRED. C. MEIER.

## SWEET Clover for Permanent Pasture Land

Sweet clover, as ordinarily handled, is a rotation or temporary pasture plant. It is grazed from midsummer of the first year until midsummer of the second year, when it matures. The animals must then be shifted to another field containing a new seeding. This practice is a common and profitable one and probably provides more high-grade pasturage per acre than any other common system of grazing. Every field, however, must be well fenced and there must be lanes connecting them. Every field also must have water and shade. Some of the fields often are far from the barns. Most important, dependence must be placed each year on a new seeding, and seedings sometimes fail. Consequently, much interest is expressed in means of utilizing sweet clover in fields of more or less permanent character.

The simplest plan is to plant a field with sweet clover and permit the crop to go to seed. After several years the surface soil becomes so full of sweet clover seed that a volunteer crop appears each year. Fields of this kind, which have been in sweet clover continuously for 10 or more years, are not uncommon. The chief objection to the plan is that, unless grazed very heavily, the fields do not contain young and old plants in the right proportion to give continuous feed. In both wild and cultivated stands, if at all dense, the second-year plants smother the seedling plants and the two rarely occur together. To overcome this condition seed is sometimes sown each year for the first three or four years, but this does not help greatly, except to build up a stand more quickly.

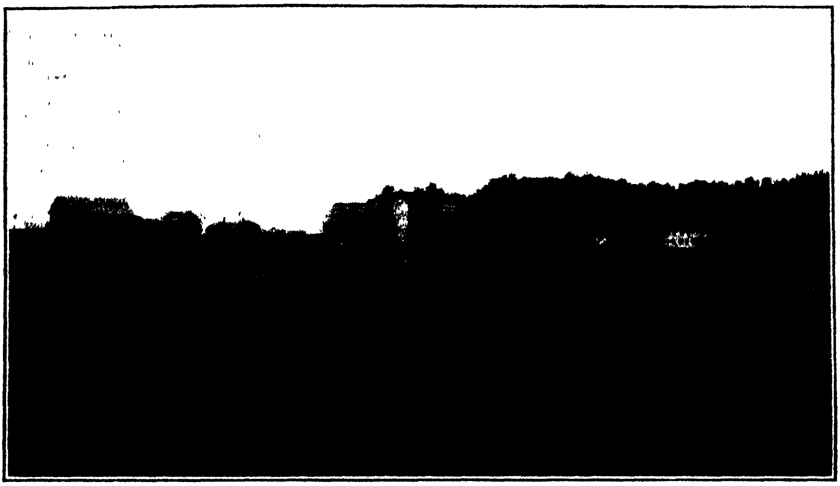

FIG. 218.—A pasture consisting of sweet clover and quack grass that has been grazed heavily with sheep for three years

FIG. 219.—A field in Oklahoma that has been in sweet clover continuously for 5 years and supports nearly 1 animal per acre for 5 months. Adjacent grass pastures support 1 animal on 2 acres for 6 months

### Yellow Variety Finds Favor

A better plan is to divide the field in halves and plant and graze them alternately. By many it is believed that the yellow sweet clover is better adapted to permanent grazing than the white variety, because it produces seed freely, even if pastured close to the ground. By others a mixture of the two varieties is favored as this lengthens the pasturing season 7 to 10 days at each end.

Sweet clover may often be used to improve the carrying capacity of an old or worn-out grass sod. In doing this it is necessary to bring the sweet clover seed actually into contact with the soil. If the seed is merely scattered over the sod, most of it is held off the soil by the old grass and only a few seedlings take root. On tillable land the seed can be cut into the sod with a disk drill. Another plan is to burn off the old grass in the spring before sowing the seed. On western prairie sod a good practice is to plow wide but shallow furrows through the sod about 3 feet apart. This provides fresh soil on which to sow the seed. The presence of the sweet clover gradually improves the grass.

Pastures of excellent quality that last several years may be made by sowing mixtures of sweet clover and other forages. One such mixture contains 2 pounds yellow sweet clover, 2 pounds white sweet clover, 3 pounds orchard grass, 2 pounds redtop, and 1 pound Kentucky bluegrass. Brome grass should be substituted for the other grasses in the northern Great Plains and Japan clover for the redtop and bluegrass in the Southern States.

L. W. KEPHART.

## SWEET Clover of New Varieties Proves Useful

The recent rapid increase in the culture of sweet clover has aroused interest in the possibility of developing new varieties better suited to the different uses to which the plant is put. Interest has centered principally in the production of better hay varieties, since the common sweet clovers, especially the white-flowered species, are too coarse and heavy to make good hay from the second year's growth. Several good hay varieties

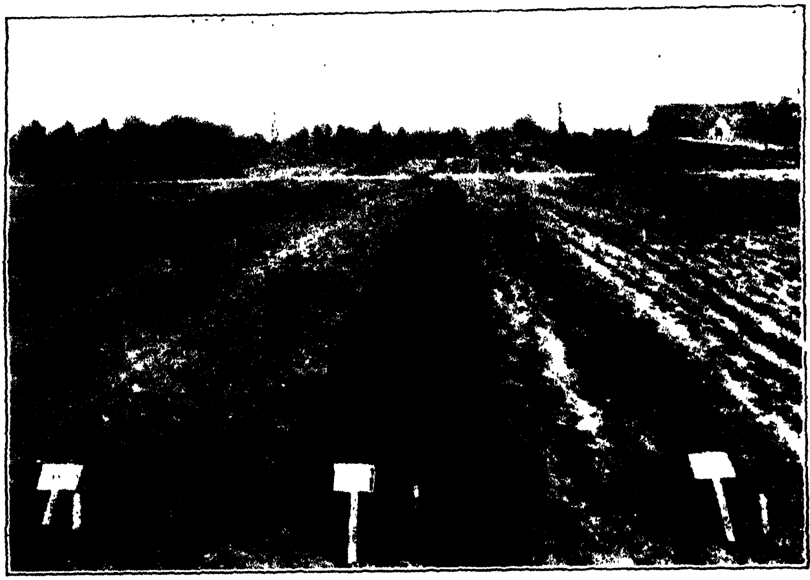

FIG. 220.—Some sweet clovers furnish pasturage much later in the season than others. On November 24, 1925, the variety in the center was still green, while the varieties on either side had been killed to the ground four weeks earlier

**have already been developed, notably the early-flowering Grundy County, Crystal Dwarf, and Early Dwarf varieties of white sweet clover and the Albotrea and Switzer varieties of yellow sweet clover.**

**A very interesting recent development in this direction has been the finding, at two of the western Canadian experiment stations, of a type of sweet clover bearing many more and finer stems than the common sorts, and in fact so closely resembling alfalfa in appearance that it is easily mistaken for that plant.** This is a very important discovery, and bids fair to add a distinct new type of forage plant to our list.

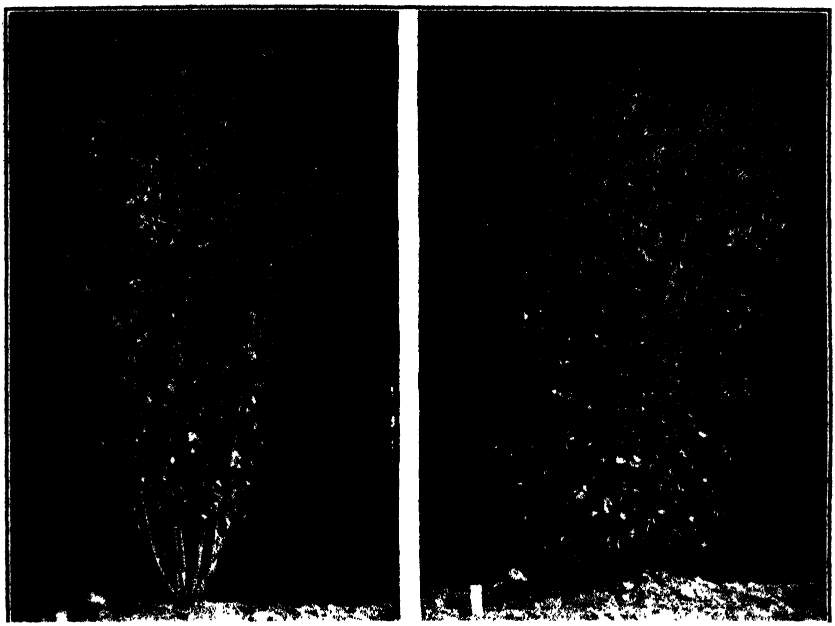

FIG. 221.—Sweet clovers differ greatly in leafiness and coarseness of stems. These two plants were taken from the same field of yellow sweet clover

The need for sweet clovers which are more winter-hardy has been met with Arctic, or Hansen's Siberian, a white-flowered variety from western Canada, and Albotrea, also from Canada. A sweet clover much better suited than common sweet clovers to the cold, dry climate of the northern Great Plains appears to have been found in an unknown yellow-flowered variety developed at the Redfield, S. Dak., field station of the United States Department of Agriculture.

### Variety Sought for Acid Soils

Several persons are endeavoring to find a sweet clover that will grow on acid soils, the need of lime in the soil being a serious hindrance to the culture of the crop in many localities. Other persons are trying to develop a sweet clover especially suited to withstanding the extreme drought and hot winds of the southern Great Plains. It is too early to say whether these efforts will succeed.

A type of sweet clover that would be exceedingly useful is one that would remain green late in the fall, start growth early the next spring, and remain green and in good feeding condition well into the following summer. Such a sweet clover would be immensely valuable for pasture purposes. A number of experimenters, both on farms and at experiment stations, have approached this type with selections of common white sweet clover. Perhaps even better results will come from tests now being made with species and varieties brought in from Europe and eastern Asia, one such species this year having remained green six weeks later than any sweet clover heretofore grown.

All sweet clovers are exceedingly variable in their habits of growth, and many distinct types and forms may be found in nearly any sweet-clover field (fig. 221). Although it would not be desirable to flood the country with new sweet clovers, there is a legitimate opportunity to develop useful types of proved superiority.

L. W. KEPHART.

## SWEET Corn Quality Due to Farm and Factory Influences

Increased competition among the canners of sweet corn has given impetus to the study of quality in the canned product and efforts are being made to determine just what constitutes quality and what those factors are by which it is affected.

Quality is influenced by two sets of factors: (1) Those which determine the character and condition of the corn as it is delivered at the factory, and (2) those concerned with cannery practices. The conditions at the factory which affect the quality of the canned corn are generally understood, and canning methods are fairly well standardized, so that these require no particular attention. The factors influencing the quality of the raw corn, however, are not so well understood.

For several years workers in the Department of Agriculture have been making a special study of this subject. Field and laboratory experiments have been made upon all the commercially important varieties of sweet corn as well as representatives of most of the other types; studies have been made of the effect of seasonal and climatic factors upon the corn; and practical canning experiments have been made on the corn at different stages of maturity. The results of these experiments have thrown considerable light upon the problem.

From these it would appear that first of importance in determining quality in corn is the tenderness or toughness of the kernel hull. This varies to some extent with the different varieties, but is particularly affected by the degree of maturity of the corn. The toughness increases very rapidly as development of the kernels proceed, being most rapid during the seasons of high temperature. In cool weather the increase is much less rapid. From the standpoint of toughness the period during which first quality corn can be packed is very short.

### Proportion of Kernel Parts

Next in importance is the nature and relative proportions of the different constituents in the kernel. In the sweet corn these are composed principally of starch and dextrin. These increase in amount as the growth of the kernel proceeds and give to the corn the desirable body or consistency. The dextrin or dextrinlike substances are responsible for the creamy texture found in first-quality corn.

Although there are different kinds of sugars in sweet corn, that which furnishes the natural sweetness in corn at canning maturity is principally sucrose or cane sugar. Since this may be added at the time of canning with fairly satisfactory results, natural sweetness is considered as third in importance.

Natural flavors appear to be next in importance. These do not vary greatly in the different varieties of corn when at canning maturity, though there are distinctive differences in the flavors of the white and the yellow varieties. When corn is too mature the desirable flavor disappears and one less desirable takes its place.

These various properties are directly affected by the degree of maturity, and in the packing of first-quality corn maturity must be given first consideration.

Tests to determine the relative merits of the different varieties have shown that the variety factor is not important in determining quality, any of the standard varieties yielding a first-class product if canned at the proper stage of maturity.

Seasonal and climatic factors, particularly that of temperature, through their influence on the rate of development, have a profound effect on the quality of corn as it appears in the can. High temperatures speed the maturing processes and shorten the time during which corn may be satisfactorily handled.

C. A. Magoon.

## SUGAR-Cane Varieties That Resist Disease

It has been increasingly apparent during the season of 1926 that, owing to the combination of low prices for sugar and low yields of sugar cane, many producers of this staple commodity in the South will be forced to discontinue the planting of cane unless some effective remedy is applied at once. The cane planters that are affected are not only the marginal producers but include some of the most experienced and successful growers utilizing the best lands. Increased per-acre production, which of course means lowering the cost of production, is the only course by which the situation can be alleviated until a readjustment of the world's production of such to meet the world's requirements establishes a more satisfactory price.

One of the most apparent causes of declining yields in the cane fields is the presence of several destructive diseases of the cane, which for a number of years have been accumulating until there now exists on many plantations a condition of disease saturation, where not a healthy plant is to be found in whole fields. That these diseases are a major factor contributing to the decline in yields is easily demonstrable by experiment. A simple and effective means of relief is offered by the substitution of disease-resisting varieties for the old varieties of cane.

### Resistant Varieties Collected

Fortunately, a number of such disease-resisting varieties have been collected by the Department of Agriculture and tested, both in small experimental plats and on a large scale under commercial plantation conditions. Increased yields of the resistant varieties indicated by these tests range from 30 to 50 per cent greater yield of sugar per acre than that produced by the old varieties. The varieties used in these tests were P. O. J. 36, 213, and 234, all of which are hybrid varieties imported from Java, and Cayana, a variety of the Chinese group of canes. Owing to the relatively low purity of the juice in the case of Cayana, it is especially adapted to sirup making.

Many other promising disease-resistant varieties are being tested by the department, but only the varieties mentioned have been commercialized. They are available in quantities sufficient to plant one-fifth to one-fourth of the total acreage in Louisiana this year, and of course if they are extended to any degree this means there would be ample seed next year to plant the entire acreage devoted to cane in the new varieties. Practically all of this represents the increase from a few cuttings of the varieties P. O. J. 36, 213, and 234, which were turned over to a plantation near Houma, La., in 1922 and 1923.

The qualities of these cane varieties that commend themselves to the sugar planter are:

(1) Resistance to mosaic and root disease resulting in increased yields as compared with the old varieties.

(2) Economy in planting material. Only 1 to 1½ tons of seed to the acre is required as compared with 4 to 6 tons of D-74 and Purple canes. This reduces costs of production very appreciably, as the value of seed cane represents a large proportion of total costs.

(3) Ability to ratoon over a longer period of years. Satisfactory stubble crops have been obtained with these varieties in other countries for seven or eight years, and, although it is yet too early to say with certainty, the indications are that double the number of stubble crops now obtained can be expected with these new varieties in Louisiana.

(4) Increased fiber production. About 20 per cent increased yield of bagasse has been reported for the new varieties. With increased utilization of the material for the manufacture of lumber substitutes, it has become an exceedingly valuable by-product.

(5) Resistance to hurricane damage. It has been demonstrated that Cayana scarcely lodges at all and P. O. J. 234 straightens up after lodging in windstorms that practically ruin varieties like D-74 by snapping off the more brittle stalks.

(6) Tolerance of cold. Where observations have been made on P. O. J. 36, 213, and 234 in other countries and on Cayana in this country a very definite tolerance of temperatures fatal to other varieties has been noted.

### Desirable Qualities Observed

The desirable qualities of these varieties have not gone altogether unnoticed in Louisiana. One plantation near Houma increased the seed of these varieties to the greatest possible extent, even in the face of much adverse criticism. The American Sugar Cane League, made up of cane growers in Louisiana, has lately made a strong effort to establish them in the State. Largely as the result of efforts by these two agencies, a remarkable increase in the quantity of available planting material of the new varieties has been effected.

E. W. Brandes.

---

**SUGAR-Supply Sources of the United States** In the five years 1921–1925 more than half of the sugar which became available for consumption in continental United States was the product of the island of Cuba. Second in volume to the Cuban supply in every year of the five was the domestic production of beet sugar. Hawaii and Porto Rico were, respectively, third and fourth in every year of the five in the volume of sugar supplied. In 1921 and 1922 domestic cane sugar was the fifth largest source of supply, with the Philippine Islands sixth; but in 1923, 1924, and 1925 the supply from the Philippines was larger than that from Louisiana. Sugar from all other sources of supply amounted to only 4 per cent of the total in 1921, 3 per cent in 1923, 1½ per cent in 1924, and less than 1 per cent in 1922 and 1925.

The gross supply of sugar by origin for each of these years, in terms of centrifugal raw sugar, is shown in Table 25. But in order to arrive at the net supply, deductions must be made for sugar exported or shipped back to the noncontiguous territories or possessions. The sugar exported is practically all refined sugar which has previously been imported in raw form. It is impossible to determine the exact origin of this sugar which passes through American refineries and goes out again to foreign markets, but it is practically all duty-paid sugar, for the quantity of sugar on which an export drawback is paid is in every year approximately equal to the domestic exports. In fact, the total on which drawback was paid in the five years 1921–1925 was actually slightly in excess of exports in those years. In the long run, however, the excess should be on the other side, at least by the quantity exported to the Virgin Islands and some minor border exports of true domestic sugar on which no drawback can be collected. Since the quantity of sugar on which drawbacks are paid is so close to the quantity of domestic exports, and since the official reports give the raw equivalent of the sugar on which drawbacks are paid, this raw equivalent rather than domestic exports of refined sugar has been deducted from imports in order to arrive at a figure for net supply. Table 26 shows the net supply made available for consumption in each of the five years, 1921–1925. This table was derived from Table 25 by deducting pro rata the raw equivalent of exports on which drawback was paid from the duty-paid imports and deducting actual shipments of refined sugar to Hawaii and Porto Rico and actual exports to the Philippines and Virgin Islands from the shipments and imports from these islands. No deductions have been made from the supplies of domestic sugar, as it is not believed that any appreciable quantity of this sugar is ever exported. No account is taken of annual shipments of about 3,000 tons to Alaska, so in this computation Alaska is in effect taken as a part of continental United States.

Table 27 is a percentage table based on Table 26, showing the relative importance of the several sources of sugar supply in each of the five years considered.

TABLE 25.—*Sources of sugar supply for continental United States,*[1] *calendar years 1921 to 1925, inclusive*

| Origin | 1921 | 1922 | 1923 | 1924 | 1925 |
|---|---|---|---|---|---|
| | *Short tons* | *Short tons* | *Short tons* | *Short tons* | *Short tons* |
| Cuba | 2, 590, 073 | 4, 527, 145 | 3, 426, 343 | 3, 692, 448 | 3, 923, 094 |
| Domestic beet | 1, 074, 000 | 726, 000 | 947, 000 | 1, 172, 000 | 981, 000 |
| Hawaii | 541, 128 | 567, 734 | 519, 195 | 676, 886 | 755, 159 |
| Porto Rico | 469, 296 | 360, 332 | 342, 157 | 392, 787 | 600, 412 |
| Philippine Islands | 164, 877 | 274, 809 | 237, 886 | 339, 007 | 492, 774 |
| Domestic cane | 327, 701 | 295, 735 | 162, 023 | 88, 483 | 197, 528 |

## STEM Rust in Many Varieties Attacks Grain

Black stem rust looks the same whether it be on wheat, oats, barley, rye, or any one of the 75 or more different kinds of grasses on which it can develop. But one can not tell from the appearance of the rust how it will behave. There are different varieties and physiologic forms of this rust.

There are at least six varieties of black stem rust, just as there are many varieties of wheat. These rust varieties differ in their ability to cause rust on the small grains. For instance, the wheat variety of rust can spread to wheat and barley but not to rye and oats. The rye variety can cause rust on rye and barley but not on wheat and oats. Still another one, the oat variety, can cause rust on oats but not on wheat, barley, or rye. There are at least three other varieties, each one able to infest certain grasses but not others.

Not only that, but each one of these rust varieties in turn consists of physiologic forms which differ in their ability to attack different varieties of the small grains. The variety of stem rust on wheat really consists of about 40 distinct physiologic forms; that on oats of 5 or 6; and that on rye of at least a dozen. Some of the forms of the wheat variety of rust attack certain varieties of wheat but not others. For example, Kanred wheat is immune from about a dozen of the forms, moderately resistant to a few, and completely susceptible to the others. Marquis wheat is completely susceptible to many of the forms but highly resistant to many others. The durum wheats as a class are resistant to many of the forms but completely susceptible to others. The same thing is true of the behavior of varieties of oats and rye to the physiologic forms of the rust varieties attacking these crops.

### Peculiar Behavior Explained

This parasitic or physiologic specialization of the black stem rust explains many things. Many people often wonder why grain fields may be heavily rusted near barberries in one year and not in the next. It often is due to the presence of different varieties of rust. For example, if rusted wheat is grown near barberry bushes one year, oats may be free from rust in the same field the next year although the barberry bushes may be heavily rusted. This is perfectly natural, as the rust on the barberries probably will be the wheat variety, which does not infect oats.

The same variety of grain may behave differently with respect to rust in different regions in the same year, or in the same region in different years. Marquis wheat usually is heavily rusted in the hard red spring wheat region if weather conditions are favorable for the development of rust. But in the Southern States and in some of the Pacific Coast States it usually is very resistant to rust, because the physiologic forms of the wheat variety of rust normally occurring in those regions can not infect Marquis. Kanred wheat is immune from rust in some regions but completely susceptible in others, also because of the occurrence of different physiologic forms of the wheat variety of rust in the different regions.

The same variety of wheat also may behave differently toward rust in the same region in different years. For instance, the durum wheats usually are resistant to rust in the upper Mississippi Valley, because in many years there are few if any physiologic forms in that region which can infect them. But in 1923 the durums rusted heavily. The explanation was simple: The most abundant rust form that year was one which attacks the durums heavily.

### Much Crossing Required

This existence of different varieties and forms of the stem-rust fungus is very important in attempting to develop rust-resistant varieties of the small grains. No varieties of bread wheats, durums, or emmers are resistant to all of the physiologic forms of the wheat variety of stem rust. This means, therefore, that it is necessary to cross and recross many varieties in attempting to get some which are resistant to all or most of the physiologic forms. Since the discovery of the peculiarities of the rust parasite, this work is being done on a sound, scientific basis, and excellent progress already has been made. And still greater progress can be expected in the future.

It is important to know whether the varieties and physiologic forms of the stem-rust fungus remain constant or whether they change their parasitic abilities. If they change rapidly, we must face a constantly changing problem in breeding resistant varieties. So far there is no evidence that they do change rapidly. But more investigations must be made to find out whether they do. This much is certain, however: There are physiologic forms of the different varieties of rust in foreign countries that have not yet been found in North America. Some of them are more virulent than any yet found in our grain-growing regions. It is very important, therefore, to avoid introducing into this country rusted straw or any other plant parts from foreign countries which might carry varieties or physiologic forms of the rust which are not yet known to occur in the United States.

## SWEET Potatoes in Canned Form Find New Uses

The sweet potato is produced in large quantities and is a highly nutritious and palatable food, but owing to its perishable nature and poor shipping qualities its use is rather restricted, and thousands of households are still unaware of the delightful properties of this really excellent food. The sweet potato is adapted to a wide variety of culinary uses. Once this has become realized and the potato has been made available in all parts of the country, and at all seasons of the year, it should become tremendously popular.

The introduction of canning methods has overcome the disadvantage of poor shipping quality and canned sweet potatoes of excellent quality have been on the market for some time. It has not been feasible in this canned product, however, to duplicate all the desirable properties of the fresh product.

There are two types of sweet potatoes, and, as might be expected, diverse opinions regarding them. The one when cooked is rather dry and mealy and the other is soft and moist. In the South the moist type is better known and is probably more widely used for table purposes, while in the northern section of the country, in general, the drier sorts are preferred. This is due no doubt to the fact that the moist varieties do not enter so generally into the northern markets.

### Many Dishes Possible

A considerable variety of delightful dishes are prepared from the sweet potato, ranging all the way from the plain boiled or baked potato to the candied slices, sweet-potato custard, puddings, pies, etc. Few persons realize how closely the southern sweet-potato pie and the New England pumpkin pie resemble each other both in appearance and in flavor.

The full natural sweetness of the sweet potato develops only after a period of storage, the sweetness being due primarily to the presence of sucrose or cane sugar which is formed during this storage period. It is customary, therefore, to store the potatoes in order to obtain this desirable sweetness.

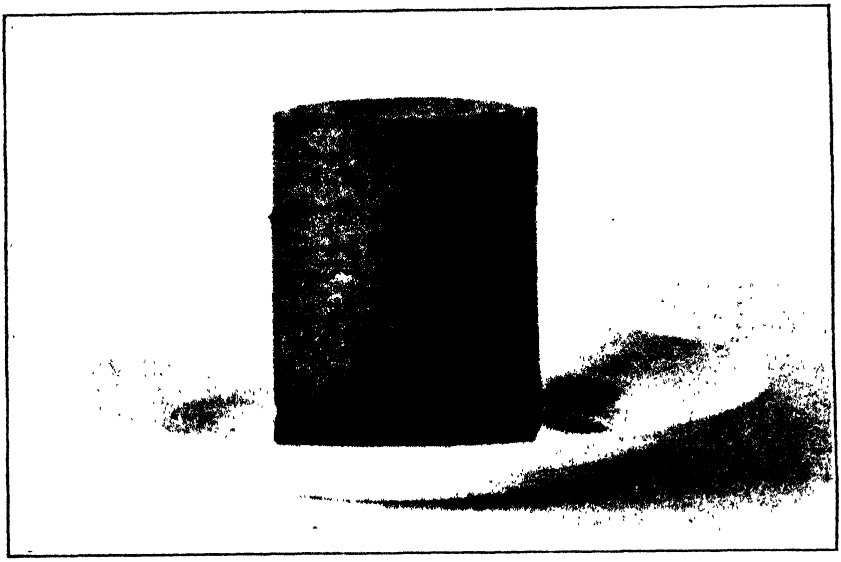

FIG. 222—Nancy Hall sweet potatoes canned immediately after digging. This product may be sliced and used like fresh potatoes

During the storage period other changes also occur within the potato which greatly affect its table quality. When freshly dug sweet potatoes are cooked the product is always firm and dry, whereas that from the stored potatoes is much softer, and varies all the way from rather dry to very moist in character. For instance, in the Big Stem Jersey, Yellow Jersey, and others of the Jersey group, the changes are not so pronounced and the cooked potatoes are rather dry, but in the Nancy Hall, Porto Rico, Southern Queen, and others of this type, the natural alterations are greater and the cooked potatoes are very soft and moist.

### Both Kinds from One Potato

Bearing in mind the preferences of the different users for a dry potato on the one hand, and a moist potato on the other, workers of the Department of Agriculture have taken advantage of these changes taking place during storage, and by a series of practical canning experiments have shown that it is entirely feasible to produce both a dry and a moist canned product from the same potato. By canning the freshly-dug potatoes of such desirable varieties as Nancy Hall, Porto Rico, Gold Skin, etc., one may obtain a product very attractive in appearance and flavor and one that may be sliced for sauteing, candying etc., just as satisfactorily as the fresh potato (fig. 222), and by canning the same variety after the usual storage period a soft moist product may be obtained which is very well adapted to the making of puddings, pies, etc. (fig. 223).

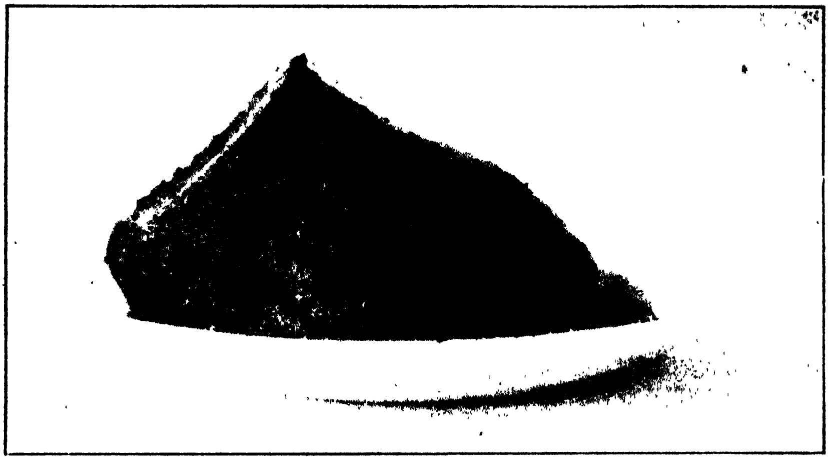

FIG 223.—Nancy Hall sweet potatoes canned after the usual storage period. This product is perfectly adapted to the making of puddings, pies, etc.

Thus, canned products perfectly well adapted to every culinary use to which the fresh sweet potato is put may be made available everywhere and at all seasons.

## SWINE Erysipelas Identified with "Diamond Skin"

Swine erysipelas has been known to exist in European countries for many years, but was not recognized as such in the United States until a comparatively recent date. Through investigations begun during 1920 by the pathological division of the Bureau of Animal Industry it was found that the so-called diamond-skin disease of swine, long known in this country, is a chronic form of swine erysipelas. The erysipelas germ was isolated from the skin lesions in a number of cases.

Further investigations have demonstrated conclusively that swine erysipelas in the acute form also exists in the United States. In this form the symptoms are somewhat similar to those seen in acute hog cholera. In fact the similarity of the symptoms in these two diseases suggests the possibility that, in some instances, there may have been losses from swine erysipelas which was mistaken for hog cholera. It has also been suggested that the "breaks" which sometimes occur in herds following immunization for the prevention of cholera may have been due in some instances to swine-erysipelas infection. We have no definite information at the present time regarding either of these possibilities.

"Diamond-skin disease," or the mild form of swine erysipelas, is manifested chiefly by the appearance of square or diamond-shaped, highly reddened areas on the skin and is of common occurrence in this country. Present knowledge regarding the prevalence of the acute form of the disease indicates that thus far it has been more or less of a sporadic nature, or confined, in most instances, to isolated cases of the disease.

The preventive treatment of swine erysipelas, as practiced also in European countries, consists in protective inoculation with immune serum and virus of the disease, being analogous to the double method of treatment used in the prevention of hog cholera.

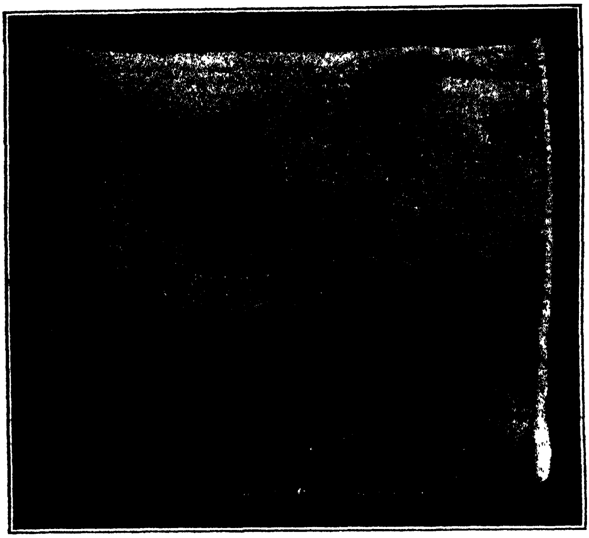

FIG. 224.—Specimen of hog skin showing typical appearance of chronic swine erysipelas

GILBERT T. CREECH.

## TANNIN Content of Chestnut Stumps and Roots

The wood of the American chestnut tree is at present our most important tanning material. At least one-half of our domestic supply of tannin comes from it. The trunks and branches, which contain from 6 to 10 per cent tannin, are cut for "extracting," a process in the preparation of commercial tanning extracts containing from 25 to 65 per cent tannin.

At present chestnut stumps and roots are not used for extract making. Recent experimental studies by the Bureau of Chemistry have shown that both the bark and wood of these parts of the trees are relatively rich in tannin. Root bark, although but a small part of the entire root, contains the most tannin, reaching in one case the very high figure of 37 per cent, and ranging between this and 25 per cent. Root wood was also found to be rich in tannin, although it showed more variation in this respect than root bark. The results for root wood ranged from 9 to 23 per cent tannin. From an analysis of a number of stumps the average tannin content of different parts of chestnut stumps was found to be as follows: Bark up to 5 feet, 12.7 per cent; heartwood, center, 9.3 per cent; heartwood, edge, 16.4 per cent; root wood, 17.4 per cent; root bark, 31.4 per cent.

On the basis of an average for present-day "extract" wood of from 7.5 to 8.5 per cent tannin, the results obtained on stumps and roots would indicate a yield from them approximately twice as great as that from the commercial run of wood. These data consequently suggest the possibility of utilizing chestnut stumps and roots as a commercial raw material for tanning extract.

Because of the rapid development under normal conditions of excellent second growth from chestnut stumps it might be considered unwise to advocate the removal of these stumps. This argument, however, is overcome by the prediction of our best authorities that within the next 15 to 20 years the chestnut blight will have killed or diseased all American chestnut trees in this country east of the Mississippi River.

Among the samples included in this study were some from old stumps and roots that had been severely weathered for a number of years. It was found that even after such weathering the tannin content was relatively high. In later years, therefore, after the supply of sound, living chestnut has been seriously depleted the stumps and roots may be worth salvaging as a commercial source of extract so far as their tannin content is concerned.

R. W. Frey.

## TAXATION of Farm Property Burdensome

The added costs of governmental service have laid increasing tax burdens on the farmers. State and local units in the country as a whole obtain 80 per cent of their total revenue from the proceeds of the general property tax. The farmer's property is of a sort that is readily discoverable by the assessor and that bears a heavier proportional share of the general property tax than do many other classes of property. In some sections of the country an almost intolerable tax burden rests on the farmer. Figures recently compiled for a number of rented farms in several Michigan counties show that for the last seven years taxes have taken about 90 per cent of what otherwise would have been the net return to the owners of these farms. It is believed that this is an exceptionally bad condition, but other studies in various sections indicate that in recent years a tax burden which takes from one-third to two-thirds of the return is by no means unusual.

Large reductions in the aggregate amounts expended by the State and local governmental units can not be expected in the immediate future. The major items of expenditure, the costs of roads and schools, will tend to increase rather than to decrease in amount.

When the public demands that the Government perform new functions or render new services, or when it demands that the old functions or services be expanded, it must be prepared to pay for them. Such an increase in governmental expenses will be dangerous if it brings with it needless extravagance and waste. Effective methods of controlling the expenditures of local units become more necessary when the amounts handled by such units are large. If, however, the Government performs the necessary services efficiently and economically, there is no reason for condemning the increased expenditures.

### Means of Relief

In view of the facts that the total expenditures of the local and State governments can not be materially reduced in the near future, and that the tax burden on farm land in many sections is oppressively great, it may be asked whether any means of relieving the tax troubles of the farmer exist. The possibilities that come from budgetary control and elimination of waste have been mentioned. There are two other possibilities that present some opportunity for the reduction of farm taxes. The cost of maintenance of schools and roads when paid mainly from local funds weighs heavily on sections of a State where the level of wealth is low. The benefits of schools and roads can be assigned to a wider area than that of the local community, and the growing tendency to pay their costs by contributions from larger areas will relieve the poorer sections.

This does not, however, necessarily relieve agriculture as a whole from its burdens. Such relief must come from the opening up of new sources of taxation. The wide extension of the gasoline tax in recent years and the general spread of State income taxes are examples of such sources. In those States where there is a large volume of nonagricultural wealth, the income tax or any other measure which obtains a contribution from intangible property will tend to lessen the burden on agriculture. Where nonagricultural wealth does not exist in large volume, a readjustment of assessments on an equitable basis may frequently relieve those sections or individuals on which the tax burden has been especially heavy and will obtain added tax contributions from property that has paid little in the past.

The recent changes in the Federal income tax have largely eliminated the farmers' direct contribution to the Federal Government. It is true that there are important indirect contributions made by farmers to pay Federal expenses, but such payments are difficult to measure and bulk much smaller than do the farmers' payments to State and local units.

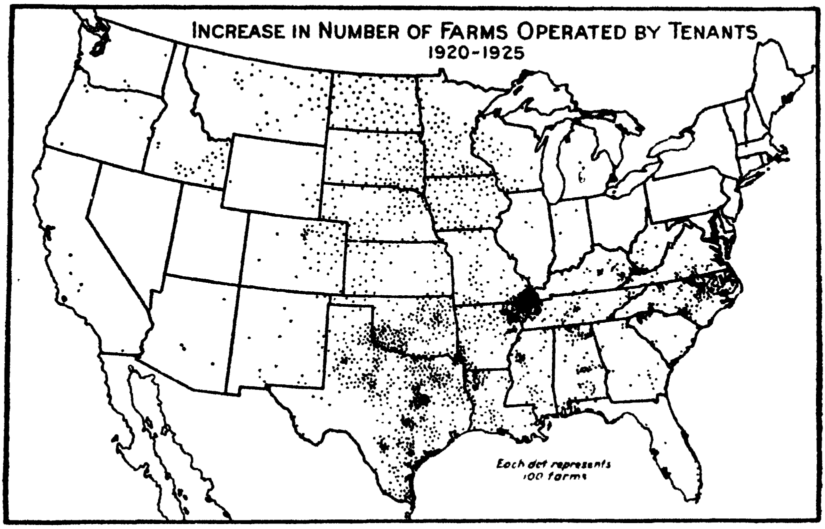
WHITNEY COOMBS.

---

## TENANCY Changes From 1920 to 1925 Not Excessive

The period 1920–1925 was one of adjustment in agriculture along many lines, and changes in tenancy and ownership were to be expected. Rising prices of farm products coupled with easy credit encouraged the purchase of farms with small down payments while the ensuing slump caused a change in ownership. Owners and tenants alike suffered from low prices and high costs but the tenants could, as a rule, move more quickly than owners. In many cases the owner-operated farm of 1920 was a tenant-operated farm in 1925. Local influences such as crop failure, low prices for some particular crop, the shifting of areas of production of a given crop all played important parts in the adjustment. There is no means of knowing at present whether these changes represented definite trends or whether they were merely the temporary results of disturbed conditions.

Accompanying this article are maps, the data for which were compiled on a county basis, showing changes that occurred in the tenure of land in different regions of the United States during the period 1920–1925. Because of the counterbalancing effect of regional changes, the net change in tenancy was rather small for the country as a whole. There were only 7,724 more tenant-operated farms in 1925 than there were in 1920, but during this period owner-operated farms declined 56,756. The net effect was that there was an increase of one-half of 1 per cent of all farms operated by tenants. This rate of increase in percentage of tenancy is almost the same as that for the period 1910 to 1920. Tenant-operated farms formed 38.1 per cent of all farms in 1920, while 38.6 per cent were so reported in 1925.



INCREASE IN NUMBER OF FARMS OPERATED BY TENANTS
1920-1925
Each dot represents 100 farms

FIG. 225.—Increases in number of tenant-operated farms were local east of the Mississippi River and very general between that river and the Rocky Mountains

A comparison of Figures 225 and 226 brings out two important observations: (1) The number of tenants has declined in most of the counties east of the Mississippi River. (2) The number of tenants has increased in most of the counties west of the Mississippi River excepting those counties west of the Rocky Mountains.

### Northeastern United States

The decline in the numbers of tenants in the area east of the Mississippi and north of the Ohio and Potomac Rivers was accom-

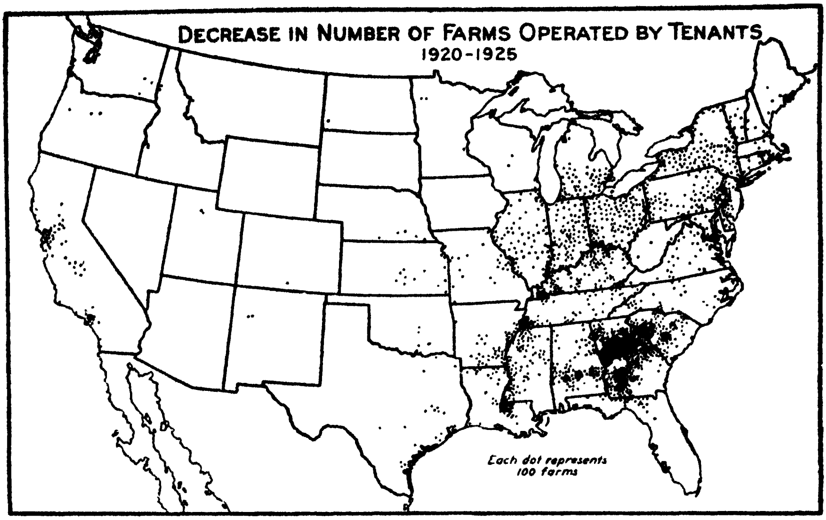


FIG. 226.—Most decreases in number of tenant-operated farms are found east of the Mississippi River

panied by an increase in the number of owner farms in most counties, though some counties showed losses of owner-operated farms. These latter were mainly in Ohio, Indiana, Illinois, Michigan, and Wisconsin. The increases in owner-operated farms were principally in those regions where agriculture is not the most important industry. (Figs. 227 and 228.) In the northeastern United States the increase in the number of owner-operated farms is apparently explained by the fact that many people who are employed in cities and towns live in the country, and farm as a side line. The percentage of tenant-operated farms has decreased in almost all counties in this part of the country.

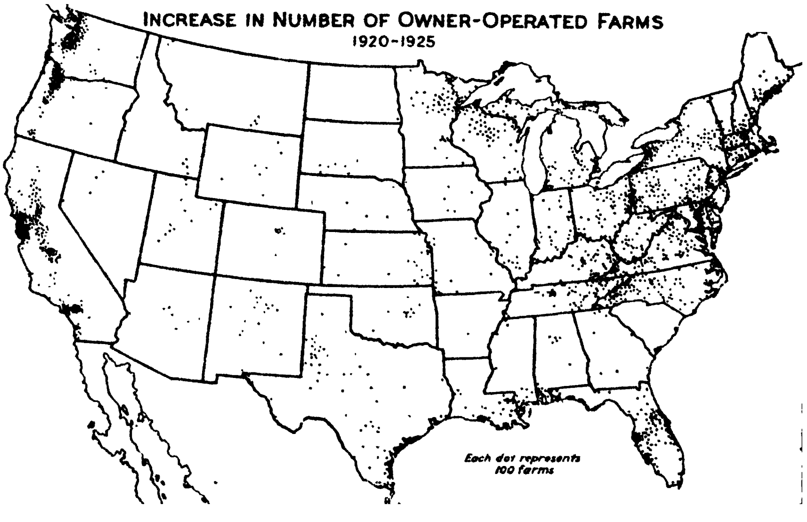

FIG. 227.—Few increases in number of owner-operated farms occur in the general farming section

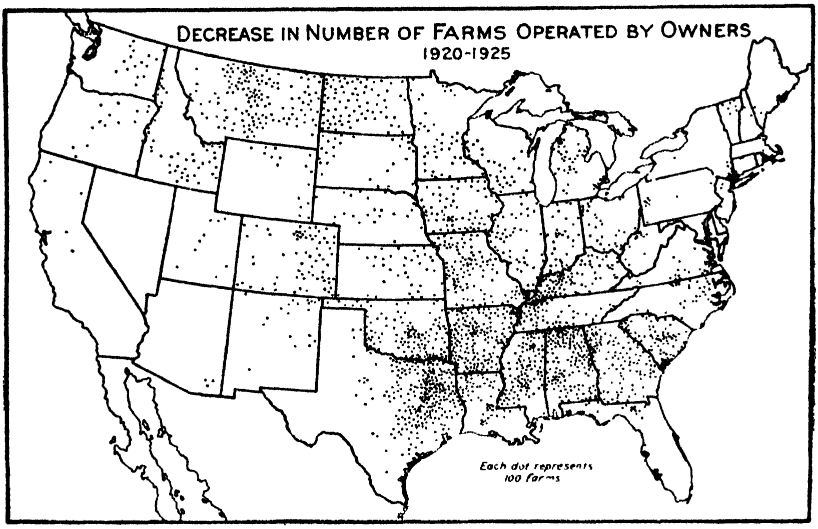
Local influences were dominant in the tenancy situation in this area. There was a great decline in number of tenants in Georgia and South Carolina. Bad years for cotton and the exodus of negroes account for it. (Fig. 226.) Increases in the number of tenants from 1920 to 1925 were local. (Fig. 225.) Cotton acreage was increased in western Kentucky and Tennessee and in adjacent areas of Illinois, Missouri, and Arkansas. Here occurred the greatest increase in numbers of tenants in the whole country. Most of the other areas showing considerable increases in numbers of tenants have recently introduced cotton or tobacco.

### Decrease in Owners

Decreases in the number of owners were very general in Mississippi, Alabama, Georgia, and South Carolina. Farming has not been very profitable in this area. Owners who had paid too much for land and others who thought that they could make more in other occupations departed. Under adverse conditions tenants may leave localities in a wholesale way while owners move less readily. The abandonment of farms by owners covers a much wider area. Increases in numbers of owner-operated farms took place mainly in the mountain regions and in Florida. Both of these increases were associated with home ownership rather than business farming.



DECREASE IN NUMBER OF FARMS OPERATED BY OWNERS
1920-1925
Each dot represents 100 farms

FIG. 228.—Decreases in number of owner-operated farms were quite general in the South and Middle West

### Western United States

Tenants decreased in numbers along the Mississippi River and in California. (Fig. 226.) The smaller number of tenant farmers along the lower Mississippi River is explained mainly by the failure of cotton in that region, while in California there has been some loss of Japanese tenants.

Increases in the number of tenant-operated farms in many parts of Texas, Oklahoma, Arkansas, Louisiana, and Missouri were the result of increased acreage of cotton in these same areas.

The larger number of tenants in the corn and wheat belts was due principally to a retrogression from ownership. Many owners became tenants and other owners, on leaving the farm, leased their land to tenants on any terms obtainable. Figures 225 to 228 when compared show that many of the areas with an increase in number of tenants had a decrease in number of farm owners. A pronounced increase in the number of owner-operated farms took place in the Pacific Coast States. These were mainly small farms.

### Changes in Percentage of Tenants

These changes are an expression of the effect of all changes in the numbers of tenants and owners in each county. There is apparently no general relationship between the increase or decrease in the percentage of tenancy and the prosperity of agriculture.

Decreases in the percentage of tenancy from 1920 to 1925 were most conspicuous in the Northeastern and Pacific Coast States. In many of the counties in the Northeastern States, a decreased percentage of tenant-operated farms resulted from a decline in the number of tenant-operated farms accompanied by an increase in the number of owner-operated farms. These owner-operated farms were in many cases small places used mainly as homes.

In the East North Central States tenant farms declined in numbers more rapidly than owner farms thus decreasing the percentage of tenant-operated farms. This statement applies also to most counties in the Southeastern States where a decreased percentage of tenant farms is shown.

In the Pacific Coast States the decreased percentage of tenant-operated farms was mainly due to a large increase in the number of owner-operated farms, mostly of small size. Increased percentage of tenancy is most conspicuous west of the Mississippi. In much of this region owner farms decreased in numbers and tenant farms increased. The percentage of tenants, of course, increased.

O. M. Johnson.

**Tenant Farmers in the U. S.** In 1925 our farm tenants were 38.6 per cent of the total number of farm operators. The percentage of tenancy in the different States and counties shows a wide variation. In some counties less than 5 per cent of the farmers are tenants. In other counties over 95 per cent are tenants. Only 3 per cent of the farmers of Maine were tenants in 1925 as contrasted with 68 per cent in Mississippi.

Farm tenants, for the most part, are young men. Tenants farming in 1920 averaged 39 years of age with 11 years' experience as tenants. Of farmers under 25 years of age, over three-fourths were tenants, but of farmers of 65 years and over only a sixth were tenants.

The large proportion of young men who are tenants is largely a result of the fact that they are using tenancy as a step in climbing the ladder to farm ownership. When beginning to farm, many start as farm laborers. Nearly half the tenants farming in 1920 had worked on farms for wages and among those who had never worked on farms for wages, there were many who had worked on farms for their parents. The experience, reputation, and capital gained while working for others gives the farm laborer the confidence, recognition, and means necessary to become a tenant.

In some parts of the country it is possible to become a farm tenant before one has money enough to own the animals and tools with which to work if one is able and willing to work as a cropper. Most farm tenants, however, own their work animals and tools from the time they start as tenants. When their accumulations are sufficient, tenants are likely to become interested in the acquisition of farm land.

### Some Owners Become Tenants

Equal progress on the tenure ladder is not made by all farmers and where there is progress there is the chance of a reversal. About a ninth of our farm tenants once farmed places of their own. Perhaps most of this ninth who no longer farmed their own land had stepped down on the tenure ladder, disposing of their equity in the land for what it would bring when they left it, but others were renting it to tenants in turn, and some others deliberately let their own land lie idle, finding it more profitable or convenient to rent land from other owners than to get a living from such small, infertile, unimproved, or inaccessible parcels as they themselves owned.

Because little capital is needed many start as farm tenants who remain farmers but a short time and most of those who continue as tenants have no property interest that can not be easily moved. Every year changes of tenants occur on an enormous number of farms, so that usually a third of the tenants are making their first crop on the farm they occupy. Before an owner farmer can move he is likely to find it necessary to obtain a customer for his farm, but no such difficulty prevents a tenant from changing farms frequently. The number of years farmers have operated the farms they are on will average, at any given time, about 12 for farmers who own and 3 for tenants.

Replies of the landlords of nearly 57,000 tenants widely distributed throughout the country indicate that about 23 per cent of the tenants were related to their landlords, the percentage being about 36 in the North Central, 24 in the Great Plains, and 12 in the Southern States. The proportion of tenants related to their landlords is about a third in Iowa, two-fifths in Wisconsin, but only a fifth in North Dakota, and a ninth in California.

The percentage of tenant farmers who are women was 3 in 1920, varying in the different States from 0.5 in Indiana and in Iowa to 7.4 in Mississippi.

### Racial Groups of Tenants

In 1920 about two-thirds (66.4 per cent) of the tenant farmers were native whites, 4.5 per cent foreign-born whites, 28.7 per cent negroes, and the other 0.4 per cent Indian, Japanese, or Chinese, as contrasted with owners, of whom 82.2 per cent were native whites, 11.8 per cent foreign-born whites, 5.5 per cent negroes, and 0.4 per cent colored farmers other than negroes. The great majority, 98.5 per cent in 1920, of colored tenants farm in the 16 Southern States.

In 1920, 561,091 of the tenant farmers of the South were croppers, so classified because they depended on the person from whom they rented to furnish the work animals as well as the land. In most cases such dependency is associated with further dependency on the landlord for feed, for supervision, work animals, implements, seed, and fertilizer used. For growing and harvesting the crop the cropper gets a share which is commonly pledged to obtain loans for necessities of life while the crop is being made. Of the entire number of croppers three-fifths were colored farmers in 1920.

In the South nearly half, 47.4 per cent, of the colored tenants farmed as croppers in 1920, whereas only a quarter, 25.6 per cent, of the white tenants of the South farmed as croppers. If one were to consider the croppers of the South in 1920 as laborers, and there is considerable justification for doing so, it would appear that 22.9 per cent of tenants of the country, or 35.3 per cent of the tenants of the South, were laborers working for a share of the crop, but with little to say as to the operation of the farm. In Mississippi and in Georgia nearly half, and in Arkansas two-fifths, of the tenants were croppers in 1920.

### Who Our Farm Landlords Are

The average farm landlord has less than two tenant farms of about a hundred acres per farm. Approximately four-fifths of the owners of rented farms own but one rented farm and over nine-tenths own but one or two rented farms.

The fact that about seven-eighths of the landlords with five or more tenants live in the South is closely connected with the difference between the North and the South in size and value of tenant farms and in the enterprise of the northern tenant as compared with the dependence of the southern tenant.

In sections of the South where negro tenants occupy most of the farms their dependency is such that the land is operated usually in large plantation units. On representative plantations a score or more of negro tenants may be employed under supervision, each being allotted a definite part of the plantation to work. The plantation system is not to be found in the North, and in the South it is prevalent only in certain regions, chiefly those where slave plantations prevailed before the Civil War. But in many parts of the South where there are no plantations a dependent cropper class exists which is commonly employed by owner farmers to work on shares land which the farmer can not tend with his own hired and family labor.

In the South farm landlordism is largely a phase of farm or plantation operation. In Northern States farm landlordism is commonly a phase of retirement from farms. Of a group of southern landlords over half reported themselves as farming as compared with a fifth of a group of northern landlords.

Owners of rented farms in the South evidently do not retain their land as long after they have reached the age of retirement from farming as is the case with northern landlords. The average age reported by representative southern landlords who had farmed and retired was 53.6 years which is the average actual age of all reporting southern landlords including those not retired. Northern landlords also retired at an age averaging 53.6 years, but northern farm landlords averaged 59.5 years in age.

### Most Owners Have Bought Their Land

In order to acquire farm land most of the present landlords have had to buy it. Of land owned by a representative group of 24,000 farm landlords over four-fifths had been purchased and only about a sixth obtained by gift or inheritance.

Less than a sixth of the reporting landlords were women and of the men who gave their farming experience almost half had farmed as tenants and three-fourths as owner farmers. Most persons who own rented farms have worked on farms. Few, even among those who inherit farm land, get it without having worked on farms.

If there has been any change in the amount and degree of absenteeism since 1900 the change has resulted in a decrease. In 1900, 21.2 per cent of the rented farms were owned by landlords resident out of the county. In 1920 only 19.6 per cent of a quarter of a million representative tenant farms were owned by landlords resident out of the county. The automobile, better roads, and rural free delivery of mail have increased the convenience with which distant residents can keep in touch with their tenants.

Over nine-tenths of the rented farms are owned by landlords who live in the county or in adjoining counties. Only about 5 per cent are owned by landlords resident out of the State and the number owned by persons resident out of the county is insignificant by comparison with the total number of tenant farms in the country.

In general less absenteeism is shown in connection with the ownership of rented farms in the East than in the West and less in the South than in the North. The proportion of tenant farms owned by landlords resident out of the county is about a third in California, two-fifths in North Dakota, a third to a fourth in Iowa, a fourth in Illinois, a fifth in Ohio, Delaware, and Alabama, a fourth in Maryland, and a sixth or seventh in Kentucky and some other Southern States.

## TERMITES Cause Modifications in Building Codes

Throughout most of the United States native termites, or white ants, cause serious damage to the foundations and woodwork of buildings and articles in the buildings. Such damage is especially serious in the Southern, Central, and Pacific Coast States and the tropical possessions of the United States. Termites damage buildings in both cities and rural regions, but the small householder usually suffers the greatest loss.

Improper construction of buildings is responsible for most termite damage, and it is a great hardship for a man of moderate means who is buying a house on time to be forced to expend several hundred dollars, a few years after making the initial payment, to repair damage done by termites

The woodwork of buildings can be protected from the attack of termites by proper construction and by the use of wood treated with preservatives. Where already established in buildings, these insects can be eliminated only by removing wood in contact with the ground and replacing it with wood chemically treated; fumigation, insecticides, or poisons are futile in permanently protecting buildings from our common termites which live in the ground.

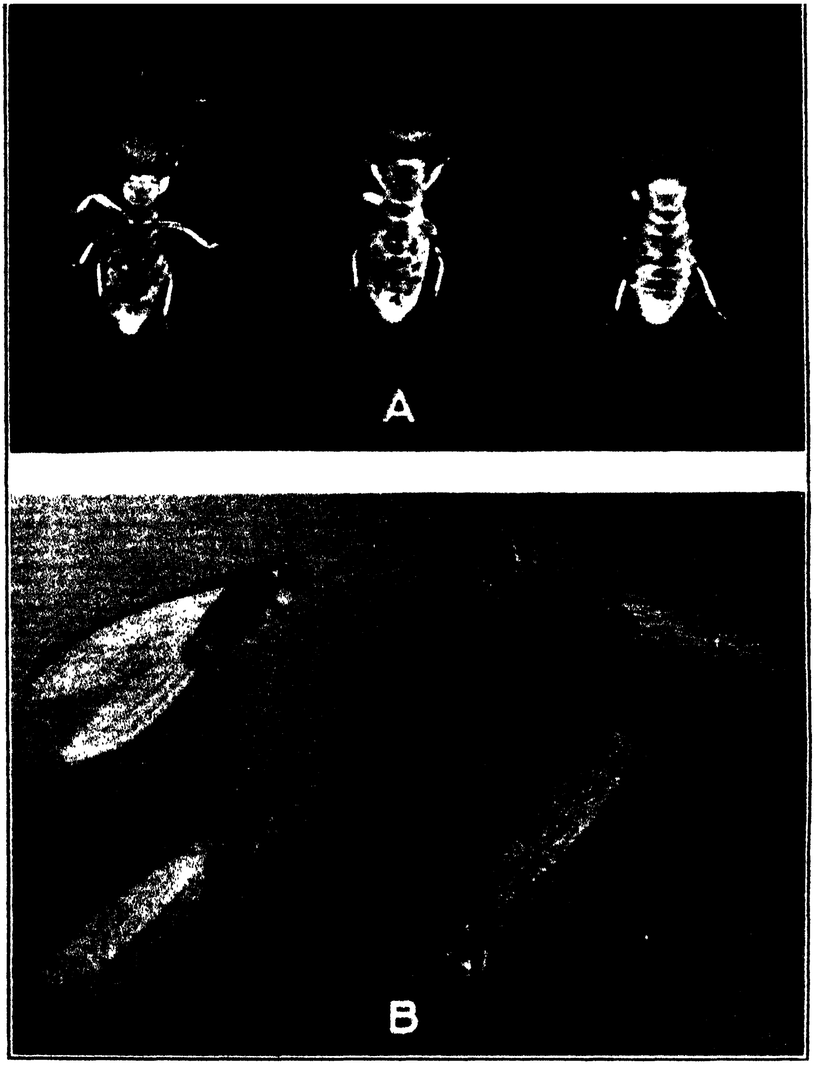

Fig. 229.– A, Worker termites of the common species that live in the ground; these remain hidden within the wood and are the destructive forms. B, The winged forms that usually appear in infested buildings in the spring are the sexual forms and should serve as a warning to the householder that damage is being done

To construct buildings so that they will be white-ant proof, make their foundations, where possible, entirely of stone, brick, or concrete, including stone or metal columns or pillars in the basement to support the floor above; make concrete walls and flooring in basement or cellar, and lay concrete floors on a gravel base. Where stone or concrete foundations are impracticable, use timber impregnated with coal-tar creosote.

In purchasing a house, insulation of all untreated woodwork from the ground should be insisted on. This is a form of home insurance and will pay in the end.

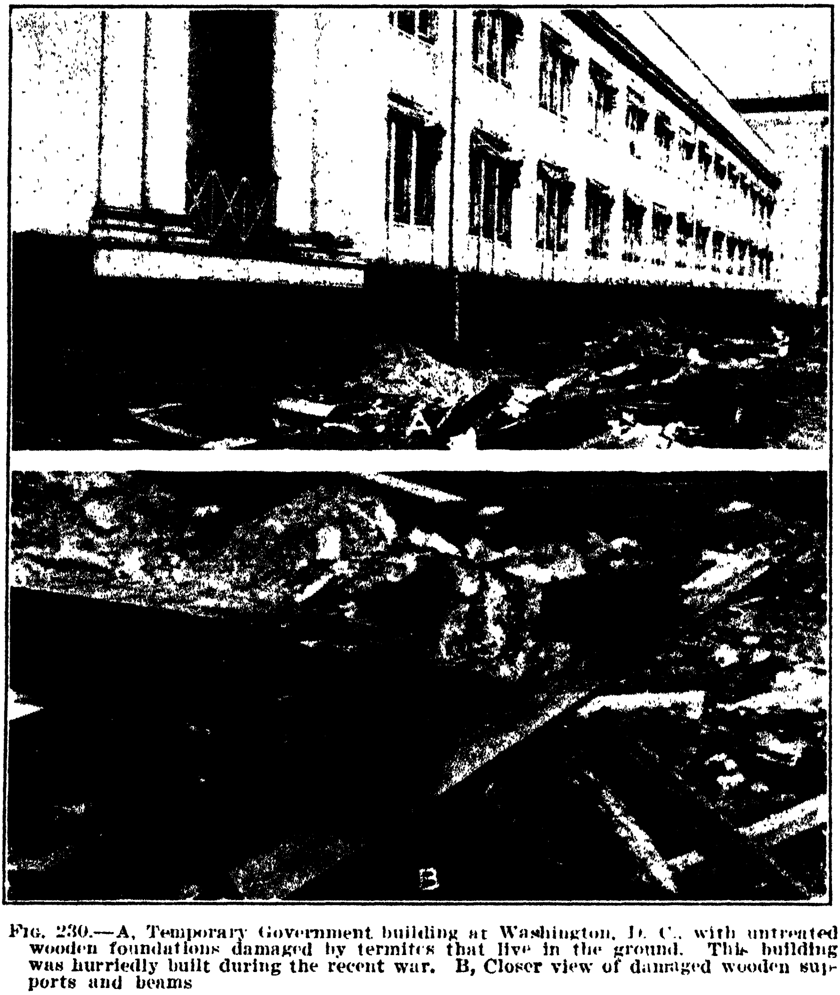

FIG. 230.—A, Temporary Government building at Washington, D. C., with untreated wooden foundations damaged by termites that live in the ground. This building was hurriedly built during the recent war. B, Closer view of damaged wooden supports and beams

One of the simplest and most effective means of preventing termite damage, is modification of city building regulations or codes so as to include a few simple rules for protection. In rural regions where there are no city engineers, county agents or community organizations could be utilized to protect the home builder.

Since the principal object is to keep all untreated wood from contact with the ground, in which the termites live and from which they get their moisture, the regulations should stipulate that no floors, sills, frames, beams, clapboard, or other parts of untreated wood may be laid on or in the earth, and that untreated beams may not be laid in concrete without at least 1 inch of concrete underneath and separating it from the earth. If damp proofing is desired, tar and tar paper between untreated wood and the earth are not effective in preventing attack and should be used only over a layer of concrete. Where mortar is used in foundations or in cellar walls where they are in contact with the earth it should be composed of 1 part Portland cement to 3 parts of sand graded from fine to coarse, with no grains larger than will pass through a No. 10 sieve, to which may be added 10 per cent by weight of the cement of some workable agent, such as hydrated lime. In preparing such mortar precaution should be taken that the lime is carefully slaked and screened. After cooling it should be thoroughly mixed with measured quantities of clean building sand free from organic impurities. All mortar joints, the central one in particular, should be thoroughly filled. Or, for greater precaution, all brickwork extending below the surface of the ground should be faced and capped with concrete at least 1 inch thick.

Where termites that attack wood directly and not from the ground occur, as well as subterranean termites, it is suggested that only woodwork impregnated with preservatives be used for exterior and interior construction, unless it is impracticable to obtain such treated wood.

Impregnation with coal-tar creosote is the most effective treatment for foundation timbers to be set in contact with the ground; for interior woodwork not in contact with the ground impregnation with zinc chloride is recommended.

Thos. E. Snyder.

## TICK Eradication Succeeding in Southern States

The history of the cattle industry of the South indicates that from the earliest plantation days the cattle disease, now commonly known as Texas or tick fever, has been the most serious obstacle confronting the southern cattle raiser.

For the last 20 years the Bureau of Animal Industry of the Department of Agriculture in cooperation with cattle owners and State and county officials has been waging a war of extermination on the cattle tick. The eradication of this tick means the eradication of Texas fever, as it is only through this particular parasite that this infectious blood disease of cattle is transmitted.

In 1906, when systematic, cooperative tick eradication was undertaken, 984 counties in 15 Southern States were below the Federal quarantine line that stretched across the country from a point on the Atlantic, near Norfolk, Va., to the Pacific coast, a little south of San Francisco, Calif. This quarantine line in a general way divided the tick-infested from the tick-free area, and all cattle in the vast territory south of this line were affected by the tick embargo.

Shipments from the quarantined area were restricted to a few of the large northern markets, where the receipt for immediate slaughter of these so-called "southern cattle" was authorized by an act of Congress passed in 1884. A recent act of Congress, approved June 28, 1926, repeals this special provision and requires that until

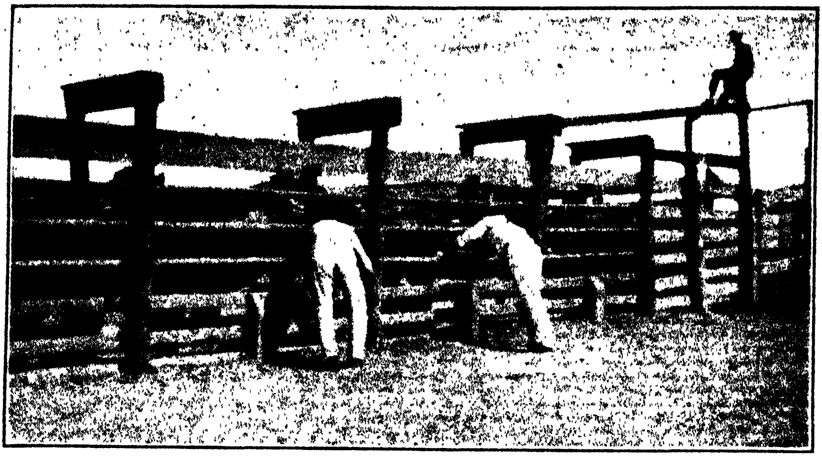

FIG. 231.—Chute inspection to determine freedom from the fever tick

May 1, 1928, cattle infested with or exposed to ticks may be shipped in interstate commerce for immediate slaughter after one dipping. After that date only tick-free cattle may be moved interstate for any purpose.

When first proposed the feasibility of evolving a practical procedure that would result in the complete eradication of the cattle tick from any considerable area was seriously doubted by many. Fortunately, however, there were others who had faith in the project or were at least willing to give it a fair trial, and later developments have amply justified the confidence of these pioneers.

As a result of the cooperative efforts 723 of the 984 counties originally quarantined, have been released from the tick-quarantine restrictions, and good headway is being made in cleaning up the remaining ticky territory. The movement of cattle from the quarantined area is no longer restricted to shipments for immediate slaughter. Cattle

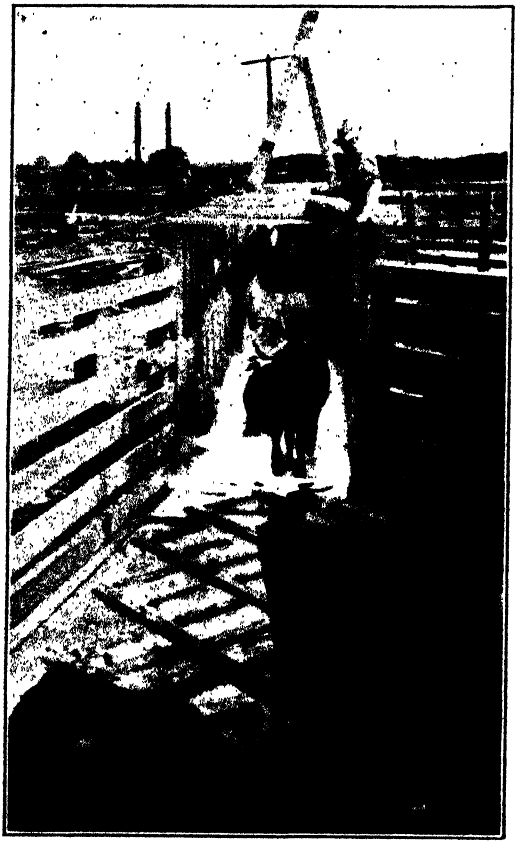

FIG. 232.—Cattle emerging from the tick-destroying arsenical bath

are now freed from ticks by dipping in an arsenical bath (fig. 232) and their shipment permitted for any purpose to any destination.

The extensive and varied sections of the country in which tick eradication has been conducted naturally presented problems that changed with local conditions. One of these which for a time was very troublesome was the "open range." In many sections of the South there are still large, unfenced range areas upon which cattle and other livestock range at will. When the work of tick eradication would reach these sections considerable difficulty was experienced in collecting all the cattle for dipping, and in ascertaining when all the cattle on a range were treated at the intervals required in systematic tick eradication.

It was soon apparent that to be successful under these conditions a system of checking that could be relied upon to identify the dipped from the undipped cattle was necessary. This difficulty was met by the simple expedient of placing a small paint mark upon each animal (fig. 233) as it went through the dipping vat. Riders then made a check inspection of the animals on the range, and those that have missed treatment are readily identified by the absence of the paint mark. Animals found without this paint mark are taken up and dipped.

FIG. 233.—The paint-mark check. Note spots on hip and shoulder for identifying cattle that have been dipped

In such ways the methods followed in the war on this pest have been improved upon from time to time as experience and investigation brought out new facts, until it may be stated that these methods have reached a degree of perfection and have had such wide use under varied conditions that the question of how to eradicate ticks is no longer the difficult part of the problem. The most important feature now is to obtain the thorough and conscientious cooperation of the cattle owners and local officials in order that the work may be completed without unnecessary delay.

W. M. MACKELLAR.

## TIMBER'S Harvest Time Depends on Soil Conditions

When is the best time to harvest the timber crop on the farm wood lot or forest area? Obviously, when the trees have reached the point of best development, according to the use to which the wood is to be put. It pays to wait many more years for saw timber than for pulp wood or fence posts. But when saw timber has reached a reasonable size and the rate of growth slackens, it is better to market the lumber and start a new fast-growing timber crop than to wait for larger growth.

The Forest Service through its forest experiment stations in every important timber region is striving to obtain figures on the rate of growth of every marketable forest tree. This work has only begun, but already approximate figures are ready for some tree species, and these are summarized for pulp wood and saw timber in Table 28. Fence posts and similar material can often be taken out each year as thinnings of the saw timber crop. Where fence posts are the main crop, the age for harvesting is about the same as for pulp wood.

[1] MBM=Thousand feet board measure.

DONALD BRUCE.

## TIMBER Measuring on the Farm Not a Difficult Task

The farmer should know how much timber he has, as well as how much corn, oats, tobacco, or cotton. With a little care and practice he can learn to estimate his standing timber as closely as any of his crops.

The log-scale stick tells how many board feet of lumber can be cut out of logs of various sizes and lengths. The Doyle rule, although in common use, does not tell this at all accurately for logs smaller in diameter than about 28 inches, and is still less accurate for logs smaller than 12 or 16 inches. For example, by the Doyle rule a 10-

inch log 16 feet long scales 36 feet, whereas by the prevailing close sawing it will yield about 64 feet.

Clearly the Doyle rule favors the buyer rather than the seller. The Doyle-Scribner rule is low for large logs as well as for small logs. A good rule that is gradually coming into general use, the International log rule, comes very close to giving the amount of lumber that can actually be sawed out by using good methods. It is recommended that so far as possible logs be measured and sold by this rule or by actual mill tally of the lumber cut from them.

TABLE 29.—*Portion of International log rule showing lumber contents of logs in board feet (saw cutting ¼-inch kerf)*

| Diameter in inches at small end of log | Length of log in feet | | | | | | |
|---|---|---|---|---|---|---|---|
| | 8 | 10 | 12 | 14 | 16 | 18 | 20 |
| | Contents in board feet | | | | | | |
| 6 | 7 | 10 | 13 | 15 | 19 | 23 | 27 |
| 7 | 12 | 15 | 19 | 24 | 28 | 33 | 39 |
| 8 | 16 | 21 | 27 | 33 | 39 | 45 | 52 |
| 9 | 23 | 29 | 36 | 43 | 51 | 59 | 68 |
| 10 | 29 | 37 | 45 | 54 | 64 | 75 | 86 |
| 11 | 36 | 46 | 57 | 68 | 80 | 92 | 105 |
| 12 | 44 | 57 | 70 | 83 | 97 | 111 | 127 |
| 13 | 52 | 68 | 83 | 100 | 116 | 133 | 151 |
| 14 | 62 | 80 | 98 | 117 | 136 | 156 | 176 |
| 15 | 73 | 94 | 114 | 136 | 157 | 180 | 204 |
| 16 | 84 | 108 | 131 | 156 | 181 | 207 | 233 |

| 23 | 186 | 235 | 285 | 337 | 388 | 442 | 497 |
| 24 | 203 | 257 | 311 | 367 | 424 | 481 | 542 |

To use a log scale, measure the diameter of the log inside the bark at the small end. Measure the length of the log in feet. Read the scale shown on the table or stick for the corresponding diameter and length. The scale is for straight and sound logs; if any defects appear, such as rot, shake, and crook, appropriate deductions should be made.

### Scale Table Method

Logs can be scaled by using an ordinary rule or yardstick and a scale table which shows the contents of logs of different lengths and diameters. The State or Federal forestry services supply such scale tables upon request.

To determine the merchantable contents of a standing tree, estimate the number of logs in the tree and the size of each log. To do this measure the diameter of the tree outside the bark at breast height (4½ feet above the ground), and also the height to the top end of the smallest log. The taper of the trunk is often about 2 inches to the 16-foot cut. Near the top it may be more. By getting the content of each log with a log rule it is then easy to estimate the total lumber content of the tree. Again, one should judge as closely as possible the necessary deduction for defects.

Tree scales have been prepared and are coming into common use. They show the contents in lumber or cords of trees of different kinds and sizes. Different kinds of trees require the use of different scales. Here again it is necessary to measure the breast-high diameter and the total merchantable height. The pines, spruces, and other conifers are easy to scale accurately. Although the hardwoods, because they are less regular in the shape of their trunks, can not be estimated so accurately, tree scales for some of the more common kinds, such as red and white oaks, ash, yellow poplar, and sweet gum are available and are being used.

Log and tree scales may be purchased from dealers, and from some of the Federal land banks. Instruments for measuring tree diameters (calipers) and heights (hypsometers) are sold by the same agencies or may be made at home. Information on the subject is always gladly furnished by the State foresters, agricultural extension foresters, or the Federal Forest Service.

It is comparatively easy to obtain a fair idea of the contents in board feet of a piece of standing timber. All the trees may be estimated or a number of small areas fairly representing the stand may be selected and measured. The latter method, or partial estimate, is commonly used except for very small wood lots.

### Representative Areas Desirable

One method is to select a number of quarter-acre plots in the best, the average, and the poorest portions of the stand. A circle with a radius of 59 feet makes one-fourth of an acre. A center tree should be selected and the distance of 59 feet measured or stepped out in four or more directions and the points marked. All the trees within the circle are measured and their contents recorded. The selection of the areas should be made with care and good judgment so as to have them truly representative.

Another method in common use is to tally every tree within a strip 2 rods (33 feet) or 4 rods (66 feet) wide. A strip 4 rods wide and 40 rods long contains 1 acre. If such strips are laid out at regular intervals, it is easy to determine what percentage of the whole stand the estimate covers. An estimate of 20 to 40 per cent of the total area is often necessary or advisable.

Wilbur R. Mattoon.

## TIMBER Selling From the Farm to Consumers

The owner of timber may prefer to sell it on the stump or he may prefer to cut it himself and sell the product. If he chooses to sell the timber standing, he may do it in any one of four ways; by the lump, by log scale, by sawed-lumber scale, or by the piece or stack.

In selling the timber on a tract for a lump sum the owner is likely to be at a disadvantage unless he gets a preliminary estimate of the contents and value of the timber. If he is unable to make such an estimate himself it will in most cases pay him well to employ outside help for this purpose.

A millman in Stark County, Ohio, several years ago bought a small block of standing wood-lot timber at the owner's lump price of $350. From it he cut 34,000 board feet of lumber, which he marketed in a town 6 miles distant at an average price of $36.83 per thousand, or a total of $1,252. Cost of logging, sawing, and delivering was $12 per thousand, or $408 for the lot. Allowing a profit of 25 per cent on the total money invested, or $189.50, the total cost of getting the material from the stump to market was $597.50. The difference between this and the market value of the lumber gives the true stumpage value, or $654.50, instead of $350 which was the amount paid. Thus the farmer practically gave the buyer $304.50. The cost of a timber estimate would not have exceeded $25.

Selling standing timber by the lump is a good method if the land is to be cleared for uses other than timber growing because the buyer usually cuts very clean. This method also has the advantage that it avoids differences in opinion between buyer and seller such as may arise over the scaling and grading of individual logs if the timber is sold by log scale. On the other hand, the method is inadvisable if the owner desires to foster young growth and provide for a future timber crop.

### Determining Sale Value in Advance

In selling by log scale, that is, at a fixed price per thousand board feet measured in the log as it is cut, the chief concern of the owner is to determine in advance the sale value per thousand feet of the timber in the tree. This may be obtained as an average log-run price for all the trees on the land, or separately for each species and for each grade of logs. Unless the timber runs nearly uniform in kind and quality the latter way is the better for an owner with experience in grading. The owner may either offer his timber at a stated price or call for bids and sell to the highest bidder.

It is very important in selling by log scale to specify the scale to be used. The Doyle rule gives very low scales for small logs such as are obtained from most second-growth timber. The International log rule gives fairly closely the amount of lumber that may be cut from a log by careful sawing; and this rule is recommended. A 16-foot log 12 inches in diameter at the small end, when carefully sawed with a circular saw of ordinary thickness (1/4-inch kerf) should cut out about 97 board feet of lumber, as is shown by the International rule. The same log scaled by the Doyle rule shows 64 board feet. Copies of the International rule can be obtained from State or Federal forest officers. It will pay the inexperienced seller to employ a competent person to check the scale. Selling by log scale should usually be chosen in preference to selling by the lump in cases in which the contents and value of the timber have not been carefully estimated in advance, and particularly if the timber is of high value.

### Board-Foot Measurements

Board-foot measurement of the lumber actually sawed out is unquestionably a more accurate basis for selling timber than either of the two methods already mentioned. Mill scales as a rule show from 10 to 30 per cent more than log scales. This method, however, causes some delay and expense, but is coming into more general use as the value of forest products rises.

Fence posts, small mining timbers, ties, poles, piling, and some other products are sold by the piece of specified dimensions. Bolts of the shorter lengths are ranked and sold by the cord; the larger ones are measured as logs. Firewood is always sold by the cord or rick. The same precautions should be taken in such sales as in selling logs.

A profitable way of marketing farm timber is for the owner to cut and haul the products to market himself. This provides winter employment for hired help and teams. Also it enables the owner to obtain profits that would otherwise go to the purchaser of standing timber.

### Selling Points

Sell direct to the consumer.

Get bids, if possible, for each piece of timber from several buyers.

Advertise in the papers and write personal letters to sawmills and manufacturing plants.

Consult neighbors who have lately sold timber.

Join with neighbors in making up cooperative carload shipments of logs, bolts, or other timber products.

WILBUR R. MATTOON.

## TOBACCO Grades Adopted Under Warehouse Act

Authority is given under the United States warehouse act for the establishment of standard grades for tobacco. It is necessary that the type and grade of tobacco be stated on warehouse receipts and certificates issued under this act, unless otherwise requested by the depositor. Standard grades form a basis by which farmers may arrive at the market value and bankers at the collateral value of a commodity.

Standard grades are needed by farmers to serve as a guide in assorting and preparing tobacco for the market if they are to obtain the best price. They are needed to facilitate the purchase of uniform packages of tobacco. A definite classification of the various types and standard grades are needed as a basis for market reports and statistical information. By means of such classification and standard grades, farmers are able to keep posted on market prices and crop conditions. Without standard classification and grading, market reports and statistics of one lot of tobacco may mean one thing to one farmer or dealer and quite a different thing to another farmer or dealer. Standard grades facilitate all commercial transactions in tobacco by giving to the farmer, dealer, warehouseman, banker, and manufacturer definite information that means the same thing to all parties.

### Plan of Type Classification and Standard Grades

In order to formulate a basis for establishing standard grades for tobacco, specific information and data from all the tobacco-producing sections were collected and analyzed. It was necessary to make a broad survey of all types of tobacco and classify their various qualities and characteristics. After extensive field studies and of research work in the laboratory, the department arrived at a plan for classifying the various types of tobacco and establishing standard grades for each type.

Under this plan all American-grown tobacco is divided into six major classes, namely, flue-cured, fire-cured, air-cured, cigar filler, cigar binder, and cigar wrapper. In the southern tobaccos (the so-called chewing, smoking, snuff, and export types) this class division is made on the basis of the method of cure. In the cigar-leaf tobaccos the division is made on the basis of the principal usage. Each of these classes covers several related types. The classification combines over 300 frequently used indefinite type names into 29 types, each designated by a definite type number. Each type having an annual production of 1,000,000 pounds or more is classified separately and all types of smaller production are classified together as "miscellaneous types." These types are produced in 25 States, some States producing several distinct types.

Tobacco varies so widely with respect to quality, color, length, and other characteristics that it was necessary to work out a simple, uniform plan for standard grades that might be easily applied by the average tobacco grader, and readily interpreted by the buyers and manufacturers. The plan adopted by the department is characterized by its simplicity. The same plan applies to all types.

### Factors in Tobacco Grading

Under this plan, a standard grade of tobacco is ordinarily composed of four factors—group, quality, color, and length. These are considered in the order named. To avoid lengthy descriptive terms, letters and numbers are used as symbols to designate each factor. The grade symbol is composed of a combination of these letters and numbers. This system makes for brevity. It also permits descriptive analysis to be made from the grade symbol. Detailed information as to the type classification and standard grades is now available.

In January, 1926, Miscellaneous Circular No. 55, "Type Classification of American Grown Tobacco," was published, and copies may be obtained either from the Department of Agriculture or from the Superintendent of Documents at Washington. This is a complete and systematic classification of all American leaf tobacco.

Tentative standard grades for 20 types of tobacco have been prepared by the department. These types cover approximately 97 per cent of the total American production. Grades have been prepared for all flue-cured, all fire-cured, four air-cured, four cigar filler, and four cigar binder types. Detailed grades for the types known as United States standard types Nos. 11, 12, 13, 14, 22, 23, 24, 31, 35, 36, 41, 54, and 55 are available in mimeograph form. In these mimeographed pamphlets the grading system is fully explained and a number of trade and technical tobacco terms are defined. The various elements entering into the quality factor are also fully presented.

Definite standards for expressing the length of tobacco have been established. These standards, known as the United States standard tobacco sizes, are now available in handbook form, with charts illustrating the sizes. These charts cover all the sizes and length variations necessary in assorting tobacco as to length for commercial purposes. There are charts for 1, 2, 4, 6, and 8 inch variations in length. The range and variation of each size are shown in inches and centimeters. Figure 234 illustrates plans for constructing three sizes of sizing boards for hand or bundle sizing tobacco, the first two of which are suitable also for leaf sizing. The dimensions of these boards are in accordance with the United States sizes for tobacco. They show the range of the 1-inch, 2-inch, and regular 4-inch sizes in inches and the United States size numbers used to designate these sizes.

### Usage of Type Classification and Grades

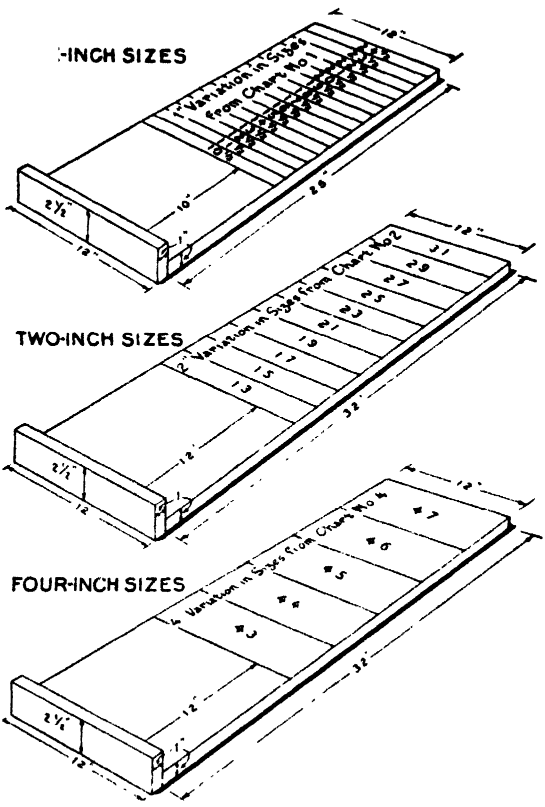

FIG. 234.—Plans for constructing three sizes of tobacco sizing boards

The type numbers and the tentative standard grades are used in stating types and grades on warehouse receipts and certificates issued under authority of the United States warehouse act. They have been used successfully for the past four years in administering this law. The cooperative associations are using the standard grades as a basis for settling with their members, and as a basis for arriving at the collateral value of the tobacco in obtaining loans. More than a billion pounds of tobacco have been graded on Government standard grades. Bankers have loaned many million dollars on Federal warehouse receipts with the standard grades as the basis for collateral value, each grade having a fixed loan value per hundred pounds of tobacco. The use of the grades by the cooperative organizations has exerted a marked influence on farmers as a whole. With some knowledge of what constitutes a grade placed before them they have been enabled to better assort and prepare their tobacco for market. The department's statistical information on acreage, production, and prices of tobacco is also based on the type classification. Other public agencies dealing with tobacco are fast coming to use the department's type classification as a basis. The use of this classification and the grades will gradually result in discussing tobacco in terms which will mean the same to all interested parties and thereby make for a more intelligent marketing of the crop.

F. B. WILKINSON.

## TOBACCO Not Always Helped by Rotation

That continuous culture of any particular crop on the same soil very commonly leads, sooner or later, to decreased yields must have been observed in the earliest days of agriculture. Doubtless the primitive form of crop rotation consisted in alternately cropping and resting the land or, in other words, following a rotation of farm crop and a crop of weeds. A hundred years ago scientists who made a study of the subject stated that replacing the weeds in this rotation by useful crops, so as to produce something of value on the soil each year, was to be considered as one of the great advances in the development of agriculture. Practical experience over a long period has abundantly proved the value of systematic crop rotation when applied to many crops, especially when legumes and other soil-improving crops are included in the rotation. It appears, however, that under some conditions tobacco can not be satisfactorily grown in rotation with various other crops.

The early settlers learned that the tobacco plant grew well on virgin land and on old land which had remained idle for a time. It was found also that in many cases after a few crops of tobacco had been grown the land became "tobacco tired," even though excellent yields of other crops could still be produced. Recent study of the problem indicates that as a rule these tobacco-sick soils are not improved, so far as concerns tobacco, by addition of fertilizer, manure, or lime.

### Cropping System Responsible

The system of cropping seems to be an important factor in the development or persistence of the trouble in the soil. Although continuous culture of tobacco may lead to the tobacco-sick condition of the soil, the use of leguminous or nonleguminous cover crops or rotations with various other crops may aggravate rather than remedy this condition. In this disease the roots of the tobacco plant fail to make normal growth and are brownish in color so that this trouble is often spoken of as brown root rot. This trouble seems to be distinct from the well known black root rot which is a fungous disease. So far no plant parasite or germ has been found to be connected with the disease and its exact nature has not been determined.

It is remarkable that crops like tobacco and its relative, the tomato, which are most susceptible to this disease are less active in producing it or in intensifying its effect than are other crops like corn, timothy, and rye on which the disease has little effect. Here is a case, then, where a crop may be injured rather than benefited by use of winter cover crops or the usual sort of crop rotation system intended to improve the productiveness of the soil. To bring out this fact more clearly some results of recent cropping tests may be cited. On sandy loam soil of a tobacco farm in Massachusetts a timothy sod was turned under in the spring. A liberal application of fertilizer was made to the soil and rotations including various crops were started. Although in the first year corn yielded more than 100 bushels per acre after the timothy, the yield of tobacco was only about 500 pounds. By continuing tobacco on the same land the yield two years later had increased to more than 1,600 pounds, while after two crops of corn the yield was 340 pounds; after two years of clover it was 480 pounds, and after two years of timothy, 280 pounds. Where the land remained idle for two years the yield of tobacco was more than 1,600 pounds.
